If probes are used instead of large metal-semiconductor contacts, then the spreading resistance (R_{sp}) under the two probes must also be added, as shown in Fig. 20.2. In this case, (20.5) becomes

$$R_{mea} = R + 2R_{sp} + 2R_c\,, \tag{20.6}$$

where R_{sp} for a cylindrical contact of radius r, and for a semi-infinite sample, it can be expressed by

$$R_{sp} = \frac{\rho}{4r}\,. \tag{20.7}$$

For a hemispherical contact of radius r, R_{sp} is given by

$$R_{sp} = \frac{\rho}{2\pi r}\,. \tag{20.8}$$

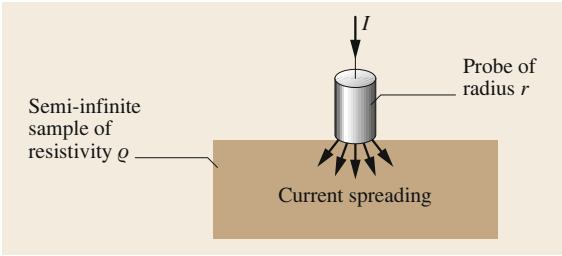

Fig. 20.2 Spreading resistance associated with a probe contact

In both cases, it is very difficult to provide a direct measurement or an accurate model of the contact resistance. So determining the bulk resistivity by this approach is not recommended, except when the spreading resistance is the dominant term in (20.6) and when (20.7) or (20.8) can be applied. In this case, the resistivity is determined by the *spreading resistance* technique measurement. Nevertheless, despite the lack of accuracy of the two contact techniques, it can be sufficient for monitoring some process steps and it is often used in the semiconductor industry as a process monitor.

Four-Point Probe Technique. In order to eliminate or at least minimize the contact contribution to the measured resistance value, techniques based on separate current injection and voltage drop measurements have been developed. First, the two-probe technique can be used, as reported in Fig. 20.1. This measurement is very simple, but it is affected by several parameters: lateral contact geometry, probe spacing, and minority carrier injection near the lateral contacts. The main disadvantage of this technique is the need for lateral contacts. This requirement is overcome with the four-point probe technique, where two probes are used for current injection and the other two probes are used to measure the voltage drop. The more usual probe geometry configuration is when the four probes are placed in a line, as shown in Fig. 20.3.

The voltage at probe 2, V_2, induced by the current flowing from probe 1 to probe 4 is given by:

$$V_2 = \frac{\rho I}{2\pi}\left(\frac{1}{s_1} - \frac{1}{s_2 + s_3}\right). \tag{20.9a}$$

The voltage at probe 3 is

$$V_3 = \frac{\rho I}{2\pi}\left(\frac{1}{s_1 + s_2} - \frac{1}{s_3}\right). \tag{20.9b}$$

Then, by measuring $V = V_2 - V_3$, the voltage drop between probes 2 and 3, and the current I through probes 1 and 4, the resistivity can be determined using (20.9a)

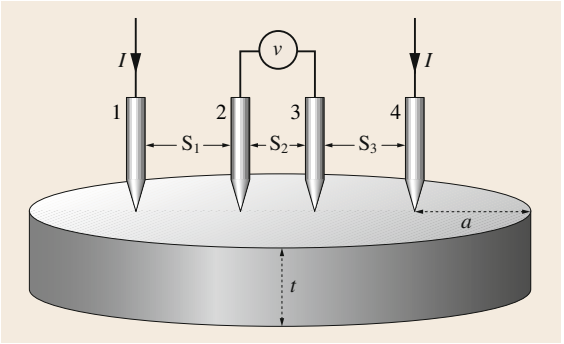

Fig. 20.3 Linear four-point probe configuration. The sample thickness is t and a is the distance from the edge or boundary of the sample

and (20.9b) as

$$\rho = \frac{2\pi V/I}{\left(\frac{1}{s_1} + \frac{1}{s_2} - \frac{1}{s_2+s_3} - \frac{1}{s_1+s_2}\right)} \tag{20.10}$$

Thus, a direct measurement of the resistivity can be made using a high-impedance voltmeter and a current source. When the probe spacings are equal ($s_1 = s_2 = s_3 = s$), which is the most practical case, then (20.10) becomes

$$\rho = 2\pi s\frac{V}{I}. \tag{20.11}$$

Equations (20.10) and (20.11) are valid only for semi-infinite samples; that is, when both t and the sample surface are very large ($\to \infty$), and the probes' locations must be far from any boundary. Because these relations can be applied only to large ingots, then in many cases a correction factor f must be introduced in order to take into account the finite thickness and surface of the sample and its boundary effects. Further, for epitaxial layers, f must also consider the nature of the substrate – whether it is a conductor or an insulator. Thus, (20.11) becomes

$$\rho = 2\pi s\frac{V}{I}f. \tag{20.12}$$

For a thin semiconductor wafer or thin semiconducting layer deposited on an insulating substrate, and for the condition $t < s/2$, which represents most practical cases because the probe spacing s is usually on the order of a millimeter, then the correction factor due to the thickness is

$$f = \frac{(t/s)}{2\ln 2} \quad \text{so that} \quad \rho = 4.532t\frac{V}{I}. \tag{20.13}$$

The noninfinite sample surface must be corrected if the ratio of the wafer diameter to the probe spacing is not

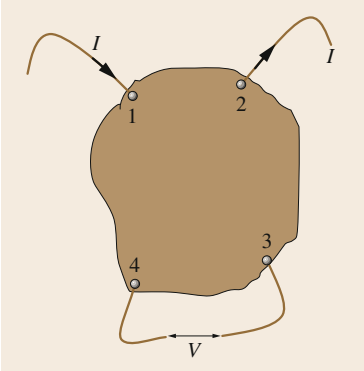

Fig. 20.4 van der Pauw method for an arbitrarily shaped sample

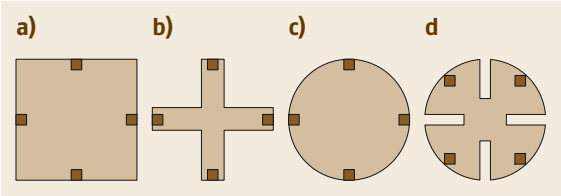

Fig. 20.5a–d Symmetrical van der Pauw structures: **(a)** square, **(b)** Greek cross, **(c)** circle and **(d)** cloverleaf

greater than 40, otherwise a correction factor of less than unity has to be introduced [20.3].

If the probe header is too close to any boundary, then (20.13) is no longer valid and another correction factor must be introduced. This correction factor is close to 1 until the ratio a/s is greater than 2, where a is the distance from the edge of the sample that is shown in Fig. 20.3. A study of various 8 inch n- and p-type silicon wafers have demonstrated that the edge exclusion limit is 5 mm [20.7].

In the case of a different arrangement of probes, for instance a square array or when a different measurement configuration of the four-point collinear probes is used, such as current injection between probes 1 and 3, other specific correction factors are required. Here, rather than detail all the different correction factors, complementary information can be found in [20.4, Chap. 4] and [20.3, Chap. 1].

Taking into account the appropriate correction factors as well as some specific material parameters such as hardness or surface oxidation, it is possible to map the resistivities of different types of semiconductor wafers or deposited semiconductor layers with an accuracy better than 1% over a large range of resistivity values using commercial equipment and appropriate computational techniques.

Van der Pauw Technique. Based on the same basic principle of separating the current injection and voltage measurement, the *van der Pauw* [20.8] measurement technique allows for the determination of resistivity on a sample of arbitrary shape using four small contacts placed on the periphery, as shown in Fig. 20.4. Then, the resistivity of a uniform sample of thickness t is given by

$$\rho = \frac{\pi t}{\ln 2}\frac{(R_\mathrm{A}+R_\mathrm{B})}{2} f \,. \tag{20.14}$$

Here, R_A and R_B are resistances measured by injecting current on two adjacent contacts and by measuring the voltage drop on the two remaining ones. With the notation in Fig. 20.4, one can define

$$R_\mathrm{A} = \frac{V_3 - V_4}{I_{1,2}} \,, \quad R_\mathrm{B} = \frac{V_4 - V_1}{I_{2,3}} \,,$$

f is a correction factor that is

$$\text{a function of the ratio} \quad R_f = \frac{R_\mathrm{A}}{R_\mathrm{B}} \,. \tag{20.15}$$

with R_f obtained from

$$\frac{(R_f - 1)}{(R_f + 1)} = \frac{f}{\ln 2}\operatorname{arccosh}\left(\frac{\exp(\ln 2/f)}{2}\right). \tag{20.16}$$

In the case of samples with symmetrical geometries, and when the contacts are also symmetrical, as shown in Fig. 20.5, then $R_\mathrm{A} = R_\mathrm{B}$, $R_f = 1$ and $f = 1$, and (20.14) becomes

$$\rho = \frac{\pi t}{\ln 2} R_\mathrm{A} = 4.532 t R_\mathrm{A} \,. \tag{20.17}$$

In order to minimize errors caused by the finite dimensions of the contacts (since ideally the contact area should be zero) and the finite thickness of the sample, then the distance between the contacts must be larger than both the diameter and the thickness of the contact. Also, the cloverleaf configuration in Fig. 20.5d is recommended to prevent contact misalignment, but this configuration requires a more complicated patterning technology.

The main advantage of the van der Pauw technique compared to the four-point probe technique is its use of a smaller area for the test structure. Therefore, this measurement technique is often used in integrated circuit technology. Also, because of its simple structure, the Greek cross configuration in Fig. 20.5b is widely used (experimental results obtained on SiGeC epitaxial layers are reported in Fig. 20.6 as an example). However, when narrows arms are used, current crowding at the corners may have a significant influence, and in this case a different Greek cross layout can be considered to reduce this current crowding effect [20.9].

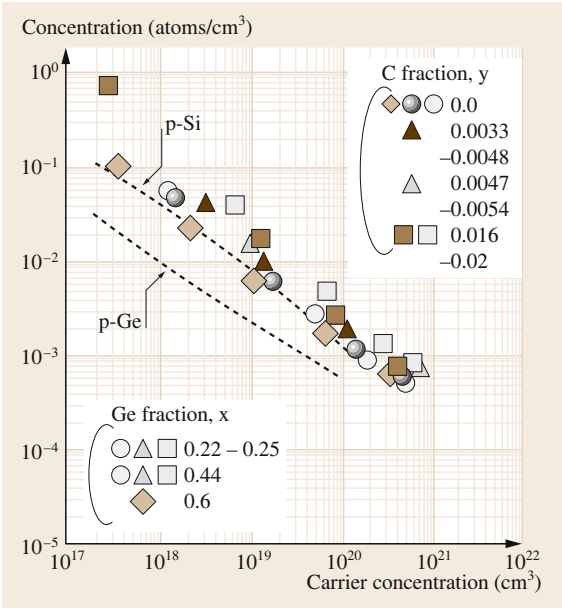

Fig. 20.6 Resistivity versus carrier concentration in $Si_{1-x-y}Ge_xC_y$ films obtained using a cloverleaf van der Pauw structure. (After [20.10])

Spreading Resistance Technique. The spreading resistance technique is based on the modeling of current spreading from a probe tip or a small metallic contact and flowing into a bulk semiconductor, as shown previously in Fig. 20.2. Equations (20.7) and (20.8) presented above are for cylindrical probes and hemispherical probes, respectively. Basically, the principle of this method is opposite to the previous four-contact techniques where the separation of the current injection from the measured voltage drop was used to avoid the spreading resistance. Here, the spreading resistance is expected to be the dominant term in (20.6). Only two contacts are needed: two closely aligned probes, a small top contact probe or a metallic contact and a large bottom contact. In the first case, surface mapping can be performed, but the main use of this compact probe configuration is for resistivity profiling using a bevelled sample [20.3]. The second configuration has been used to measure the substrate resistivity of silicon integrated circuits where simple test structures – for example the square top contact of $25\,\mu m \times 25\,\mu m$ and $50\,\mu m \times 50\,\mu m$ shown in [20.12] – have been included on a test chip.

More recently, semiconductor resistivity has been nanocharacterized using scanning spreading resistance microscopy (SSRM) with a standard atomic force microscope (AFM) of lateral resolution of 10 to 20 nm. A SSRM image of a $0.5\,\mu m$ nMOSFET is given in Fig. 20.7a [20.11]. The resistance is low in the highly doped regions (dark) and high in the lower doped regions (bright): source, drain, gate and well regions are clearly observed in Fig. 20.7a or the resistance profile in Fig. 20.7b. With such a high resolution, scanning the lateral and vertical diffusion of dopants in active regions of submicron transistors is possible. An example is shown in Fig. 20.7c where the extra implantations (halo and lightly doped drain (LDD)) in a $0.35\,\mu m$ nMOSFET process are clearly visible and result in a change of L_{eff} from 295 nm without extra implantations to 229 nm with the extra implantations.

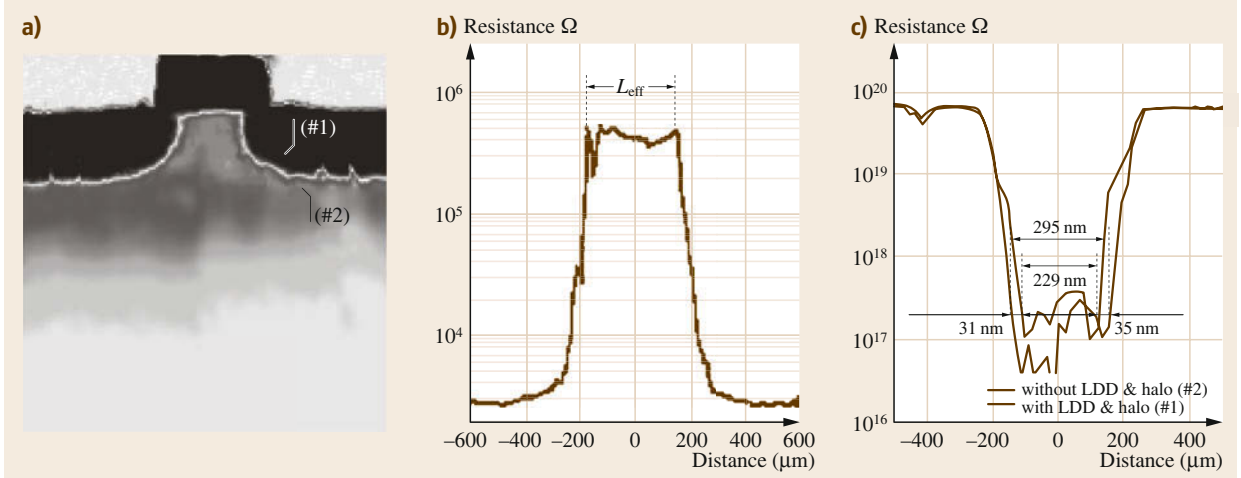

Fig. 20.7 (a) SSRM resistance image (scan size: $1.5\,\mu m \times 1.5\,\mu m$) of a $0.5\,\mu m$ nMOSFET; (b) lateral section taken 10 nm under the gate oxide of the same transistor; (c) lateral carrier concentration profiles measured with SSRM 10 nm under the gate oxide for two $0.35\,\mu m$ nMOSFETs (with and without halo and LDD process). 20.1.2 Contact Resistivity

The contact resistance of an active device and interconnection becomes larger as the dimensions are scaled down. As a consequence, the performance of single transistors as well as integrated circuits can be seriously limited by increasing *RC* time constants and power consumption. This is of major interest for the semiconductor industry, as reported by the International Technology Roadmap for Semiconductors, ITRS 2001 [20.5], and in [20.13].

Contact Resistance Elements

Basically, the contact resistance R_c is the resistance localized from a contact pad, a probe or from the metallization process to an active region. However, it does not include all of the access resistances between these two regions, as shown in Fig. 20.8a for a horizontal contact and Fig. 20.8b for a vertical contact.

Starting from the contact pad (Figs. 20.8a and 20.9), the contact resistance includes the resistance of the metal R_m, the interfacial metal-semiconductor resistance R_i, and the resistance associated with the semiconductor just below the contact in the contact region R_{sc}. Thus, the contact resistance can be expressed as

$$R_c = R_m + R_i + R_{sc} \,. \tag{20.18}$$

The last component R_{sc} cannot be accurately defined because the boundary between the contact and access regions is very difficult to determine due to (for example) interdiffusion of metal and semiconductor atoms, and because the current flow into this region is not homogeneous due to current spreading and lateral or vertical current crowding at the periphery of the contact. The relative importance of each component of R_c is strongly dependent on different parameters of the process itself – annealing temperature, doping density and the geometry used (lateral or vertical).

When comparing different contact technologies and different contact areas, the most convenient parameter

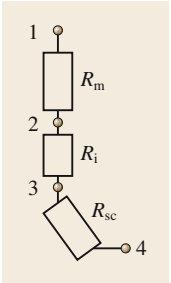

Fig. 20.9 Different components of the contact resistance

to use is the contact resistivity ρ_c, which is referred to as the specific contact resistance in $\Omega\,cm^2$, and ρ_c is given by

$$\rho_c = R_c A_{ceff} \,, \tag{20.19}$$

where A_{ceff} is the effective contact area; that is, the current injection area. The concept of an effective contact area can be approximated by the contact geometry in the case of a vertical contact in Fig. 20.8b. However, A_{ceff} is more difficult to specify for a lateral contact, where a transfer length L_T, representing the length where the current flow transfers from the contact into the semiconductor just underneath, must be introduced, as shown in Fig. 20.8a. L_T is defined as the length over which the voltage drops to e^{-1} of its value at the beginning of the contact [20.3], and is given by

$$L_T = \sqrt{\frac{\rho_c}{\rho_{sc}}} \,, \tag{20.20}$$

where ρ_{sc} is the sheet resistivity of the semiconductor below the contact.

Because of its various components, it is difficult to accurately model the contact resistivity. Nevertheless, a theoretical approach to the interfacial resistivity (see R_i in (20.18)), ρ_i, can be determined from the well-known Schottky theory of metal–semiconductor contacts. The interfacial resistivity ρ_i is defined by

$$\rho_i = \left.\frac{\partial V}{\partial J}\right|_{V=0} \,. \tag{20.21}$$

This metal–semiconductor structure is equivalent to an abrupt p-n junction. According to the Schottky theory (for more details see [20.14, Chap. 5]), the J–V characteristic of a metal–semiconductor contact in the case of a low-doped semiconductor is given by

$$J = A^* T^2 \exp\left(-\frac{q\phi_B}{kT}\right)\left[\exp\left(\frac{qV}{kT}\right) - 1\right], \tag{20.22}$$

where A^* is Richardson's constant, and T the absolute temperature. ϕ_B is the barrier height formed at

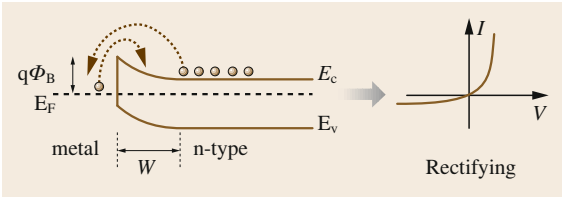

Fig. 20.10 Energy-band diagram of an n-type semiconductor–metal contact and related rectifying contact. W is the width of the depletion layer

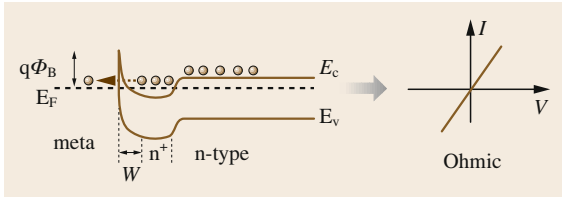

Fig. 20.11 Energy-band diagram of an n^+-n semiconductor–metal structure and related ohmic contact

the metal–semiconductor interface – the difference between the vacuum level and the Fermi level of the metal and of the semiconductor materials respectively, and ϕ_B is given by

$$\phi_B = \phi_M - \chi \tag{20.23}$$

where ϕ_M is the metal work function and χ the semiconductor electron affinity.

The energy band diagram for a low-doped n-type semiconductor–metal contact is shown in Fig. 20.10. In this case, the current transport is dominated by the thermionic emission current, resulting in a rectifying contact.

Thus, when the conduction mechanism is controlled by the thermionic emission (TE), the interfacial resistivity in (20.21) is simply obtained from the derivative of (20.22), and $\rho_{i,TE}$ is

$$\rho_{i,TE} = \frac{k}{qA^*T} \exp\left(\frac{q\phi_B}{kT}\right) \tag{20.24}$$

Due to the presence of surface states, the barrier height ϕ_B is positive and weakly dependent on the metal–semiconductor material. ϕ_B is $\approx 2E_g/3$ for an n-type semiconductor and $\approx E_g/3$ for a p-type semiconductor. Therefore, high values of interfacial resistivity $\rho_{i,TE}$ are usually obtained except when narrow bandgap semiconductors are used.

The way to fabricate ohmic contacts with low contact resistivity values is to process the metal on a heavily doped semiconductor layer. In this case, the depletion width decreases ($W \approx N_D^{-1/2}$) and the probability of carrier tunneling through the barrier increases. Thus, the conduction mechanism is dominated by tunneling, as shown in Fig. 20.11.

The electron tunneling current is expressed as

$$J_{tun} \approx \exp\left(\frac{q\phi_B}{E_{00}}\right), \tag{20.25}$$

where

$$E_{00} = \frac{q\hbar}{2}\sqrt{\frac{N_D}{\varepsilon_s m_n^*}}, \tag{20.26}$$

ε_s is the permittivity of the semiconductor and m_n^* is the effective mass of the electron.

From (20.21), (20.25) and (20.26), the interfacial resistivity $\rho_{i,T}$ is found to be

$$\rho_{i,T} \propto \frac{2\sqrt{\varepsilon_s m_n^*}}{\hbar} \frac{\phi_B}{\sqrt{N_D}}. \tag{20.27}$$

Comparing $\rho_{i,TE}$ from (20.24) to $\rho_{i,T}$ from (20.27), we see that a highly doped layer can significantly reduce the interfacial resistivity. For $N_D \geq 10^{19}\,cm^{-3}$, the tunneling process dominates the interfacial resistivity, while for $N_D \leq 10^{17}\,cm^{-3}$, the thermionic emission current is dominant.

As most semiconductors such as Si, SiGe, GaAs, InP are of relatively wide bandgap, the deposition of a heavily doped layer before the metallization is commonly used in order to form a tunneling contact. For compound semiconductor manufacturing processes, the contact layer is generally formed from the same semiconductor material, or at least from the same material as the substrate. For silicon and related materials such as SiGe alloys or polysilicon, silicidation techniques are commonly used to make the contact layer with very thin silicide layers such as $CoSi_2$ or $TiSi_2$ layers.

Measurement Techniques

As mentioned above, it is difficult to accurately model the contact resistance, so direct measurements of the contact resistance or of the contact resistivity are of great importance. The two main test structures used to determine contact characteristics will now be discussed: the *cross Kelvin resistor* (*CKR*) *test structure* and the *transmission line model* (*TLM*) structure.

Kelvin Test Structure. The Kelvin test structure, also referred to as the cross Kelvin resistor (CKR) test structure, is shown in Fig. 20.12. The contact resistance R_c is determined from the potential drop in the contact window (V_{34}) when a current I is forced through the contact window from contact pad 1 to pad 2, and R_c is

$$R_c = \frac{V_{34}}{I}. \tag{20.28}$$

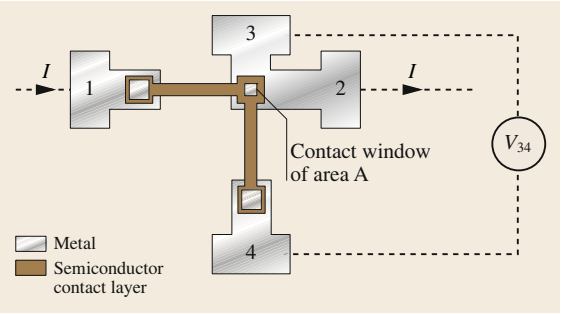

Fig. 20.12 Cross Kelvin resistor test structure

Therefore, a measure of R_c and knowledge of the contact area A allows for direct extraction of the contact resistivity ρ_c, given by

$$\rho_c = R_c A \,. \tag{20.29}$$

This basic approach is not valid when parasitic effects are present. One of the main problems is current crowding around the contact. In order to extract accurate values for the contact resistivity using Kelvin test structures, it is necessary to take into account the two-dimensional current-crowding effect. This is achieved using the results from numerical simulations [20.15]. Nevertheless, the development of ohmic contacts with very low values of contact resistivities require complex technology with different materials and usually with several interfaces. In this case, a large discrepancy between the extracted and the measured contact parameters can be found [20.15, 16]. To improve the accuracy, three-dimensional models are now used to take into account the different interfacial and vertical parasitic effects [20.17].

Transmission Line Model Test Structures. The transmission line model test structure (TLM) consists of depositing a metal grid pattern of unequal spacing L_i between the contacts. This leads to a scaled planar resistor structure. Each resistor changes only by its distance L_i between two adjacent contacts, as shown in Fig. 20.13, and it can be expressed by

$$R_i = \frac{\rho_s L_i}{W} + 2R_c \tag{20.30}$$

Then, by plotting the measured resistances as a function of the contact spacing L_i, and according to (20.30), the layer sheet resistivity ρ_s and the contact resistance R_c can be deduced from the slope and from the intercept at $L_i = 0$ respectively, as shown in Fig. 20.14

$$\text{Slope} = \frac{\rho_s}{W}\,;\; R_i(\text{intercept}) = 2R_c\,;$$
$$\text{and}\;\; |L_i(\text{intercept})| = 2L_T \tag{20.31}$$

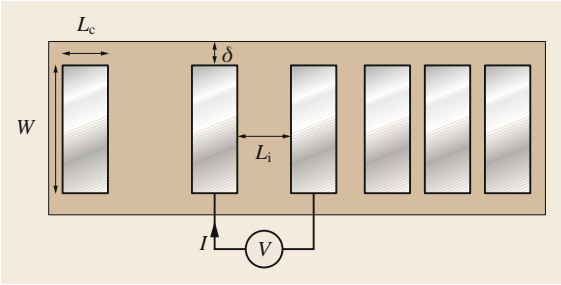

Fig. 20.13 Transmission line model (TLM) test structure

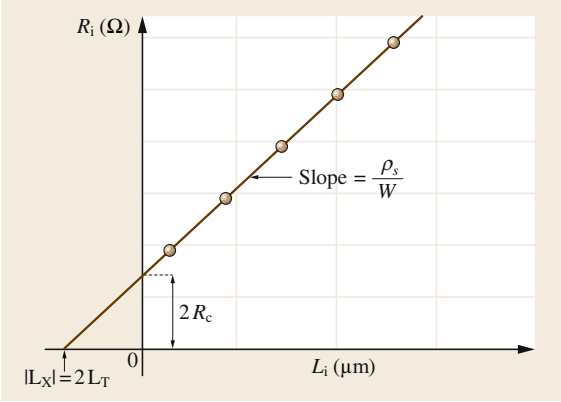

Fig. 20.14 Determination of the sheet resistivity and characterization of the contact using a TLM test structure

As discussed in Sect. 20.1.2, the most suitable parameter for characterizing a contact is its contact resistivity (ρ_c) or the specific contact resistance ($R_c A_{ceff}$), given by

$$\rho_c = R_c A_{ceff} = R_c W L_T \tag{20.32}$$

As shown in Fig. 20.8a, for a planar resistor, the effective contact area requires the notion of the transfer length L_T. According to (20.20), and assuming that the sheet resistance under the contact ρ_{sc} is equal to the sheet resistance between the contacts ρ_s, then L_T can be expressed by (20.20).

Therefore, the substitution of R_c into (20.32) in (20.30) leads to

$$R_i = \frac{\rho_s}{W} L_i + \frac{\rho_s}{W} 2L_T \tag{20.33}$$

Now, extrapolation to $R_i = 0$ allows us to determine the value of L_T. The main advantage of the *TLM* method is its ability to give two main electrical parameters, the resistivity of the semiconductor contact layer ρ_s and the contact resistance R_c. However, this is done at the expense of a questionable assumption that the sheet resistance under the contact must be equal to the sheet resistance between the contacts. More on this technique can be found in [20.3].

20.2 Hall Effect

As mentioned before, the resistivity of a semiconductor is not a fundamental material parameter. One can consider the carrier density (n or p) or the carrier mobility (μ_n or μ_p) to be fundamental or microscopic parameters. For a semiconductor material, the resistivity is related to these two parameters (density and mobility) by (20.2). The strength of the Hall effect is to directly determine the sheet carrier density by measuring the voltage generated transversely to the current flow direction in a semiconductor sample when a magnetic field is applied perpendicularly, as shown in Fig. 20.15a. Together with a resistivity measurement technique such as the four-point probe or the van der Pauw technique, Hall measurements can be used to determine the mobility of a semiconductor sample.

In modern semiconductor components and circuits, knowledge of these two fundamental parameters n/p and μ_n/μ_p is critical. Currently, Hall effect measurements are one of the most commonly used characterization tools in the semiconductor industry and research laboratories. This is not just because of the parameters that can be extracted for use in device modeling or materials characterization, but also because of the quantum Hall effect (QHE) in condensed matter physics [20.18]. Moreover, in the applied electronics domain, one should note the development of different sensors based on the physical principle of the Hall effect, such as commercial CMOS Hall sensors.

As is very often the case, the development of a characterization technique is related to its cost, simplicity of implementation and ease of use. Since these practical characteristics are satisfied even when specially shaped samples are required, then the Hall effect measurement technique has become a very popular method of characterizing materials.

In this section, we will first present the physical principle of the Hall effect. Then we will show how it can be used to determine the carrier density and mobility. Finally, the influence of the Hall scattering factor will be presented, followed by some practical issues about the implementation of the Hall effect method.

20.2.1 Physical Principles

The Hall effect was discovered by *Hall* in 1879 [20.19] during an experiment on current transport in a thin metal strip. A small voltage was generated transversely when a magnetic field was applied perpendicularly to the conductor.

The basic principle of this Hall phenomenon is the deviation of some carriers from the current line due to the Lorentz force induced by the presence of a transverse magnetic field. As a consequence, a voltage drop V_H is induced transversely to the current flow. This is shown in Fig. 20.15a for a p-type bar-shaped semiconductor, where a constant current flow I_x in the x-direction and a magnetic field in the z-direction results in a Lorentz force on the holes. If both holes and electrons are present, they deviate towards the same direction. Thus, the directions of electrical and magnetic fields must be accurately specified.

The Lorentz force is given by the vector relation

$$F_L = q(\boldsymbol{v} \times \boldsymbol{B}) = -q v_x B_z \,, \tag{20.34}$$

where v_x is the carrier velocity in the x-direction. Assuming a homogeneous p-type semiconductor

$$v_x = \frac{I}{qtWp} \,. \tag{20.35}$$

As a consequence, an excess surface electrical charge appears on one side of the sample, and this gives rise to an electric field in the y-direction E_y. When the magnetic force F_L is balanced by the electric force F_{EL}, then the Hall voltage V_H is established, and from a balance between F_L and F_{EL}, we get

$$F = F_L + F_{EL} = -q v_x B_z + q E_y = 0 \,, \tag{20.36}$$

$$\text{so } E_y = \frac{BI}{qtWp} \,. \tag{20.37}$$

Also, the Hall voltage V_H is given by

$$V_H = V_y = E_y W = \frac{BI}{qtp} \,. \tag{20.38}$$

So if the magnetic field B and the current I are known, then the measurement of the Hall voltage gives the hole sheet concentration p_s from

$$p_s = pt = \frac{BI}{qV_H} \,. \tag{20.39}$$

If the conducting layer thickness t is known, then the bulk hole concentration can be determined (see (20.41)) and expressed as a function of the Hall coefficient R_H, defined as

$$R_H = \frac{tV_H}{BI} \tag{20.40}$$

$$\text{and } p = \frac{1}{qR_H} \tag{20.41}$$

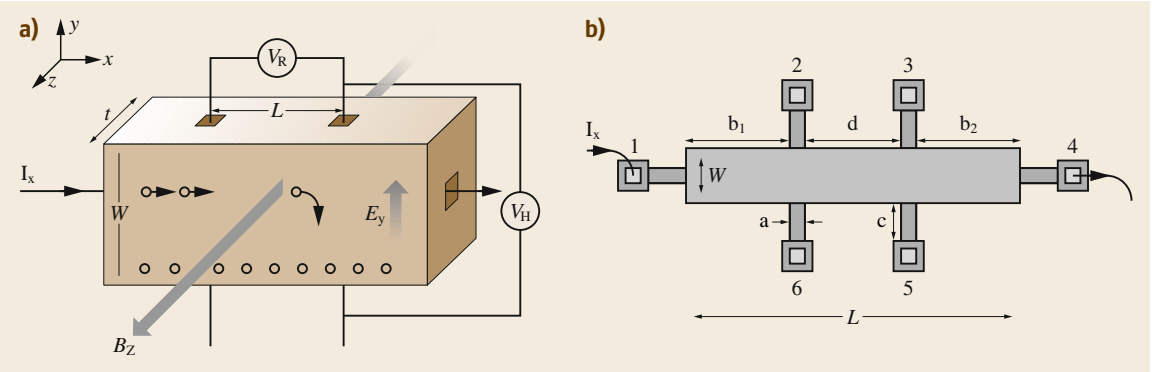

Fig. 20.15 **(a)** Representation of the Hall effect in an p-type bar-shaped semiconductor. **(b)** Practical sample geometry: a six-terminal Hall-bar geometry

Using the same approach for an n-type homogeneous semiconductor material leads to

$$R_H = -\frac{tV_H}{BI}\,, \tag{20.42}$$

$$\text{and } n = -\frac{1}{qR_H} \tag{20.43}$$

Now, if the bulk resistivity ρ is known or can be measured at the same time using a known sample such as a Hall bar or van der Pauw structure geometry in zero magnetic field, then the carrier drift mobility can be obtained from

$$\mu = \frac{|R_H|}{\rho} \tag{20.44}$$

There are two main sample geometries commonly used in Hall effect measurements in order to determine either the carrier sheet density or the carrier concentration if the sample thickness is known, and the mobility. The first one is the van der Pauw structure presented in Sect. 20.1.1. The second one is the Hall bar structure shown in Fig. 20.15b, where the Hall voltage is measured between contacts 2 and 5, and the resistivity is measured using the four-point probes technique presented in Sect. 20.1.1 (contacts 1, 2, 3 and 4). Additional information about the shapes and sizes of Hall structures can be found in [20.3, 4, 20].

Whatever the geometry used for Hall measurements, one of the most important issues is related to the offset voltage induced by the nonsymmetric positions of the contact. This problem, and also those due to spurious voltages, can be controlled by two sets of measurements, one for a magnetic field in on direction and another for a magnetic field in the opposite direction.

The Hall effect has also been investigated on specific structures, and an interesting example can be found in reference [20.21], where a Hall bar structure was combined with a double-gate n-silicon-on-insulator (SOI) MOSFET. This was done in order to understand the mobility behavior in ultra-thin devices and to validate the classical drift mobility extraction method based on current–voltage measurements.

In the Hall effect experiment, the measurement of the Hall coefficient R_H leads to the direct determination of the carrier concentration and mobility. Moreover, the sign of R_H can be used to determine the type of conductivity of the semiconductor sample. If various types of carriers are present, then the expression for R_H becomes more complex and approximations in the limit of low and high magnetic field are necessary [20.3, Chap. 8].

We have so far discussed the Hall effect on a uniformly doped substrate or single semiconductor layer deposited on an insulating or semi-insulating substrate. In the case of a semiconductor layer deposited on a semiconducting substrate of opposite doping type, Hall effect measurements can be performed if the space charge region can act as an insulator. In the case of multilayers, the problem is more difficult, but an approximation for transport experiments has been developed for two-layer structures [20.22] and applied to different metal–semiconductor field-effect-transistor (MESFET) structures, for instance [20.23].

20.2.2 Hall Scattering Factor

The relations presented above are based on an energy-independent scattering mechanism. With this assumption made, the Hall carrier concentration and the Hall mobility are equal to the carrier concentration and the carrier drift mobility. When this assumption is no longer valid, these electrical parameters are different and the Hall scattering factor r_H must be taken into account. In this case (20.41), (20.43) and (20.44) must be modified

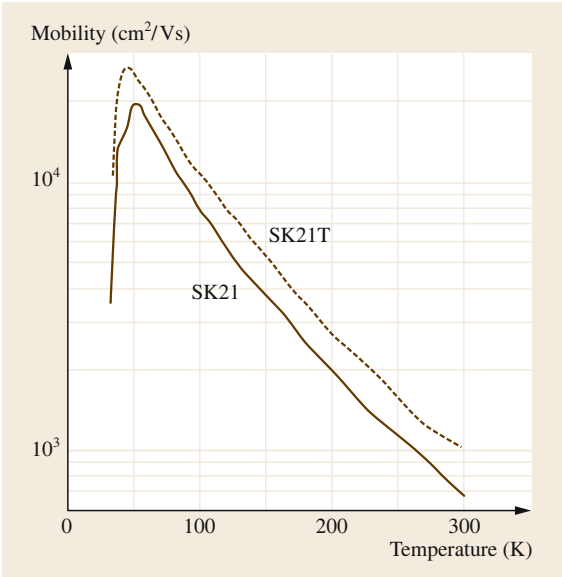

Fig. 20.16 Hall mobility as a function of temperature on two SOI films. (After [20.24])

as follows

$$p_{\mathrm{H}} = \frac{r_{\mathrm{H}}}{qR_{\mathrm{H}}} = r_{\mathrm{H}} p \,, \tag{20.45}$$

$$n_{\mathrm{H}} = -\frac{r_{\mathrm{H}}}{qR_{\mathrm{H}}} = r_{\mathrm{H}} n \,, \tag{20.46}$$

and

$$\mu_{\mathrm{H}} = r_{\mathrm{H}} \frac{|R_{\mathrm{H}}|}{\rho} = r_{\mathrm{H}} \mu \,. \tag{20.47}$$

The Hall scattering factor [20.25] is related to the energy dependence of the mean free time between carrier collisions $\tau(E)$, and r_{H} is given by

$$r_{\mathrm{H}} = \frac{\langle \tau^2 \rangle}{\langle \tau \rangle^2} \,. \tag{20.48}$$

According to theory [20.3], the Hall scattering factor tends to unity in the limit of high magnetic field. Therefore, r_{H} at low magnetic fields can be determined by measuring the Hall coefficient in the limit of both high and low magnetic fields [20.25] using

$$r_{\mathrm{H}} = \frac{R_{\mathrm{H}}(B)}{R_{\mathrm{H}}(\infty)} \tag{20.49}$$

Depending on the scattering mechanism involved (lattice, ionized or neutral impurity, electron, or phonon scattering), r_{H} is found to vary between 0.6 and 2 [20.26]. However, due to valence band distortion effects, values as low as 0.26 have been found in strained p-type SiGe epilayers [20.27]. Therefore, the Hall carrier concentration and especially the Hall mobility must be distinguished from carrier concentration and carrier drift mobility.

As the different scattering mechanisms have different temperature (T) dependences, then the Hall mobility as function of temperature is often used to separate the different scattering processes. An example is given in Fig. 20.16 for silicon-on-insulator (SOI) films [20.24]. The increase in the mobility between 4 and 45 K, which is given by $\mu \propto T^{2.95}$, is related to the ionized donor scattering mechanism. The decrease in mobility between 46 and 120 K given by $\mu \propto T^{-1.55}$ is associated with lattice scattering. However, after 150 K, the rapid decrease in mobility observed, where $\mu \propto T^{-2.37}$, suggests that other scattering mechanisms as well as the lattice scattering mechanism, such as electron or phonon scattering, must be taken into account.

20.3 Capacitance–Voltage Measurements

Capacitance–voltage (C–V) measurements are normally made on metal-oxide semiconductor (MOS) or metal-semiconductor (MS) structures in order to determine important physical and defect information about the insulator and semiconductor materials. For example, high-frequency (HF) and low-frequency (LF) or quasi-static C–V measurements in these structures are used to determine process and material parameters – insulator thickness, doping concentration and profile, density of interface states, oxide charge density, and work function or barrier height. In this section, we describe various C–V measurements and how they can be used to provide process parameters as well as valuable information about the quality of the materials. A typical C–V curve for a MOS capacitor with an n-type semiconductor is shown in Fig. 20.17. For a MOS capacitor with a p-type substrate, the C–V curve be similar to that in Fig. 20.17, but reflected about the y-axis.

20.3.1 Average Doping Density by Maximum–Minimum High-Frequency Capacitance Method

The maximum–minimum high-frequency (HF) capacitance method uses the HF capacitance under strong accumulation (C_{OX}) and strong inversion ($C_{\mathrm{HF,min}}$) to

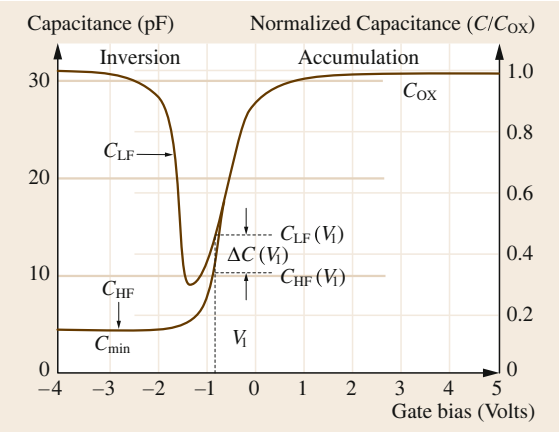

Fig. 20.17 Typical C–V curve for a MOS capacitor on an n-type substrate. (After [20.28])

determine the average doping density [20.29, pp. 406–408]. Note that under strong inversion and at high frequencies, the interface trap capacitance is negligible ($C_{it} \approx 0$). Under strong inversion, the depletion width (w_{max}) is a maximum and so the high frequency capacitance per unit area $C_{HF,min}$ is a minimum, since the minority carriers cannot respond to the high-frequency signal. Since the inversion layer is very thin compared to the depletion layer, then

$$w_{max} = \varepsilon_{Si}\left(\frac{1}{C_{HF,min}} - \frac{1}{C_{OX}}\right), \tag{20.50}$$

where ε_{Si} is the permittivity of silicon and C_{OX} is the gate oxide capacitance per unit area.

At the conditions for w_{max}, the band bending ψ_{max} is a maximum, and it is

$$\begin{aligned}\psi_{max} &= 2\phi_B + \frac{kT}{q}\ln\left(2\frac{q}{kT}\phi_B - 1\right)\\ &= 2\frac{kT}{q}\left\{\ln\left(\frac{n}{n_i}\right) + \frac{1}{2}\ln\left[2\ln\left(\frac{n}{n_i}\right) - 1\right]\right\},\end{aligned} \tag{20.51}$$

where $\phi_B = (k_B T/q)\ln(n/n_i)$ is the shift of the Fermi level from the intrinsic Fermi level $\phi_i = (E_c - E_v)/2q$ in the bulk of the silicon in the MOS structure due to the doping concentration n, and n_i is the thermally generated carrier concentration in silicon. For a uniformly doped sample,

$$w_{max}^2 = \frac{2\varepsilon_{Si}\psi_{max}}{qn} \tag{20.52}$$

and from (20.50) and (20.52), a relation between the doping concentration n and the measured capacitance

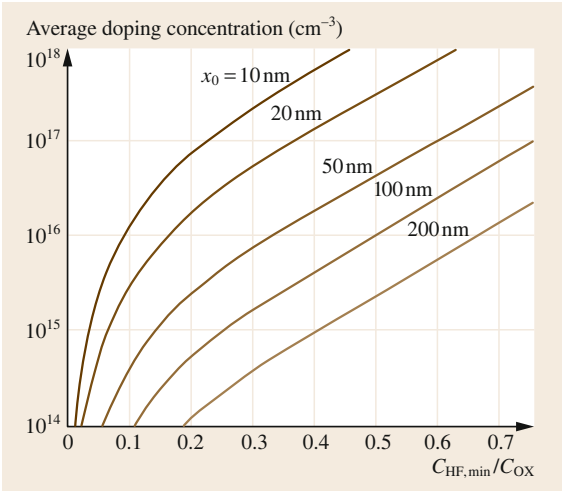

Fig. 20.18 Doping concentration n as function of $C_{HF,min}/C_{OX}$ with oxide thickness, based on (20.53). (After [20.29])

can be established [20.29, p. 407] as

$$\begin{aligned}&\frac{n}{\ln\left(\frac{n}{n_i}\right) + \frac{1}{2}\ln\left[2\ln\left(\frac{n}{n_i}\right) - 1\right]}\\ &= \frac{4kT}{q^2\varepsilon_{Si}}\frac{C_{OX}^2}{\left(\frac{C_{OX}}{C_{HF,min}} - 1\right)^2}.\end{aligned} \tag{20.53}$$

Equation (20.53) is a transcendental equation in average doping concentration n that can be solved numerically by iteration. Figure 20.18 shows the solutions as function of $C_{HF,min}/C_{OX}$ with oxide thickness, and this can be used to obtain the average doping n graphically. Equation (20.53) can be further simplified by neglecting the term $0.5\ln[2\ln(n/n_i) - 1]$, and assuming $C_{OX} = C_{HF,max}$ [20.30]. Also, an approximation of (20.53) for the average doping concentration n in unit cm^{-3} is obtained in [20.4] and [20.31] for silicon MOS structures at room temperature, and this is given by

$$\begin{aligned}\log_{10}(n) = {} & 30.38759 + 1.68278\\ & \times \log_{10}(C_{DM} - 0.03177)\\ & \times [\log_{10}(C_{DM})]^2,\end{aligned} \tag{20.54}$$

where the depletion capacitance (per cm^2 of area) C_{DM} is defined as

$$C_{DM} = \frac{C_{HF,min}C_{OX}}{C_{OX} - C_{HF,min}}, \tag{20.55}$$

where all capacitances are in units of F/cm^2.

20.3.2 Doping Profile by High–Frequency and High–Low Frequency Capacitance Methods

The doping profile in the depletion layer can be obtained [20.29, Sect. 9.4] by assuming that the depletion capacitance per unit area C_D and the oxide capacitance per unit area C_{OX} are connected in series; that is, that the measured high frequency capacitance C_{HF} is given by

$$\frac{1}{C_{HF}} = \frac{1}{C_D} + \frac{1}{C_{OX}} \Rightarrow \frac{1}{C_D} = \frac{1}{C_{HF}} - \frac{1}{C_{OX}} \,. \quad (20.56)$$

For a particular gate biasing V_G of the MOS structure, the depletion thickness $w(V_G)$ is obtained from C_D as

$$w(V_G) = \varepsilon_{Si}\left(\frac{1}{C_{HF}} - \frac{1}{C_{OX}}\right). \quad (20.57)$$

The doping concentration $n(V_G)$ is given by the slope of the $(1/C_{HF})^2$ versus V_G characteristic, given by

$$n(w) = \frac{-2}{q\varepsilon_{Si}\frac{\partial}{\partial V_G}\left(\frac{1}{C_{HF}^2}\right)} \,. \quad (20.58)$$

Note that a plot of $1/C_{HF}^2$ versus V_G (Fig. 20.19) can yield important information about the doping profile. The average n is related to the reciprocal of the slope in the linear part of the $1/C_{HF}^2$ versus V_G curve, and the intercept with V_G at a value of $1/C_{OX}^2$ is equal to the flat-band voltage V_{FB} caused by the fixed surface charge Q_{SS} and the gate–semiconductor work function ψ_{MS} [20.3, 30].

Equation (20.58) does not take into account the impact of interface traps, which cause the C–V curve to stretch. The traps are slow and do not respond to the high frequency of the test signal, but they do follow the changes in the gate bias. Therefore, ∂V_G must be replaced with ∂V_{G0} in (20.58), with ∂V_{G0} representing the case when no interface traps are present.

The value of ∂V_{G0} can be obtained by comparing high- and low-frequency (quasi-static) C–V curves for a MOS structure at the same gate biases V_G. Therefore, the ratio $\partial V_{G0}/\partial V_G$ can be found at any gate bias V_G, since the band-bending is the same for both HF and LF capacitances. In [20.29, Sect. 9.4], it is shown that

$$\frac{\partial V_{G0}}{\partial V_G} = \frac{C_{OX} + C_D}{C_{OX} + C_D + C_{IT}} = \frac{1 - C_{LF}/C_{OX}}{1 - C_{HF}/C_{OX}} \,. \quad (20.59)$$

In this case (20.58) is modified to

$$n(w) = \frac{-2}{q\varepsilon_{Si}\frac{\partial}{\partial V_G}\left(\frac{1}{C_{HF}^2}\right)} \frac{1 - C_{LF}/C_{OX}}{1 - C_{HF}/C_{OX}} \quad (20.60)$$

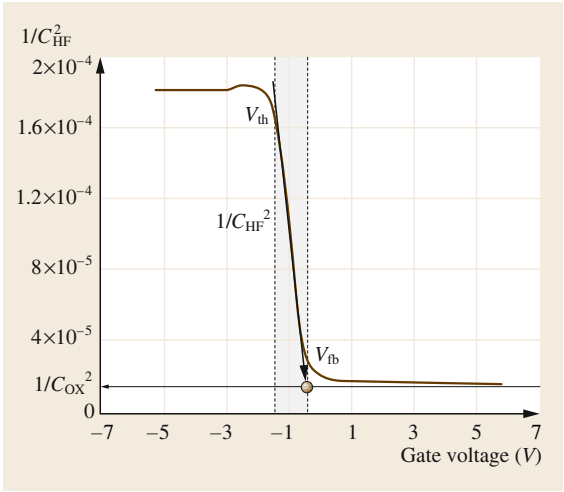

Fig. 20.19 A $1/C_{HF}^2$ versus V_G plot [20.30]. The slope of the *fitted arrow line* is proportional to the average doping, and the *arrow* points to the flat-band voltage V_{FB}, obtained at the V intercept with $1/C_{OX}^2$, shown with the *second horizontal arrow*

as originally proposed in [20.32] and illustrated in Fig. 20.20. As seen from Fig. 20.20, the stretching of the C–V curves due to the interface states induced by stress in Fig. 20.20a causes a disparity in the doping profile in Fig. 20.20b if only the high frequency capacitance is used. The disparity is well-suppressed in Fig. 20.20c by the high–low frequency capacitance measurement, taking into account the stretching of the C–V characteristics. Provided that the depletion layer capacitance is measured at a high frequency, the depletion layer width w is still obtained by (20.57).

Note that the maximum depth w_{max} (20.52) and the resolution Δ_w of the doping profile by means of C–V measurements is limited by the maximum band-bending ψ_{max} and the extrinsic Debye length λ_{Debye}, given by (20.51) and (20.61), respectively, and λ_{Debye} is

$$\lambda_{Debye} = \sqrt{\frac{\varepsilon_{Si}kT}{q^2 n}} \,. \quad (20.61)$$

The doping profile obtained in this way is reliable for depths w of between $3\lambda_{Debye}$ and $w_{max}/2$, when the MOS structure is in depletion and weak inversion, but not in accumulation. That is, $C_{LF} < 0.7C_{OX}$ as a simple rule. As illustrated in Fig. 20.21, the range of w values between $3\lambda_{Debye}$ and equilibrium, obtained via quasi-static C–V measurements, cover about half-a-decade. With proper corrections, the lower distance decreases

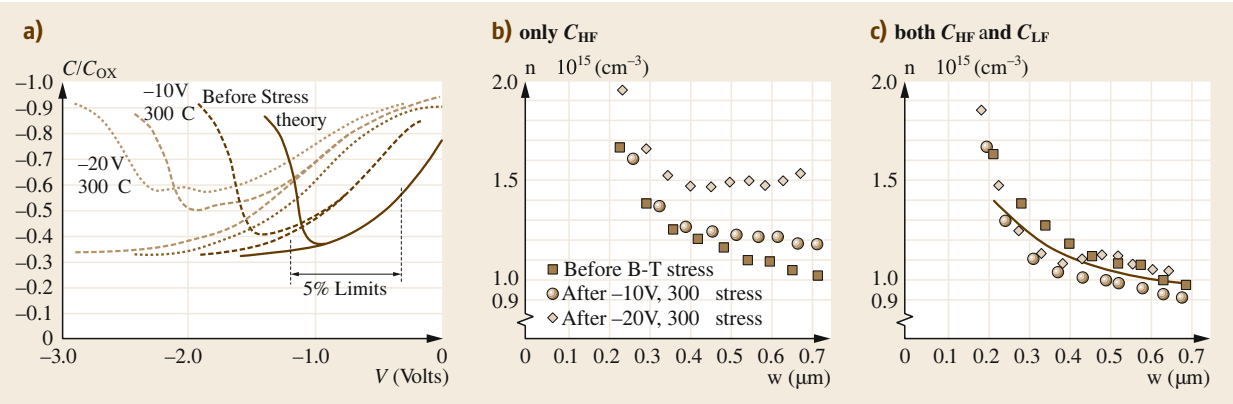

Fig. 20.20a–c *C–V* curves and doping profiles of a MOS structure with 145 nm oxide and uniform doping of 10^{15} cm^{-3} before and after bias temperature stress [20.32]. **(a)** Theoretical and (stretched) measured *C–V* curves. **(b)** Doping profile deduced from only C_{HF} (see (20.58)); **(c)** Doping profile deduced from both C_{HF} and C_{LF} (see (20.60)). (After [20.32])

to one Debye length [20.30]. Using nonequilibrium (transient) *C–V* measurements in deep depletion, the profiling can be extended to higher distances by about an order of magnitude, but further limitations can appear due to the high-frequency response of the interface charge, measurement errors, avalanche breakdown in deep depletion, or charge tunneling in highly doped substrates and thin oxides. More details are presented in [20.29].

20.3.3 Density of Interface States

Interface traps change their charge state depending on whether they are filled or empty. Because interface trap occupancy varies with the slow gate bias, stretching of the *C–V* curves occurs, as illustrated in Fig. 20.20. A quantitative treatment of this *stretch-out* can be obtained from Gauss' law as

$$C_{OX}(V_G - \psi_S) = -Q_S - Q_{IT} = -Q_T \,, \qquad (20.62)$$

where Q_S and Q_{IT} are the surface and interface trap charges (per unit area), which are both dependent on the surface band-bending ψ_S, $Q_T = Q_S + Q_{IT}$ is the total charge in the MOS structure, C_{OX} is the gate capacitance (per unit area), and V_G is the bias applied at the gate of the MOS structure. For simplicity, the (gate metal)-to-(semiconductor bulk) potential ψ_{MS} is omitted in (20.62), but in a real structure the constant ψ_{MS} must be subtracted from V_G. As follows from (20.62), small changes ∂V_G in gate bias cause changes $\partial\psi_S$ in the surface potential bending, and the surface C_S and interface trap C_{IT} capacitances (both per unit area) can represent Q_S and Q_{IT}, given by

$$C_{OX}\partial V_G = (C_{OX} + C_S + C_{IT})\partial\psi_S \,. \qquad (20.63)$$

C_S and C_{IT} are in parallel and in series with the C_{OX}, respectively. Therefore, the measured low-frequency capacitance C_{LF} (per unit area) of the MOS structure becomes

$$C_{LF} = \frac{\partial Q_T}{\partial V_G} = \frac{\partial Q_T}{\partial\psi_S}\frac{\partial\psi_S}{\partial V_G} = \frac{C_{OX}\,(C_S + C_{IT})}{C_{OX} + C_S + C_{IT}} \,. \qquad (20.64)$$

Equation (20.64) shows that stretch-out in the C–V curve can arise due to a non-zero value of C_{IT}, which deviates from the ideal case of $C_{IT} = 0$.

According to [20.29, p. 142], D_{IT} is the density of interface states per unit area (cm^2) and per unit energy (1 eV) in units of $cm^{-2}\,eV^{-1}$. Since the occupancy of the interface states has a Fermi–Dirac distribution, then upon integrating over the silicon band-gap, the relation between C_{IT} and D_{IT} is

$$C_{IT}(\psi_S) = qD_{IT}(\phi_B + \psi_S)\,, \tag{20.65}$$

where $\phi_B = (k_BT/q)\ln(n/n_i)$ is the shift of the Fermi level from the intrinsic level $\phi_i = (E_c - E_v)/2q$ in the silicon bulk of the MOS structure due to the doping concentration n, and n_i is the thermally generated carrier concentration in silicon. Since the derivative of the Fermi–Dirac distribution is a sharply peaking function, then $C_{IT}(\psi_S)$ at particular ψ_S probes $D_{IT}(\phi_B + \psi_S)$ over a narrow energy range of k_BT/q, in which D_{IT} can be assumed to be constant and zero outside this interval. Thus, varying the gate bias V_G, and therefore ψ_S, (20.65) can be used to obtain the density of states D_{IT} at a particular energy shift $q(\phi_B + \psi_S)$ from the silicon intrinsic (mid-gap) energy E_i.

It is evident from (20.64) and (20.65) that the experimental values for D_{IT} can be obtained only when C_{IT}, and ψ_S are determined from C–V measurements. The simplest way to determine ϕ_B is to get the average doping density n using the maximum–minimum high-frequency capacitance method (see (20.53) and Fig. 20.18), or to use the values of n from doping profiles at $0.9\,w_{max}$ – see (20.59) [20.30]. Either the high-frequency or the low-frequency $C-V$ measurement can be used to obtain C_{IT}, but it is necessary to calculate C_S as function of ψ_S, which makes it difficult to process the experimental data.

The most suitable technique for experimentally determining D_{IT} is the combined high–low frequency capacitance method [20.29, Sect. 8.2.4, p. 332]. The interface traps respond to the measurement of low–frequency capacitance C_{LF}, whereas they do not respond to the measurement of the high-frequency measurement C_{HF}. Therefore, C_{IT} can be obtained from measurements by *subtracting* C_{HF} from C_{LF}, given by

$$C_{IT} = \left(\frac{1}{C_{LF}} - \frac{1}{C_{OX}}\right)^{-1} - \left(\frac{1}{C_{HF}} + \frac{1}{C_{OX}}\right)^{-1}. \tag{20.66}$$

Denoting $\Delta C = C_{LF} - C_{HF}$, the substitution of (20.66) into (20.65) provides a direct estimate of D_{IT} from C–V measurements (see also [20.3, p. 371]) as

$$D_{IT} = \frac{\Delta C}{q}\left(1 - \frac{C_{LF}}{C_{OX}}\right)^{-1}\left(1 - \frac{C_{HF}}{C_{OX}}\right)^{-1} \tag{20.67}$$

Note that the combined high–low frequency capacitance method provides C_{IT} and D_{IT} as function of gate bias V_G. However, if D_{IT} needs to be plotted as a function of the position in the energy band-gap, the surface band-bending ψ_S must also be determined as function of gate bias V_G, as follows from (20.65).

There are several ways to obtain the relation between ψ_S and V_G. One way is to create a theoretical plot of C_{HF} versus ψ_S and then, for any choice of C_{HF}, a pair of values for ψ_S and V_G is found [20.29, p. 327]. This method is relatively simple if the doping concentration n in the silicon is uniform and known, because the high-frequency silicon surface capacitance C_S under depletion and accumulation is a simple function of the band-bending ψ_S, and the flat-band capacitance C_{FB} [20.29, pp. 84, 97, 164] is given by

$$C_{FB} = \frac{\varepsilon_{Si}}{\lambda_{Debye}} = \sqrt{\frac{\varepsilon_{Si}q^2n}{k_BT}} \tag{20.68}$$

$$C_S(\psi_S) \approx \begin{cases} \dfrac{C_{FB}}{\sqrt{2}}\dfrac{\exp\left(\frac{q\psi_S}{k_BT}\right)-1}{\sqrt{\exp\left(\frac{q\psi_S}{k_BT}\right)-\frac{q\psi_S}{k_BT}-1}}\,, \\ \qquad \psi_S > 0 \text{ in accumulation} \\ C_{FB},\ \psi_S = 0 \text{ at flat band}, \\ \dfrac{C_{FB}}{\sqrt{2}}\dfrac{1-\exp\left(\frac{q\psi_S}{k_BT}\right)}{\sqrt{\exp\left(\frac{q\psi_S}{k_BT}\right)-\frac{q\psi_S}{k_BT}-1}}\,, \\ \qquad \psi_S < 0 \text{ in depletion}\,. \end{cases} \tag{20.69}$$

Since C_S is in series with C_{OX}, then the theoretical C_{HF} is obtained as a function of the band-bending ψ_S by

$$\frac{1}{C_{HF}(\psi_S)} = \frac{1}{C_{OX}} + \frac{1}{C_S(\psi_S)} \tag{20.70}$$

For a uniformly doped silicon with SiO_2 as the insulator, the ratio $C_{HF}(V_{FB})/C_{OX}$ at gate bias for flat-band conditions is given [20.3, p. 349] by

$$\frac{C_{HF}(V_{FB} \text{ or } \psi_S = 0)}{C_{OX}} = \frac{1}{1 + \frac{136\sqrt{T/300}}{t_{ox}\sqrt{n}}}\,, \tag{20.71}$$

where t_{ox} is the oxide thickness (cm), n is the doping (cm^{-3}), and the T is the temperature (K).

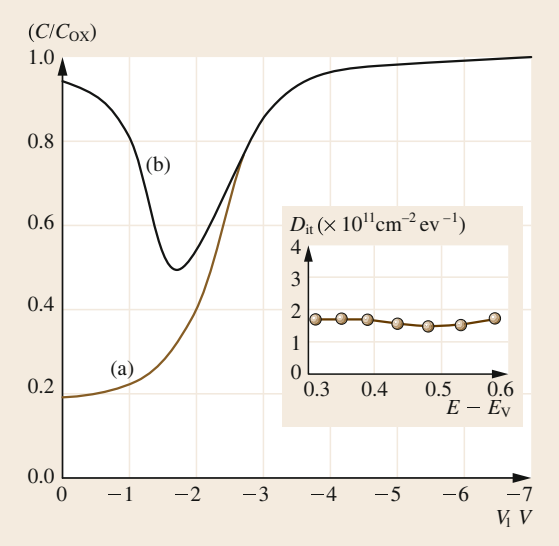

Fig. 20.22 Results from the combined high–low frequency capacitance method [20.33]. *(a)* High-frequency C–V curve; *(b)* low-frequency C–V curve. The energy profile for the density of interface states D_{IT} is shown in the *inset*, as calculated by (20.65), (20.67) and (20.72)

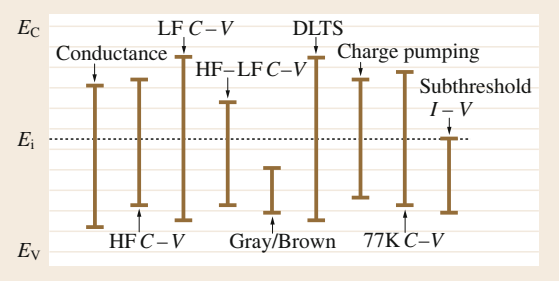

Fig. 20.23 Energy ranges in the silicon band-gap of a p-type substrate over which the density of interface traps can be determined using various measurement methods and characterization techniques. (After [20.3, p. 104])

It was demonstrated in [20.29] that the method of using a theoretical plot to obtain the relation between ψ_S and V_G works well in the case of uniformly doped silicon even if only high-frequency C–V measurements are used to obtain the density of states; that is, the $1/C_{HF}^2$ versus V_G plot is almost a straight line. However, with substrates that are not uniformly doped, the method is inconvenient because the corrections in (20.68) and (20.69) are difficult to implement. Therefore, in practice, a method based on low-frequency C–V measurement is preferred [20.30].

Low-frequency C–V measurement was first used to obtain the relation between ψ_S and V_G [20.34]. This method is based on the integration of (20.66) from an initial gate bias V_{G0}, arbitrarily chosen either under strong accumulation or strong inversion, to the desired V_G at which the band-bending $\psi_S(V_G)$ is to be obtained. Since C_{IT} is part of (20.66), then the low-frequency C–V curve [20.29, p. 93] is integrated as

$$\psi_S(V_G) = \psi_{S0} + \int_{V_{G0}}^{V_G} \left(1 + \frac{C_{LF}(V_G)}{C_{OX}}\right) \mathrm{d}V_G \,. \qquad (20.72)$$

The value of ψ_{S0} is selected such that $\psi_S(V_{FB}) = 0$ when integrating from V_{G0} to the flat-band gate voltage V_{FB}. In this case, V_{FB} is usually obtained beforehand from the point of V-intercept with $1/C_{OX}^2$ when extrapolating the linear part of the $1/C_{HF}^2$ versus V_G curve toward the V_G axis (Fig. 20.19). After determining ψ_{S0}, (20.72) provides the relation between ψ_S and V_G. Thus, the density of states D_{IT} obtained from (20.67) as function of V_G using the combined high–low frequency capacitance method can be plotted against the position of D_{IT} in the silicon band gap, as given by (20.65). High and low frequency C–V measurements can therefore be used to plot the data, as illustrated in the insert of Fig. 20.22.

Overall, many different techniques are used to determine the density of states D_{IT} (Fig. 20.23). For some of these techniques, the ability to sense the energy position of D_{IT} in the band-gap of silicon is summarized in [20.3]. Most of them use C–V measurements, but others are based on I–V measurements taken during the subthreshold operation of MOS transistors, deep-level transient spectroscopy (DLTS), charge pumping (CP) in a three-terminal MOS structure, cryogenic temperature measurements, and so on. Each technique has its strengths and weaknesses, which are discussed in [20.3, 35].

In the methods discussed above, it has been assumed that the gate bias V_G varies slowly with time, 20–50 mV/s, and that the MOS structure is in equilibrium; that is, the minority carriers are generated and the inversion layer is readily formed in the MOS structure when V_G is above the threshold. However, the time constant for minority carrier generation is high in silicon (≈ 0.1 s or more), and it is possible to use nonequilibrium high-frequency C–V measurements to further analyze the properties of the MOS structure. Some applications of these methods are presented later.

20.4 Current–Voltage Measurements

20.4.1 *I–V* Measurements on a Simple Diode

Current–voltage measurements of mainstream semiconductor devices are perhaps the simplest and most routine measurements performed, and they can provide valuable information about the quality of materials used. For example, if we consider the *I–V* characteristics of a p-n diode structure, the source–substrate or drain–substrate junctions can provide useful information on the quality of the junction, such as whether defects are present (they give rise to generation–recombination currents or large parasitic resistances for the contacts at the source, drain or substrate terminals).

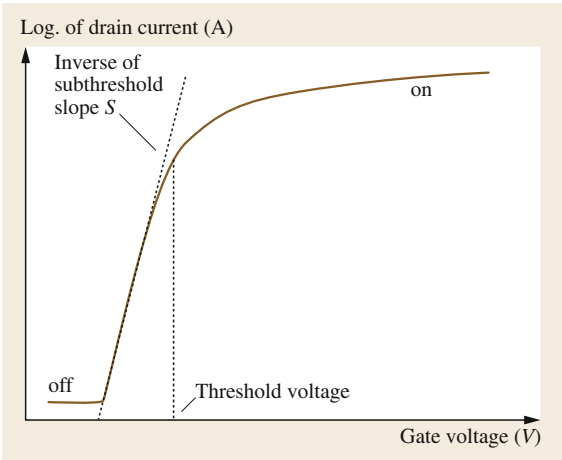

Fig. 20.24 Typical subthreshold characteristics of a MOSFET. The interface state density can be extracted from *S*

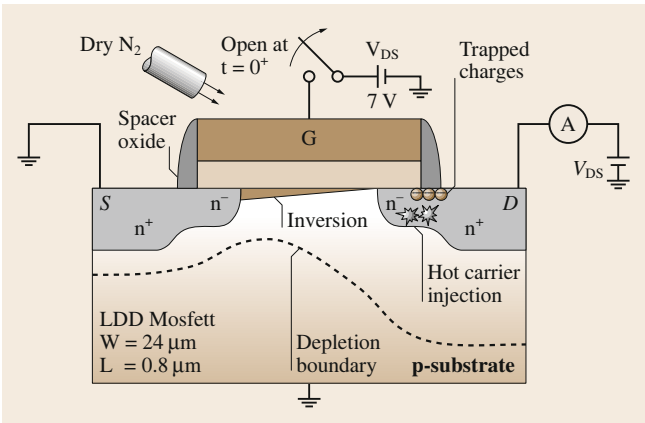

Fig. 20.25 Schematic diagram showing the set-up used for floating gate measurements. The area where charge is trapped after hot electrons are applied is shown

This is easily seen from the current–voltage relation given by the sum of the diffusion (I_{DIFF}) and recombination (I_{GR}) currents

$$I_D = I_{DIFF} + I_{GR} = I_{D0}\left[\exp\left(\frac{eV_D}{nk_BT}\right) - 1\right] + I_{GR0}\exp\left(\frac{eV_D}{2k_BT}\right) \tag{20.73}$$

where I_{D0} and I_{GRO} are the zero-bias diffusion and recombination currents respectively, n is an ideality factor (typically 1), and V_D is the voltage across the intrinsic diode, which is given by

$$V_D = V_{applied} - I_D R_{parasitic}\,. \tag{20.74}$$

For (20.73), a plot of $\ln(I_D)$ versus V_D allows us to separate out the diffusion and the recombination current components. From (20.73) and (20.74), we can also use the diode's *I–V* characteristics to determine the parasitic resistance in series with the intrinsic diode, as described in detail in [20.36]. In most cases, this $R_{parasitic}$ is dominated by the contact resistance.

20.4.2 *I–V* Measurements on a Simple MOSFET

Simple current–voltage measurements – drain current versus gate voltage (I_{DS}–V_{GS}), and I_{DS} versus drain voltage (V_{DS}) – are routinely taken on MOSFETs in order to study their electrical characteristics; however, these can also be used to obtain useful information on the quality of the semiconductor, contacts, oxide and semiconductor–oxide interface. For example, the $I_{DS} - V_{GS}$ characteristics at very small V_{DS} biases (linear region of operation) for a set of test transistors of fixed channel width and different channel lengths is often used to extract parameters such as the threshold voltage (V_T), the transconductance (g_m), the intrinsic mobility (μ_o) and the mobility degradation coefficients θ_0 and η, the parasitic source (R_S) and the drain resistances (R_D) in series with the intrinsic channel, the channel length reduction ΔL, the output conductance (g_{DS}) and the subthreshold slope (S) [20.37].

These parameters are required for modeling and they directly impact the device's performance. However, some of these parameters can also be used to assess the quality of the silicon–silicon dioxide (Si–SiO_2) interface [20.38, 40]. For example, interface states at the Si–SiO_2 interface can change the threshold voltage,

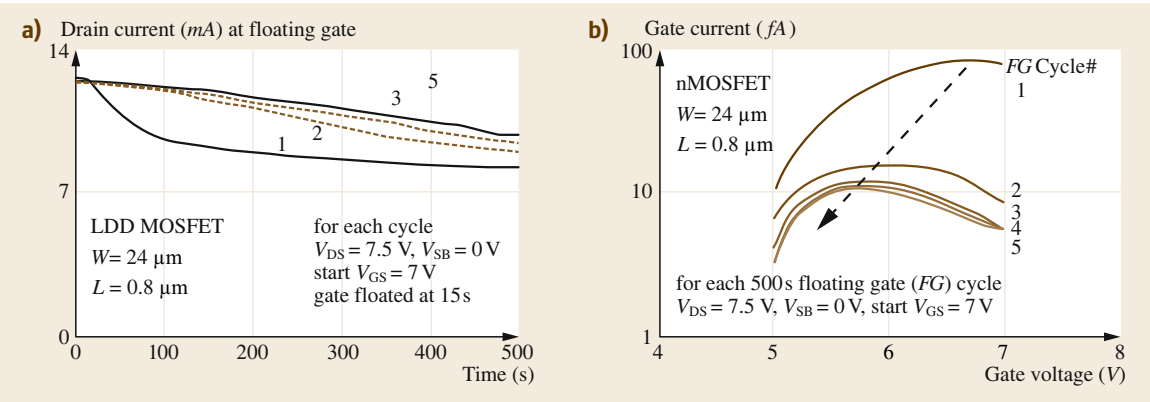

Fig. 20.26 **(a)** Evolution of the drain current over five floating gate cycles. Biasing conditions were chosen to maximize hot-electron gate currents. Note that the maximum drop in drain current occurs after the first floating gate cycle. **(b)** Extracted gate currents using (20.78) and the measurements in **(a)**. As with the drain current, the maximum change in gate current occurs between floating gate cycles 1 and 2. The shift in the peak of the gate current is explained in [20.38, 39]

the subthreshold slope and the mobility, all of which will impact on the drain–source (I_{DS}) current flowing through the device. Here, we look at one parameter in more detail – the subthreshold slope S in mV (of V_{GS})/decade (of I_{DS}).

First, the interface trap density (D_{IT}) can be determined from a semi-log plot of $I_{DS} - V_{GS}$ characteristics at very low drain biases, as shown in Fig. 20.24. We start with the expression for the subthreshold slope

$$S = \frac{k_B T}{q} \ln(10) \left(1 + \frac{C_D + C_{IT}}{C_{OX}}\right) \tag{20.75}$$

in which

$$C_D = \frac{q\varepsilon_{Si} N_A}{\sqrt{2\psi + |V_B| - \frac{k_B T}{q}}} \tag{20.76}$$

D_{IT} can then be calculated from

$$C_{IT} = qD_{IT} \tag{20.77}$$

once C_{IT} is determined from (20.75). In fact, a recent comparison in [20.41] of the interface trap densities extracted from capacitance, subthreshold and charge pumping measurements produced similar results, demonstrating that simple and fast I–V measurements based on the subthreshold technique can provide useful information on the Si–SiO_2 quality.

20.4.3 Floating Gate Measurements

The floating gate technique is another simple I–V measurement in which the evolution of the drain current I_{DS} is monitored after the gate bias has been removed. It has been shown to be particularly useful when monitoring early-mode hot-carrier activity in MOS transistors [20.39, 41]. In this measurement, we first check the oxide quality by biasing the transistor in the strong linear region (very low V_{DS} and a V_{GS} well above V_T), and then lift the gate voltage probe so that $V_{GS} = 0$ V and measure the evolution of I_{DS} with time. For a high-quality gate and spacer oxide, I_{DS} remains constant for a long time, indicating that there is negligible carrier injection across the gate oxide through Fowler–Nordheim tunneling or other leakage mechanisms.

A second precaution is to have a dry or inert gas such as nitrogen flowing over the chip to reduce the possibility of other leakage mechanisms such as that from water vapor. The measurement set-up for this experiment is shown in Fig. 20.25. The evolution of the floating gate current over several cycles with the gate voltage applied and then removed is shown in Fig. 20.26. The biasing voltages and time at which the gate is floated are also given in Fig. 20.26a. For this experiment, a biasing condition of $V_{GS} \approx V_{DS}$ was chosen for a high-impact ionization-induced gate current, but a lower-than-maximum electron injection situation was used for the initial biasing condition.

From the evolution of I_{DS} and the $I_{DS} - V_{GS}$ characteristics of a virgin (not intentionally stressed) transistor at the same V_{DS} as the floating gate measurements, and from measurements of the total capacitance associated with the gate (C_G), the gate current (I_G) evolution after each floating gate cycle can be determined using

$$I(V_{GS}) = C_G \frac{dV_{GS}}{dt} . \tag{20.78}$$

This $I_G - V_{GS}$ evolution is shown in Fig. 20.26b. An ancillary benefit of the floating gate technique

is that very small gate currents (in the fA range or even smaller) can be easily determined by measuring much larger drain currents using, for example, a semiconductor parameter analyzer. The reason for this is that the gate current is not directly measured in this technique – it is determined from $I_{DS} - V_{GS}$ and (20.78). Also, the change in the floating gate current after the first few cycles can be used to monitor for early mode failure after statistical evaluation.

20.5 Charge Pumping

Charge pumping (CP) is another electrical technique that is well suited to studying semiconductor–insulator interfaces in MOSFETs [20.42–47]. There are several versions of the CP technique: spatial profiling CP [20.43–47], energy profiling CP [20.48], and, more recently, new CP techniques [20.49] that permit the determination of both interface states (N_{IT}) and oxide traps (N_{OT}) away from the interface and inside the oxide. The charge pumping technique is more complicated than either of the I–V or floating gate methods. However, it is a very powerful technique for assessing interface quality and it works well even with very small transistor geometries and very thin gate oxides, where tunneling can be a problem.

The charge pumping technique was first used in 1969 [20.50] to measure the interface traps at Si−SiO_2 interface. Since then, there have been numerous publications with enhancements, refinements and applications of the technique to a variety of semiconductor–insulator interfacial studies. In the basic charge pumping experiment, the gate of an NMOST (for example) is pulsed from a low value (V_L) when the device is in accumulation to a high value (V_H) when the device is in inversion. This results in the filling of traps between $E_{F,ACC}$ (corresponding to V_L) and $E_{F,INV}$ (corresponding to V_H) with holes and electrons, respectively. When pulsing the gate between accumulation at V_L and inversion at V_H, a current flows due to the repetitive recombination at the interface traps of minority carriers from the source and drain junctions with majority carriers from the substrate. This current is termed the charge pumping current, and it was found to be proportional to the frequency of the gate pulse, the gate area and the interface state density. Its sensitivity is better than $10^9\,\mathrm{cm}^{-2}\,\mathrm{eV}^{-1}$. In the traditional CP experiment shown in Fig. 20.27, but with $\Delta V_S = |V_D - V_S| = 0\,\mathrm{V}$, the gate G is connected to a pulse generator, a reverse bias V_R or no bias is applied to both sources S and drain D terminals, and the charge pumping current flowing in the substrate terminal, I_{CP}, is measured. To generate a typical charge pumping curve (as shown in the top part of Fig. 20.28), the base level of the pulse is varied, taking the transistor from below flat-band to above surface inversion conditions, as shown in the bottom part of Fig. 20.28.

In the traditional CP experiment, the charge pumping current I_{CP} is given by

$$I_{CP} = qA_{GATE}\overline{D_{IT}}\Delta E\,, \tag{20.79}$$

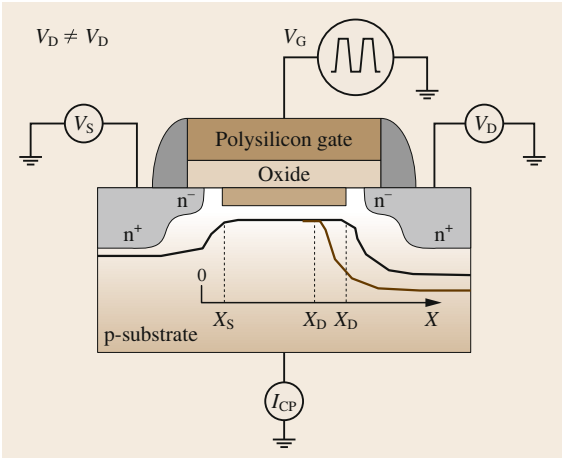

Fig. 20.27 Example of spatial profiling charge-pumping set-up used when the source and drain biases are slightly different

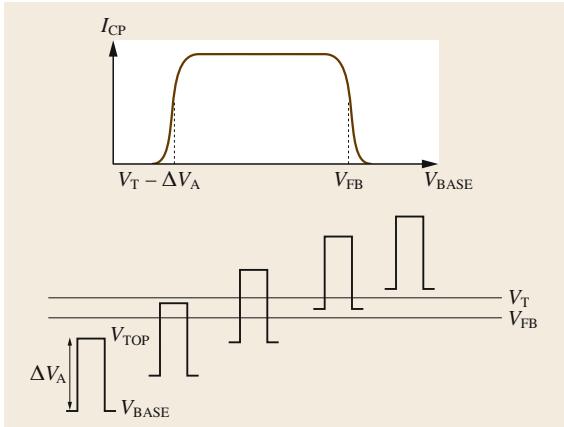

Fig. 20.28 Demonstration of how the CP curve is generated by varying the base level of the pulse so that the entire pulse is between V_{FB} and V_T

where

$$\Delta E = (E_{\mathrm{F,INV}} - E_{\mathrm{F,ACC}})\,. \tag{20.80}$$

This expression assumes that the electrical and physical channel lengths are the same. However, for short channel devices, this assumption results in an error. Therefore, a more accurate expression is

$$I_{\mathrm{CP}} = qf\,W \int_{x_s}^{x_d} N_{\mathrm{IT}}(x)(q\Delta\psi_{\mathrm{SO}}) \tag{20.81}$$

$$x_{\mathrm{d}} = L - \sqrt{\frac{2\varepsilon_{\mathrm{Si}}}{qN}}\left(\sqrt{V_{\mathrm{D}} + \psi_{\mathrm{S}}} - \sqrt{\psi_{\mathrm{S}}}\right). \tag{20.82}$$

The interface state density at the edge of the drain depletion region ($N_{\mathrm{IT}}(x_{\mathrm{d}})$) is given by

$$N_{\mathrm{IT}}(x_{\mathrm{d}}) = \frac{1}{qf\,Wq\Delta\psi_{\mathrm{S0}}}\left(\frac{\mathrm{d}x_{\mathrm{s}}}{\mathrm{d}V_{\mathrm{S}}}\right)^{-1}\left(\frac{\mathrm{d}I_{\mathrm{CP}}}{\mathrm{d}V_{\mathrm{S}}}\right)_{V_{\mathrm{D}}=\mathrm{constant}} \tag{20.83}$$

When performing spatial profiling CP experiments, some precautions are required. The first is that a voltage difference ΔV_{S} between V_{D} and V_{S} that is too small results in a difference in I_{CP} that is too small as well, and hence a large error in $N_{\mathrm{IT}}(x)$, as indicated from (20.83). On the other hand, values of ΔV_{S} that are too large result in a I_{D} that is too high and hence more substrate current I_{B}. This current I_{B} can interfere with I_{CP} if ΔV_{S} is large or if L is very short, resulting in a large error in $N_{\mathrm{IT}}(x)$. The range 50–100 mV for ΔV_{S} seems to be a good compromise for the devices investigated in [20.43, 44]. Experimental results for spatial profiling CP measurements indicate that $N_{\mathrm{IT}}(x)$ peaks near S/D edges. However, after normal mode stress, $N_{\mathrm{IT}}(x)$ only increases near D. This is shown in Fig. 20.29. More details about charge pumping can be found in a recent review [20.51].

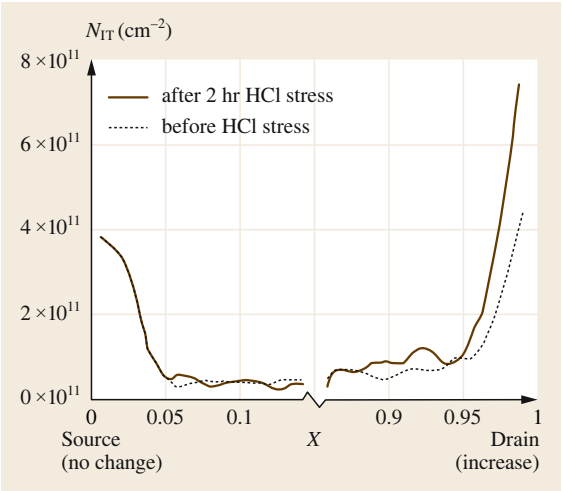

Fig. 20.29 Spatial interface state distribution over the channel in a 1 μm-long device. The stress was applied for 2 h at $V_{\mathrm{DS}} = 5\,\mathrm{V}$ and $V_{\mathrm{GS}} = 2.4\,\mathrm{V}$

20.6 Low-Frequency Noise

20.6.1 Introduction

Low-frequency noise (LFN) spectroscopy requires very good experimental skills in the use of low-noise instrumentation as well as grounding and shielding techniques. Other special considerations are also required, which are discussed later. Although it is time-consuming to perform, it has been widely used to probe microscopic electrical transport in semiconductors and metals. LFN is very sensitive to defects in materials and devices, and large differences in LFN characteristics can be observed in devices with identical electrical current–voltage characteristics. This is mainly because electrical I–V measurements only probe the average or macroscopic transport in devices and so are not as sensitive to defects as LFN. Due to its sensitivity to defects, traps or generation–recombination centers, LFN has been proposed as a good tool for predicting device reliability. For example, LFN has been used to predict the reliabilities of metal films [20.52], and has been used in processing steps that produce photodetectors with better performance [20.53, 54]. LFN noise is sensitive to both bulk and surface defects or contaminants of a material.

Using low-frequency noise spectroscopy and biasing the transistor in saturation, we can spatially profile the defect density near the drain and source terminals for devices in normal and reverse modes of operation [20.55]. Low-frequency noise in the linear region also allows us to extract the average defect density over the entire channel region at the silicon–silicon dioxide interface [20.56, 57]. Noise experiments were performed on small-geometry polysilicon emitter bipolar transistors to investigate the number of interface states in the thin interfacial oxide layer between the monocrystalline and polycrystalline silicon [20.58–

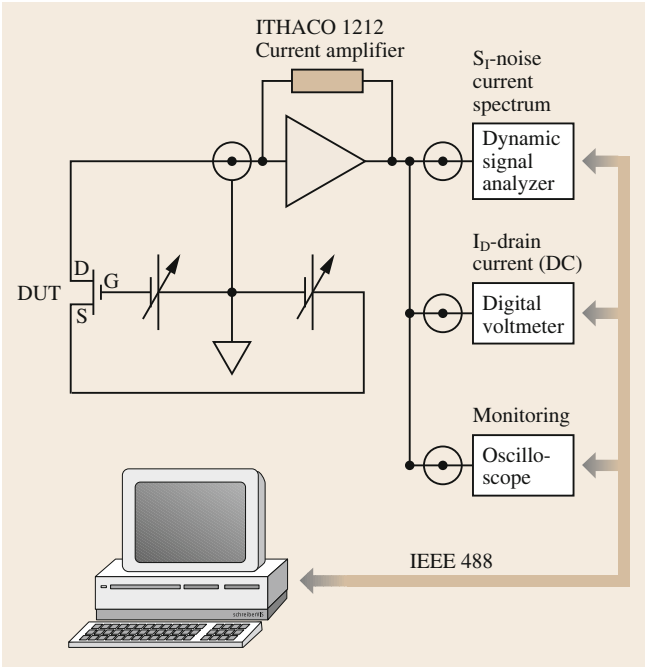

Fig. 20.30 System for measuring low-frequency noise. In this diagram, the device under test is any field-effect or thin-film transistor

68]. Recent experiments using body or substrate bias (V_B) in a MOS transistor allowed us to look at the contribution of bulk defects (defects away from the silicon–silicon dioxide interface) and their contribution to device noise [20.69–71]. This is important since substrate biasing has been proposed as a means to cleverly manage power dissipation and speed in emerging circuits and systems [20.72].

We will discuss how low-frequency noise (LFN) spectroscopy can be applied to the interfacial oxide layer between the mono-silicon and polysilicon emitter in bipolar junction transistors (BJTs) here. The experimental system shown in Fig. 20.30 is used for LFN measurements of field-effect transistors (FETs); the same system can also be used for BJTs.

As mentioned before, special attention must be paid to grounding and shielding in LFN measurements, as this is crucial to minimizing the effects of experimental and environmental noise sources on the device under test (DUT). Because electric power supplies are noisy, especially at 60 Hz (in North America) and its harmonics, and this noise can dominate the noise of the DUT, batteries are often used to supply the voltage. Metal film resistors are the preferred means of changing the biasing conditions, because of their better low-noise characteristics compared to carbon resistors, for example.

With these experimental precautions taken, the noise signal from the transistor might still be too low to be directly measured using a spectrum or signal analyzer. Therefore, a low-noise voltage or current amplifier, whose input noise sources are lower than that of the noise signal, is used to boost the noise signal. In addition, other instruments might be used to measure currents or voltages, or to display the waveforms (as shown in Fig. 20.30). An example of a low-frequency noise characterization system that we have used to study the noise in thin film polymer transistors is shown in Fig. 20.30. Note that LFN measurements are time intensive because a large number of averages are required for smooth spectra. Also, in noise measurements, the power spectrum densities S_V and S_I for the noise voltages and currents are measured, in units V^2/Hz and A^2/Hz, respectively.

20.6.2 Noise from the Interfacial Oxide Layer

Here we present some sample results and show how low-frequency noise spectra in ultrasmall devices can

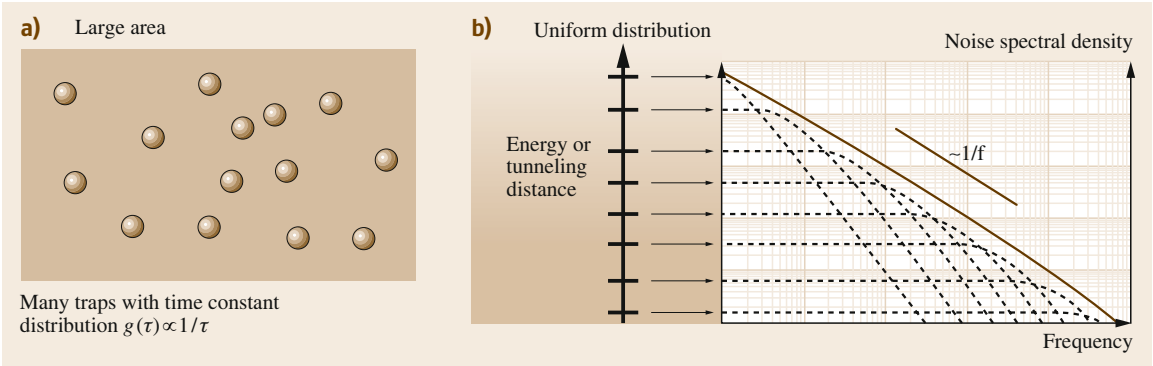

Fig. 20.31 Schematic representation of a *large*-area PE-BJT with many traps distributed uniformly across the band gap and the emitter area, and with a $g(\tau) = 1/\tau$ distribution for the time constant. The resulting spectrum is $1/f$ noise

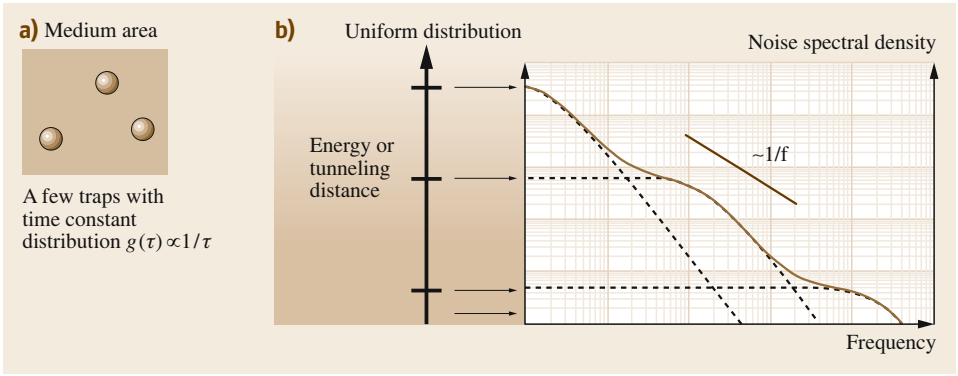

Fig. 20.32 Schematic representation of a *medium*-area PE-BJT ($\approx 0.5\,\mu m^2$) with a few traps. Note that g–r bumps appear for each trap since there are only a few traps

be used to estimate the oxide trap density. Generally, the low-frequency noise spectra of polysilicon emitter (PE) BJTs are made up of $1/f$ noise, generation–recombination (g–r) noise and shot noise sources. In the case of the base current, the noise spectra can be modeled as

$$S_{I_B} = \frac{K_F I_B^{A_F}}{f} + \sum_{i=1}^{n} \frac{B_i \tau_i}{1 + (2\pi f \tau_i)^2} + 2qI_B \,, \qquad (20.84)$$

where the symbols have their usual meanings, see [20.68] for example.

As described in [20.63–68], the LFN in PE BJTs originates from the thin layer of oxide between the monocrystalline and polycrystalline silicon emitter. The defects at this interface may be dangling oxygen bonds, oxygen vacancies, interface states or oxide traps [20.63]. Devices with large emitter areas have many traps, and these produce generation–recombination noise which produce $1/f$ noise when added. This is schematically shown in Fig. 20.31.

As the device area is reduced, and assuming a constant trap density (which is normally true for devices on the same wafer), then there are fewer traps in the interfacial oxide layer for smaller area devices. In this case, the spectral density of the noise changes and it gains characteristic *bumps* associated with resolvable g–r noise components. This is schematically shown in Fig. 20.32.

In very small devices with only a single trap, for example, the noise spectrum changes dramatically; only g–r noise is observed in the frequency domain along with a random telegraph signal (RTS) in the time domain. This is schematically shown in Fig. 20.33. Real experimental results are shown for three sizes of transistors (2.4, 0.64 and $0.16\,\mu m^2$) in Fig. 20.34. Here, one can see how $1/f$ noise is made up of g–r spectra as the emitter geometries are scaled to smaller and smaller values. For the PE BJT with an emitter area of $0.16\,\mu m^2$, a lower bound of $\approx 10^9\,cm^2$ can be approximated for the oxide trap density. Similar results have been obtained for MOSFETs [20.73].

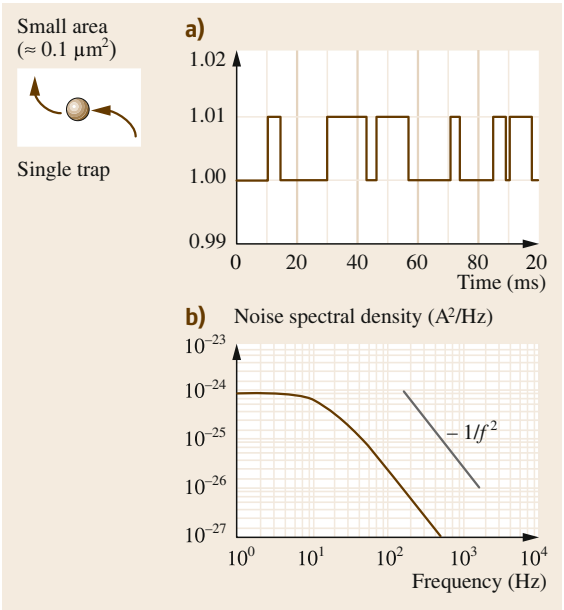

Fig. 20.33 Schematic representation of a *small*-area PE-BJT ($\approx 0.1\,\mu m^2$) with one trap. Note that **(a)** a single RTS and **(b)** g–r spectrum appear because there is only one trap

20.6.3 Impedance Considerations During Noise Measurement

Two basic circuits can be employed when measuring the low-frequency noise (LFN) in a device. These configurations are sketched in Fig. 20.35. In voltage noise measurement (Fig. 20.35a), a low-noise preamplifier senses the voltage across the device, and this signal is sent to a spectrum analyzer or a fast Fourier transform (FFT) analyzer. In current noise measurements (Fig. 20.35b), the low-noise preamplifier senses the current through the device, converts it into a voltage,

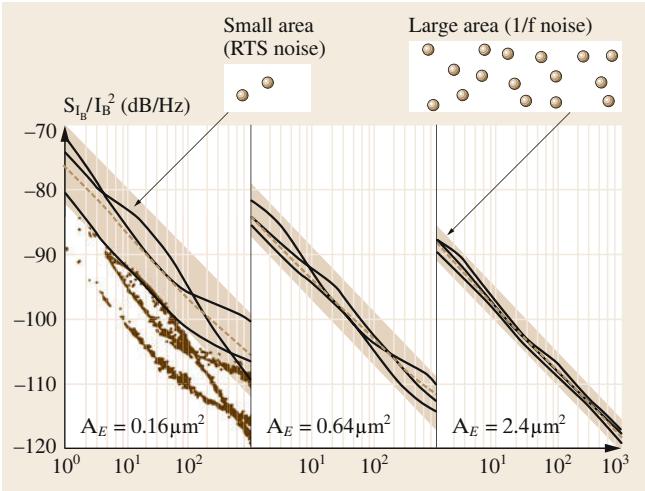

Fig. 20.34 Experimental results for low-frequency noise spectra from sets of large-, medium- and small-area PE-BJTs. In all cases, the average spectrum is $1/f$ noise and the relative magnitude of the $1/f$ noise is the same; that is, the area of $K_F\times$ is the same for the three sets of transistors. (After [20.59–62])

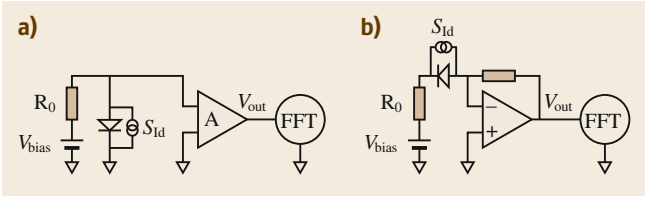

Fig. 20.35a,b Basic circuits used to measure the low-frequency noise (LFN) in a device (DUT). **(a)** Voltage noise measurement; **(b)** current noise measurement

and forwards the voltage to a FFT or spectrum analyzer.

In principle, both configurations can be used for LFN measurement, but the impact of the nonideality of the amplifier (such as the input impedance, noise voltage and current) changes when the device impedance changes. Also, the noise from the bias source varies with each measurement set-up.

The noise equivalent circuit used for voltage measurement is shown in Fig. 20.36. The noise from the amplifier is represented by the input-referred noise voltage (S_{Vn}) and noise current (S_{In}) sources. The noise voltage from the bias is represented by S_{V0}. The impedance of the bias source is R_0, whereas the input impedance of the amplifier is neglected, since it is usually very high compared to R_0. The impedance of DUT is r_d. The noise current S_{Id} of the device that can be measured, assuming that the noise voltage at the input of the amplifier $S_{Vm} = S_{Id}r_d^2$. However, the amplifier sees

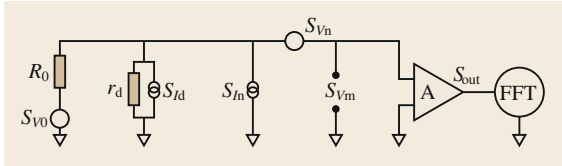

Fig. 20.36 Noise equivalent circuit for voltage noise measurements

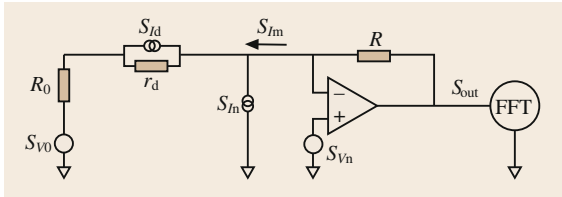

Fig. 20.37 Noise equivalent circuit of the current noise measurement

a different level of S_{Vm}, given by

$$S_{Vm} = \frac{S_{OUT}}{A^2} = S_{V0}\left(\frac{r_d}{r_d + R_0}\right)^2 + S_{Vn} + (S_{II} + S_{II})Z^2 \quad (20.85)$$

where

$$Z = (r_d//R_0) = \frac{r_d R_0}{r_d + R_0} \quad (20.86)$$

and A is the voltage gain of the amplifier. Therefore, the estimated value for S_{Id} is

$$S_{Id} = \frac{S_{Vm} - S_{Vn}}{Z^2} - \frac{S_{V0}}{R_0^2} - S_{In}\,. \quad (20.87)$$

The uncertainty in (20.87) is

$$\frac{\Delta S_{Id}}{S_{Id}} = \frac{\Delta S_{Vn}}{S_{Vm}} + \frac{\Delta S_{V0}}{S_{Vm}}\left(\frac{Z}{R_0}\right)^2 + \frac{\Delta S_{In}}{S_{Vm}}Z^2 \quad (20.88)$$

where $\Delta S \leq S$ denotes the uncertainty in each noise source. As seen from (20.88), the impact of the bias source noise ΔS_{V0} and the input current noise ΔS_{In} can be reduced if the impedance of the measurement circuit Z is low and the ratio r_d/R_0 is kept much less than 1; in other words, the *voltage noise measurement is more appropriate for low-impedance devices, such as diodes at forward biasing*, and the noise floor of the measurement is limited by the input-referred voltage noise S_{V_n} of the amplifier.

For the other (dual) case, current noise measurement, the noise equivalent circuit is shown in Fig. 20.37. The corresponding equations for the measured noise

current $S_{I\mathrm{m}}$, Z, the device noise $S_{I\mathrm{d}}$, and the uncertainty, respectively, are given by (20.89–20.92) below

$$S_{I\mathrm{m}} = \frac{S_{\mathrm{OUT}}}{R^2} = \frac{S_{V0}}{(r_\mathrm{d}+R_0)^2} S_{I\mathrm{n}} + \frac{S_{V\mathrm{n}}}{Z^2} + S_{I\mathrm{d}} \left(\frac{r_\mathrm{d}}{r_\mathrm{d}+R_0}\right)^2 \tag{20.89}$$

$$Z = (r_\mathrm{d}+R_0)\,//R = \left(\frac{1}{R} + \frac{1}{r_\mathrm{d}+R_0}\right)^{-1} \tag{20.90}$$

$$S_{I\mathrm{d}} = (S_{I\mathrm{m}} - S_{I\mathrm{n}}) \left(1+\frac{R_0}{r_\mathrm{d}}\right)^2 - \frac{S_{V0}}{r_\mathrm{d}^2} - \frac{S_{V\mathrm{n}}}{Z^2}\left(1+\frac{R_0}{r_\mathrm{d}}\right)^2 \tag{20.91}$$

$$\frac{\Delta S_{I\mathrm{d}}}{S_{I\mathrm{d}}} = \frac{\Delta S_{I\mathrm{n}}}{S_{I\mathrm{m}}} + \frac{\Delta S_{V0}}{S_{I\mathrm{m}}} \frac{1}{(r_\mathrm{d}+R_0)^2} + \frac{\Delta S_{V\mathrm{n}}}{Z^2 S_{I\mathrm{m}}} \tag{20.92}$$

As expected from duality, it is apparent from (20.92) that the impact of the bias source noise ΔS_{V0} and the input voltage noise $\Delta S_{I\mathrm{n}}$ can be reduced if the impedance of the measurement circuit Z and $(r_\mathrm{d}+R_0)$ are both high; in other words, the *current noise measurement is more appropriate for high-impedance devices, such as diodes at reverse biasing*, and the noise floor of the measurement is limited by the input-referred current noise S_{I_n} of the amplifier.

This analysis above demonstrates that the choice of the measurement configuration follows our expectation that voltage should be measured in low-impedance devices and current in high-impedance devices. Also, the noise floor limiting parameter of the preamplifier is of the same type as the type of measurement; that is, input-referred noise voltage for voltage noise measurement and input-referred noise current for current noise measurement. Note that there is a trade-off between the voltage and current noise in amplifiers, which implies that the measurement configuration – either voltage or current measurement – should also be carefully selected with respect to the impedance of the device under test. In addition, four-point connection can be used to measure the noise in very low impedance devices ($r_\mathrm{d} < 100$). These and other considerations for low-frequency noise instrumentation are discussed in many papers, for example [20.74–76].

20.7 Deep-Level Transient Spectroscopy

Deep-level transient spectroscopy (DLTS) is a fairly complicated electrical characterization technique where the temperature is varied in large range from cryogenic temperatures ($< 80\,\mathrm{K}$) to well above room temperature ($> 400\,\mathrm{K}$). However, it is a powerful and versatile technique for investigating deep-level defects and it also gives accurate values for the capture cross-sections of defects. There are several DLTS techniques and [20.77, 78] provide recent reviews of the subject. In DLTS, the semiconductor device or junction is pulsed with an appropriate signal, and the resulting transient (such as capacitance, voltage or current) is monitored at different temperatures. Using these recorded transients at different temperatures, it is possible to generate a spectrum with peaks, each of which is associated with a deep level. The heights of the peaks are proportional to the defect density.

Here, we will focus on a new version of DLTS: the constant resistance (CR) DLTS technique [20.79–81]. We were able to accurately investigate bulk defects in a variety of test structures with CR-DLTS. Using body bias in a MOS transistor, we were able to distinguish interfacial and bulk defects that are important for different applications. For example, interfacial defects are important for electronic applications, and bulk defects are important for imaging or radiation detection applications. Examples of results from DLTS studies with and without body bias will be discussed.

CR-DLTS is well-suited to investigations of electrically active point defects that are responsible for the creation of deep levels in the semiconductor band-gap. CR-DLTS can also be used to distinguish bulk traps and interface traps in MOSFETs.

A conventional DLTS system is shown schematically in Fig. 20.38. In DLTS, an excitation pulse is applied to the sample to fill all of the traps and then the pulsing is stopped. The next step is to detect the transient signal from the sample due to charge emission from the traps. The right side of Fig. 20.38 shows capacitance transients at eight different temperatures. By selecting a time window from t_1 to t_2, and then plotting $[C(t_1) - C(t_2)]$ as a function of temperature, a DLTS spectrum with a characteristic peak is obtained as shown in the bottom of Fig. 20.38.

This peak is a signature from a specific defect level. To determine the properties of the defect (its energy level and capture cross-section), the time window ($\tau = t_2 - t_1$) is changed. In this case, different DLTS spectra are obtained at different temperatures. Using the time difference τ and the temperatures at which the peaks occur,

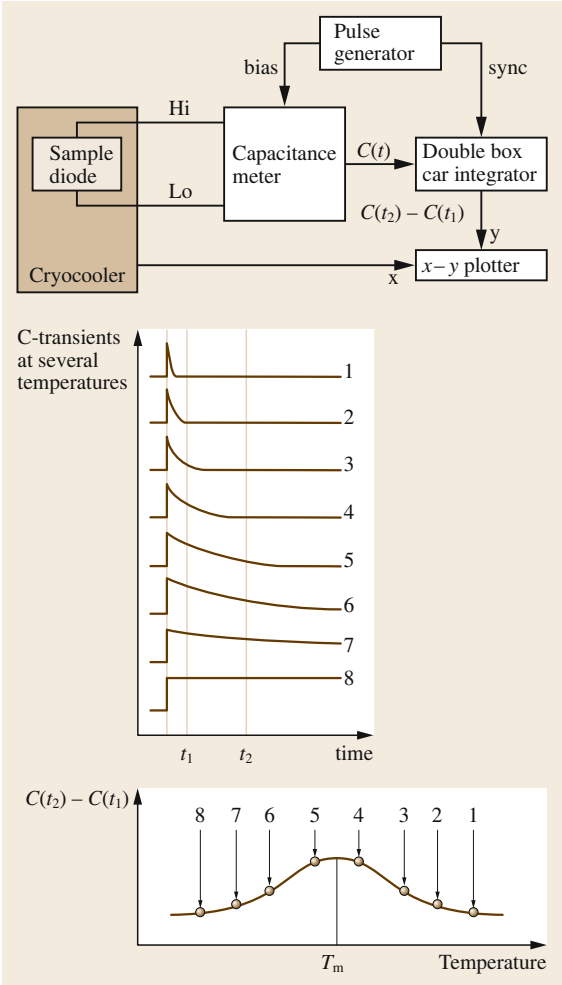

Fig. 20.38 Schematic representation of a conventional DLTS system. The time scans from which the DLTS temperature spectrum is obtained are shown on the *right*

Arrhenius plots are constructed in order to determine the defect energy level and its capture cross-section. Examples of DLTS spectra and Arrhenius plots associateed with CR-DLTS are presented later (in Fig. 20.40).

A block representation of the CR-DLTS system is shown in Fig. 20.39. More details can be found in [20.79–83]. A discussion of the signal processing and averaging techniques used with this DLTS technique can be found in [20.82]. Here, the gate bias voltage of the field-effect transistor is adjusted using a feedback circuit so that the resistance corresponding to the source–drain conductance matches that of a reference resistor R_{ref}, which is typically around 1 MΩ. The voltage transient due to the change in occupancy of the traps appears as a compensation voltage on the gate. This voltage change can be regarded as a threshold voltage change because the flat-band voltage of the device changes when the occupancy of the traps change. More details on how this change in the threshold is related to the traps can be found in [20.77, 79, 81].

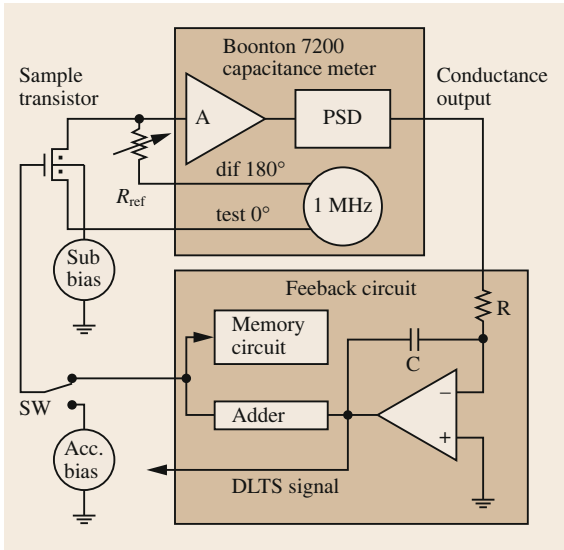

Fig. 20.39 Block diagram representation of the CR-DLTS system

Some important advantages of the CR DLTS technique are that the surface mobility of the MOS transistors does not need to be high, and that it is theoretically independent of the gate area of the transistor. This is expected, since the small amount of charge trapped beneath the gate must be balanced by a correction voltage applied across a relatively small gate–substrate capacitance.

Figure 20.40a shows six DLTS spectra for a junction field-effect transistor (JFET) damaged with 2.7×10^9 protons/cm^2 [20.79, 81] with six selected rate windows. Using the temperatures at which the peaks occur and the rate windows, Arrhenius plots can be constructed as shown in Fig. 20.40b, where the energies of five electron trap levels below the conduction band are also indicated. For the five traps, the extracted capture cross sections were 4.6×10^{-15} cm^2 (E1), 6.3×10^{-15} cm^2 (E2), 1.2×10^{-16} cm^2 (E3), 8.5×10^{-16} cm^2 (E4) and 3.4×10^{-15} cm^2 (E5).

Figure 20.41 shows CR-DLTS spectra as the source–body bias voltage is varied. The scans with a body bias of −1 V are lower in magnitude than those without substrate bias, except for the peak associated with the hole trap at 0.13 eV above the valence band [20.81]. When the reverse substrate bias is increased, the gate control of the space charge region near the channel decreases, meaning that fewer interface traps participate in the capture and emission of

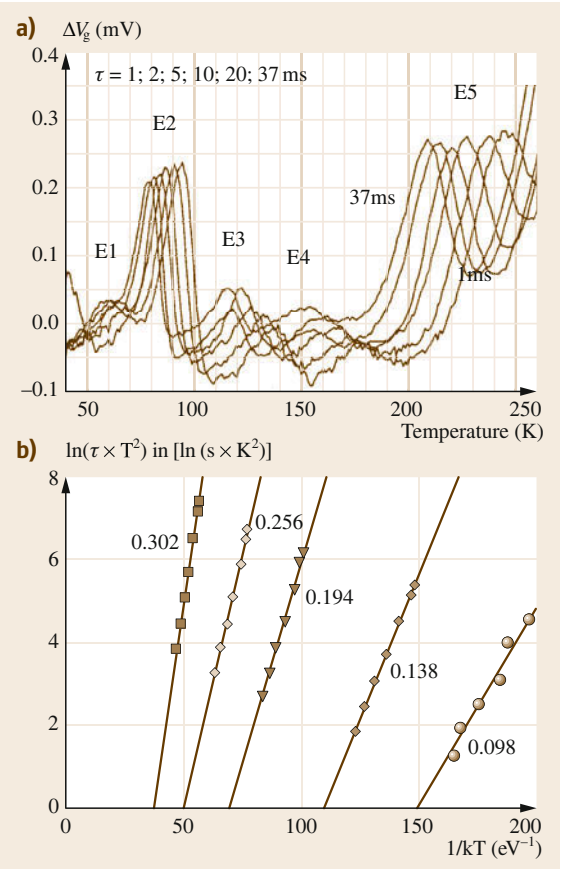

Fig. 20.40 **(a)** CR-DLTS spectra of a 50 µm × 20 µm MOSFET damaged with 2.7×10^9 proton/cm^2. **(b)** Arrhenius plot derived from the CR-DLTS spectra, showing the energies of the five traps E1–E5. (After [20.80, 83])

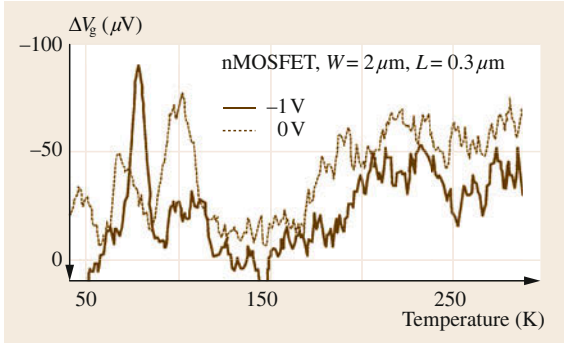

Fig. 20.41 Effect of body bias on CR-DLTS spectra. The body bias affects the surface and bulk traps in different ways

charges. However, the increased reverse substrate bias results in an increased space charge region in the silicon beneath the gate, so more bulk deep levels can participate in the capture and emission processes. This explains the increased deep-level peak (below 75 K) when −1 V is applied to the body. These differences between the CR-DLTS spectra demonstrate the ability to distinguish bulk traps from surface traps when the substrate bias of the MOSFET is varied.

Acknowledgments. The authors are very grateful to Drs. O. Marinov and D. Landheer for their careful review of the manuscript and their assistance. They are also grateful to several previous students and researchers whose collaborative research is discussed here. Finally, they are grateful to NSERC of Canada, the Canada Research Chair program and the CNRS of France for supporting this research.

21. Single-Crystal Silicon: Electrical and Optical Properties

Mark Auslender, Shlomo Hava

Electrical and optical properties of crystalline semiconductors are important parts of pure physics and material science research. In addition, knowledge of parameters related to these properties, primarily for silicon and III–V semiconductors, has received a high priority in microelectronics and optoelectronics since the establishment of these industries. For control protocols, emphasis has recently been placed on novel optical measurement techniques, which have proved very promising as nondestructive and even non-contact methods. Earlier they required knowledge of the free-carrier-derived optical constants, related to the electrical conductivity at infrared frequencies, but interest in the optical constants of silicon in the visible, ultraviolet (UV) and soft-x-ray ranges has been revived since the critical dimensions in devices have become smaller.

This chapter surveys the electrical (Sect. 21.2) and optical (Sect. 21.3) properties of crystalline silicon. Section 21.2 overviews the basic concepts. Though this section is bulky and its material is documented in textbooks, it seems worth including since the consideration here focuses primarily on silicon and is not spread over other semiconductors – this makes the present review self-contained. To avoid repeated citations we, in advance, refer the reader to stable courses on solidstate physics [21.1, 2], semiconductor physics [21.3], semiconductor optics [21.4] and electronic devices [21.5]; seminal papers are cited throughout Sect. 21.2.

References 520

We realize how formidable our task is – publications on electrical and optical properties of silicon amount to a huge number of titles, most dating back to the 1980s and 1990s – so any review of this subject will inevitably be incomplete. Nevertheless, we hope that our work will serve as a useful shortcut into the silicon world for a wide audience of applied physics, electrical and optical engineering students.

21.1 Silicon Basics

21.1.1 Structure and Energy Bands

Normally silicon (Si) crystallizes in a diamond structure on a face-centered cubic (fcc) lattice, with a lattice constant of $a_0 = 5.43$ Å. The basis of the diamond structure consists of two atoms with coordinates (0, 0, 0) and $a_0/4(1, 1, 1)$, as seen in Fig. 21.1. Other solids that can crystallize in the diamond structure are C, Ge and Sn. The important notion for the electronic band structure is the Brillouin zone (BZ). The BZ is a primitive cell in the reciprocal-space lattice, which proves to be a body-centered cubic (bcc) lattice for an fcc real-space lattice. For this case, the BZ with important reference points and directions within it is shown in Fig. 21.2.

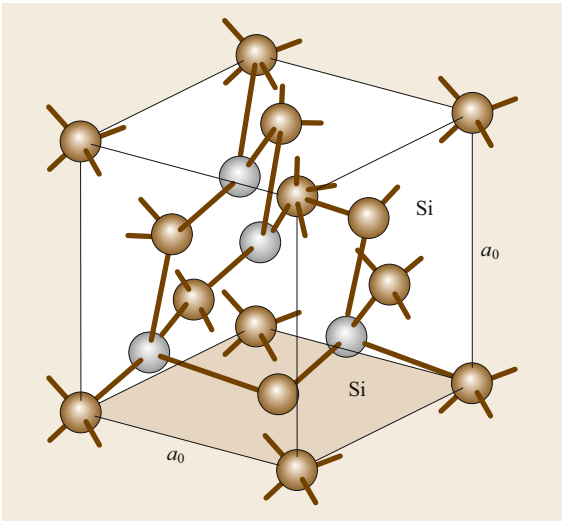

Fig. 21.1 Diamond crystal structure of Si

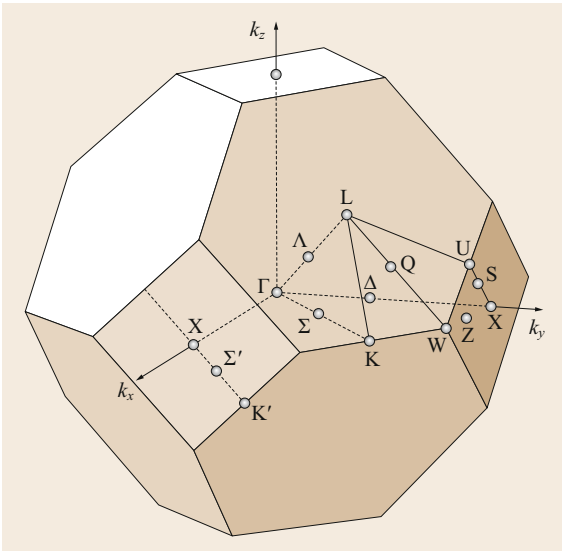

Fig. 21.2 Brillouin zone of the fcc lattice

The states of electrons in solids are described by wave functions of the Bloch type

$$\psi(\boldsymbol{r}) = \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} u_{s\boldsymbol{k}}(\boldsymbol{r}) \,, \tag{21.1}$$

where $\boldsymbol{k}$ is the wave vector that runs over reciprocal space, s is a band index and $u_{s\boldsymbol{k}}(\boldsymbol{r})$ is the periodic function of the direct lattice (Bloch amplitude). Both $u_{s\boldsymbol{k}}(\boldsymbol{r})$ and the corresponding energy-band spectrum $E_s(\boldsymbol{k})$ are periodic in $\boldsymbol{k}$, which allows one to restrict consideration to within the BZ. The bands are arranged so that there are energy regions for which no states given by (21.1) exist. Such forbidden regions are called energy gaps or band gaps and result from the interaction of valence electron with the ion cores of crystal. In semiconductor science the term *band gap* is accepted for the energy distance between the maximum of $E_s(\boldsymbol{k})$ for the highest filled (valence) band and the minimum of $E_s(\boldsymbol{k})$ for the lowest empty (conduction) band (denoted by E_g). The band gap is called *direct* if the aforementioned maximum and minimum occur at the same point of the BZ, e.g., Γ (Fig. 21.2), and *indirect* if they occur at different points of the BZ, e.g., Γ and X (Fig. 21.2).

Si is an indirect-band-gap semiconductor with $E_\mathrm{g} = 1.1700\,\mathrm{eV}$ at 4.2 K. The calculated energy-band structure, that is the curves of $E_\nu(\boldsymbol{k})$ for selected directions in the BZ, is shown in Fig. 21.3a. The conduction-band minimum lies at six equivalent points Δ on the Γ–X lines (Fig. 21.2). In some vicinity (called the *valley*) of every such point the band spectrum is quadratic in $\boldsymbol{k}$, e.g., for the valley ⟨100⟩

$$E_\mathrm{c}(\boldsymbol{k}) = E_{\mathrm{c}0} + \frac{\hbar^2 (k_x - k_0)^2}{2m_\mathrm{l}} + \frac{\hbar^2 \left(k_y^2 + k_z^2\right)}{2m_\mathrm{t}} \,, \tag{21.2}$$

where $k_0 \approx 1.72\pi/a_0$, m_l and m_t are the longitudinal and transverse effective masses. The spectra for other five valleys are obtained from (21.2) by 90° rotations and inversions $k_0 \to -k_0$. Though the constant-energy surface for (21.2) is an ellipsoid (Fig. 21.3b), the density of states (DOS) proves to be the same as for an isotropic parabolic spectrum with an effective mass

$$m_\mathrm{de} = 6^{2/3} m_\mathrm{l}^{1/3} m_\mathrm{t}^{2/3} \,, \tag{21.3}$$

which is called the *DOS effective mass*. Another mass, m_ce, which appears in the direct-current (DC) and optical conductivity formulas, is defined via the harmonic mean

$$\frac{1}{m_\mathrm{ce}} = \frac{1}{3}\left(\frac{1}{m_\mathrm{l}} + \frac{2}{m_\mathrm{t}}\right) . \tag{21.4}$$

For this reason, m_c is called the *conductivity/optical effective mass*. Equation (21.2) holds at $E_\mathrm{c} - E_{\mathrm{c}0} < 0.15\,\mathrm{eV}$, but at larger energies the ellipsoids warp strongly, especially near the X point; the change of the spectrum with energy is mostly due to the increasing m_t, while m_l increases weakly [21.6].

The valence-band maximum is at the Γ point ($\boldsymbol{k} = 0$), where the Bloch-wave state $u_{n0}(\boldsymbol{r})$ has the full symmetry of an atomic p-orbital, being six-fold degenerate in the nonrelativistic limit. The spin–orbit interaction splits off from the bare band top a four-fold degenerate $\mathrm{p}_{3/2}$ level up by $1/3\,\Delta_\mathrm{so}$, and a two-fold degenerate $\mathrm{p}_{1/2}$

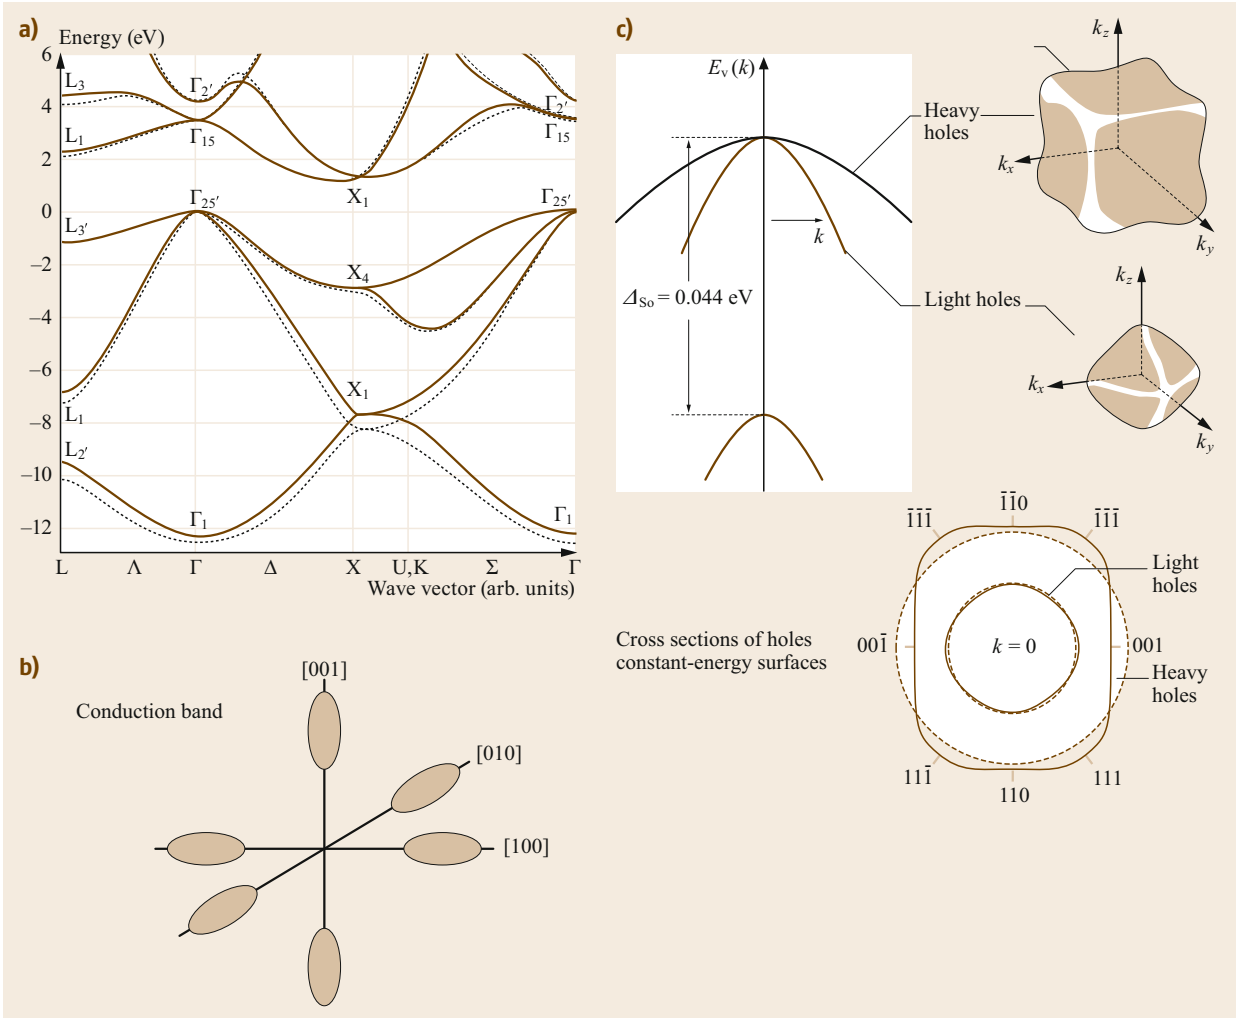

Fig. 21.3a–c Electronic band structure of Si: **(a)** Energy dispersion curves near the fundamental gap. (After [21.7] with permission); **(b)** The constant-energy ellipsoids of the conduction band; **(c)** The constant-energy warped spheres and schematic of the valence band

level down by $-2/3\Delta_{so}$. The spectrum at $\boldsymbol{k} \neq 0$, even at energies near the top E_{v0}, is very complex. It consists of three branches, which are in general nonparabolic and nonisotropic [21.8]. At $E_{v0} - E_v \ll \Delta_{so}$ there are two nonparabolic anisotropic $p_{3/2}$-derived sub-bands with the energy spectra

$$E_{v1,2}(\boldsymbol{k}) = E_{v0} + \frac{\hbar^2}{2m_0} \times \left[Ak^2 \pm \sqrt{B^2k^4 + C^2\left(k_x^2k_y^2 + k_x^2k_z^2 + k_y^2k_z^2\right)}\right], \quad A < 0 \tag{21.5}$$

and at $E_{v0} - E_v \ll 2\Delta_{so}$ there is an isotropic parabolic $p_{1/2}$-derived split-off band with the energy spectrum

$$E_{v3}(\boldsymbol{k}) = E_{v0} - \Delta_{so} + \frac{\hbar^2k^2}{2m_0}A', \quad A' < 0. \tag{21.6}$$

Here m_0 is the free electron mass, A, B, C and A' are inverse hole-mass parameters (for small Δ_{so}, $A' \approx A$). In (21.5) the $-$ sign corresponds to heavy holes and the $+$ sign to light holes. The constant-energy surfaces for (21.5) are warped spheres (Fig. 21.3c), the DOS is nevertheless parabolic and is described by the effective

mass

$$m_{dh} = \left(m_{d1}^{3/2} + m_{d2}^{3/2}\right)^{2/3}, \tag{21.7}$$

where $m_{d1,2}$ are the partial DOS effective masses. Quite different masses enter various physical quantities for heavy (light) holes, and are complicated functions of A, B and C [21.17], however, the split-off band is characterized by only one effective mass: $m_3 = m_0/|A'|$.

These band-structure parameters, obtained from cyclotron-resonance data and calculations, are presented in Tables 21.1 and 21.2. The unreferenced values of m_{de}, m_{ce} and m_3 were calculated from the referenced data using (21.3) and (21.4) and the assumption $A' = A$. Optical data for m_{ce} are discussed in Sect. 21.3, while the specific-heat data for m_{de} are not considered here.

Considerable uncertainty and errors in the values of B and C have a small effect on the light-hole effective-mass values (m_{d2} and optical m_{c2}) but lead to an ambiguity in the heavy-hole effective-mass (m_{d1} and optical m_{c1}) values (Table 21.2). In each data set $m_{d2} \approx m_{c2}$, which means that an isotropic approximation is reasonable for the light-hole spectrum. The experimental data [21.13, 16] and band-structure calculations [21.14] are in good agreement; the former is used in theoretical papers on hole transport in Si [21.18, 19].

Nonparabolic parts in the electron [21.6] and hole spectra [21.8] lead to apparent dependence of effective-mass measurements on the temperature and carrier concentration [21.20]. Recently the DOS mass issue was revisited [21.21] in connection with the intrinsic carrier concentration.

21.1.2 Impurity Levels and Charge-Carrier Population

In highly purified Si electrons and holes are thermally generated with equal concentrations ($n = p$), equal the intrinsic concentration n_i given by

$$n_i = 2\left(\frac{2\pi\sqrt{m_{de}m_{dh}}k_B T}{h^2}\right)^{3/2} \exp\left(-\frac{E_g}{2k_B T}\right), \tag{21.8}$$

where k_B and h are the Boltzmann and Planck constants, respectively, and T is the absolute temperature. To assess $n_i(T)$ theoretically one should take into account possible changes of $m_{de,h}$ and E_g with T. An early experimental plot of $n_i(T)$ for Si is shown in Fig. 21.4, giving $n_i(300\,\mathrm{K}) = 1.38 \times 10^{10}\,\mathrm{cm}^{-3}$. This and the early textbook value ($1.45 \times 10^{10}\,\mathrm{cm}^{-3}$) do not fit (21.8) with the established low-temperature values of $m_{de,h}$ and $E_g(300\,\mathrm{K}) = 1.1242\,\mathrm{eV}$, giving $(0.662–0.694) \times 10^{10}\,\mathrm{cm}^{-3}$ for the best available data. This discrepancy was eliminated [21.21] by critically evaluating measurements of $n_i(T)$ and incorporating the latest data for the hole DOS effective mass. The reassessed value of

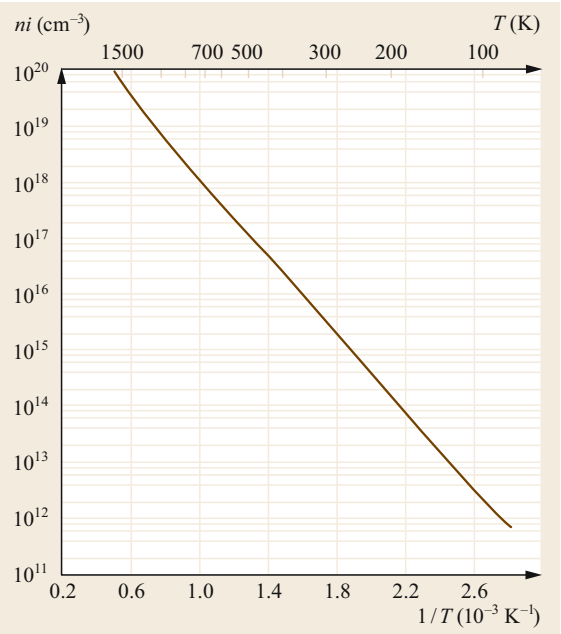

Fig. 21.4 Intrinsic concentration in Si versus temperature. (After [21.24] with permission)

n_i (300 K), verified by measurements on solar-cell devices [21.22], is $1.08(8)\times10^{10}\mathrm{cm}^{-3}$ (in a very recent textbook [21.23] the unreferenced value $n_i(300\,\mathrm{K}) = 1.00\times10^{10}\,\mathrm{cm}^{-3}$ is adopted). This is obtained from (21.8) using $m_{\mathrm{de}}(300\,\mathrm{K}) = 1.08m_0$, which is quite close to the tabular values presented, and $m_{\mathrm{dh}}(300\,\mathrm{K}) = 1.15m_0$, which is 1.8–2.1 times larger than the tabular values presented. Such a strong increase of m_{dh} when increasing T from 4.2 to 300 K is anticipated from the nonparabolic part of the hole spectra [21.8].

In impure samples $n \neq p$, the charge-neutrality condition is then

$$n - N_{\mathrm{d}}^{+} = p - N_{\mathrm{a}}^{-} \tag{21.9}$$

together with the known expressions for n, p (with $np = n_i^2$ holding until the carriers become degenerate) and the concentrations of charged donors N_{d}^{+} and acceptors N_{a}^{-} via the Fermi energy E_{F} and impurity ionization energies E_{d} and E_{a} allows one to calculate E_{F} (and hence all the concentrations) as a function of T and doping.

An impurity is called *shallow* if $|E_{c(v)0} - E_{\mathrm{d(a)}}| \ll E_{\mathrm{g}}$, and *deep* if $|E_{c(v)0} - E_{\mathrm{d(a)}}| \approx 0.5E_{\mathrm{g}}$. Shallow group V donors (Sb, P, As) and group III acceptors (B, Al, Ga, In) are well soluble in Si [21.25]. The ionization energy was calculated using the effective-mass approximation, and the Bohr model for donors (*Kohn* and *Luttinger*, 1955 [21.26, 27]) and acceptors (*Kohn* and *Schechter*, 1955 [21.28]). The value of $E_{\mathrm{d(a)}}$ calculated in this way is insensitive to the specific shallow donor (acceptor). Actual thermal (i. e., retrieved from electrical measurements) ionization energies are given in Table 21.3. It is seen that shallow impurities have different ionization energies. This difference is small for donors and larger for acceptors. The same trend was observed for optical ionization energies, although they are different from the thermal values [21.29, 30]. For shallow impurities, $E_{\mathrm{d(a)}}$ decreases as doping becomes heavier, and becomes zero as $N_{\mathrm{d(a)}}$ approaches the corresponding insulator–metal transition concentration [21.31]. Deep impurities (except for Mn, Fe and Zn) are amphoteric, i. e., they act simultaneously as donors and acceptors. For such a donor (acceptor) state, the level may lie closer to the valence (conduction) than the conduction (valence) band. The deep impurities are mostly unionized at room temperature due to their large $E_{\mathrm{d(a)}}$, so their direct contribution to n or p is negligible. The unionized deep impurities may, however, trap the carriers available from the shallow impurities or injection, thus decreasing the conductivity or the minority-carrier lifetime. Atoms that behave in Si in this manner, for example Au, Ag and Cu, are added for lifetime control. The properties of these impurities in Si have been studied in detail [21.32, 33].

Table 21.3 Energy levels of impurities in Si

Impurity	Donor/ acceptor	Below conduction band (eV)	Above valence band (eV)
Ag	D	0.310	
	A		0.210
Al	A		0.057
As	D	0.049	
Au	D		0.330
	A	0.540	
B	A		0.045
Cu	A		0.490

21.1.3 Carrier Concentration, Electrical and Optical Properties

Concentration and Electrical Measurements

Measurements of carrier concentrations, as well as electrical and optical characteristics are most tractable if either $n \gg p$ (strongly n-type conduction) or $p \gg n$ (strongly p-type conduction). Since the np product is constant versus doping, the contribution of minority carriers to the conductivity becomes unimportant when $N_{d(a)}$ increases significantly over n_i. A standard route for determining $n(p)$ is Hall-effect measurements. The Hall coefficient R^H, measured directly on a long thin slab in a standard crossed electric and magnetic field configuration, is retrieved by

$$R^H = 10^{-8}\frac{V_H d}{IB}\,, \tag{21.10}$$

where V_H is the Hall voltage (volt), I is the current (ampere), d is the sample thickness (cm) in the z-direction, and B is the magnetic field strength (Gauss) applied in this direction. There are two limiting cases. One, the high-field regime is defined by $qB\tau/mc \gg 1$, where m and τ are the appropriate mass and relaxation-time parameters, respectively. In this case

$$\begin{aligned} R^H_e(\infty) &= -\frac{1}{qn}\,, \\ R^H_h(\infty) &= \frac{1}{qp}\,. \end{aligned} \tag{21.11}$$

The other, low-field, regime holds with the opposite inequality; in this regime

$$\begin{aligned} R^H_e(0) &= -\frac{r_e}{qn}\,, \\ R^H_h(0) &= \frac{r_h}{qp}\,, \end{aligned} \tag{21.12}$$

where the constant of proportionality $r_{e(h)}$, called the electron (hole) Hall factor, depends on the details of the scattering process and band structure. Thus the majority-carrier concentration is determined directly from $R^H_{e(h)}$ using a high-field Hall measurement. For typical laboratory magnetic fields, this regime is attainable only with extremely high mobility and low effective mass, which excludes moderately and heavily doped Si, for which very high magnetic fields are required. In some cases the Hall factor is quite close to unity, e.g., $r_e = 3\pi/8$ for the phonon scattering in the isotropic and parabolic (standard) band.

The electrical properties are fully described by the drift-diffusion relation for the electron (hole) current density $\boldsymbol{j}_{e(h)}$

$$\begin{aligned} \boldsymbol{j}_e &= -qn\boldsymbol{v}_{de} + qD_e\nabla n\,, \\ \boldsymbol{j}_h &= qp\boldsymbol{v}_{dh} - qD_h\nabla p\,, \end{aligned} \tag{21.13}$$

where $\boldsymbol{v}_{de} = -\mu_e E$ ($\boldsymbol{v}_{dh} = \mu_h E$) is the drift velocity, $\mu_{e(h)}$ is the drift mobility, E is the electric field strength, and $D_{e(h)}$ is the diffusion coefficient; in general, $\mu_{e(h)}$ and $D_{e(h)}$ depend on E. In the homogeneous case (21.13) converts into the material equation $\boldsymbol{j}_{e(h)} = \sigma_{e(h)}E$, where $\sigma_{e(h)} = qn\mu_{e(h)}$ is the electron (hole) conductivity; the total conductivity equals $\sigma = \sigma_e + \sigma_h$. In the weak-field DC (ohm) and alternating current (AC: microwave or light, except for intense laser, irradiation) regimes, $D_{e(h)}$ is proportional to $\mu_{e(h)}$ being both constant versus E, depending on the radiation frequency ω.

Combining the high-induction Hall and Ohm resistivity ($\rho = \sigma^{-1}$) measurements one obtains the drift mobility

$$\mu_{e(h)} = R^H_{e(h)}(\infty)\sigma\,. \tag{21.14}$$

Replacing $R^H_e(\infty)$ by $R^H_e(0)$ in the right-hand side of (21.14), one arrives at the so-called Hall mobility

$$\mu^H_{e(h)} = R^H_{e(h)}(0)\sigma = r_{e(h)}\mu_{e(h)}\,, \tag{21.15}$$

which never equals the drift mobility, although it may be fairly close to it in the cases mentioned above. In general, when $n(p)$ is extracted from $R^H_{e(h)}(0)$, the calculation of the $r_{e(h)}$ factor is completed. Magnetoresistance (MR), i. e., ρ versus B measurement, is an important experimental tool as well. Another established method is the Haynes–Shockley experiment, which allows one to measure the minority-carrier drift mobility. In high-electric-field conditions, a noise-measurement technique is used. A relatively novel, time-of-flight technique was used in the latest (to our knowledge) mobility and diffusion-coefficient measurements on lightly doped crystalline Si samples, both in the low- and high-field regimes [21.19].

Basic Optical Parameters

The electromagnetic response of homogeneous nonmagnetic material is governed by the dielectric constant tensor ε, which connects the electric displacement vector $\boldsymbol{D}$ inside the material to $\boldsymbol{E}$ through the material equation $\boldsymbol{D} = \varepsilon E$. For cubic crystals, such as Si, ε is a scalar. An effective-medium homogeneous dielectric constant may be attributed to inhomogeneous and composite materials if the nonhomogeneity feature size is smaller than the radiation wavelength $\lambda = 2\pi c/\omega$. Actually, ε characterizes the material's bulk and therefore loses its sense in nanoscale structures (superlattices,

quantum wells etc.). The dependence $\varepsilon(\omega)$ expresses the optical dispersion in the material. The dielectric constant is usually represented via its real and imaginary parts: $\varepsilon = \varepsilon_1 + \mathrm{i}\varepsilon_2$ $(\varepsilon_2 \geq 0)$, connected to each other by the Kramers–Kronig relation (KKR)

$$\varepsilon_1(\omega) = 1 + \frac{2}{\pi} \int_0^\infty \frac{\Omega}{\Omega^2 - \omega^2} \varepsilon_2(\Omega) \mathrm{d}\Omega \,. \tag{21.16}$$

At low frequency (radio, microwave), in the absence of magnetic fields, $\varepsilon_1 \approx \varepsilon(0)$ and ε_2, which is responsible for dielectric loss, is small. At optical wavelengths, from far-infrared (IR) to soft x-rays, the basic quantity is the complex refractive index $\sqrt{\varepsilon} = n + \mathrm{i}k$. The real refractive index n, which is responsible for wave propagation properties, and the extinction index k, responsible for the field attenuation, are referred to as *optical constants*. They are related to the dielectric constant via

$$\begin{aligned} \varepsilon_1 &= n^2 - k^2 \,, \\ \varepsilon_2 &= 2nk \,, \\ n &= \sqrt{\frac{\left(\varepsilon_1^2 + \varepsilon_2^2\right)^{1/2} + \varepsilon_1}{2}} \,, \\ k &= \sqrt{\frac{\left(\varepsilon_1^2 + \varepsilon_2^2\right)^{1/2} - \varepsilon_1}{2}} \,. \end{aligned} \tag{21.17}$$

21.1.4 Theory of Electrical and Optical Properties

Boltzmann-Equation Approach

The response of carriers in a band to perturbations away from the thermal-equilibrium state, such as applied electric and magnetic fields or impinging electromagnetic radiation, is described by the deviation of the carrier distribution function $f_\mathrm{s}(\boldsymbol{k}, \boldsymbol{r}, t)$ from the equilibrium Fermi–Dirac distribution $f_0[E_s(\boldsymbol{k})]$. The current density equals $\boldsymbol{j}_\mathrm{s} = q \int \boldsymbol{v}_\mathrm{s}(\boldsymbol{k}) f_\mathrm{s}(\boldsymbol{k}, r, t) \mathrm{d}\boldsymbol{k}$, where $\boldsymbol{v}_\mathrm{s}(\boldsymbol{k}) = \partial E_s(\boldsymbol{k}) / (\hbar \partial \boldsymbol{k})$ is the microscopic carrier velocity and the integration is performed over the BZ. The process that balances the external perturbations is scattering of carriers by lattice vibrations (phonons), impurities and other carriers. Impurity scattering dominates transport at low temperatures and remains important at room temperature for moderate and high doping levels, although carrier–carrier scattering also becomes appreciable. Under appropriate conditions, one being that $\hbar\omega \ll \bar{E}$ (where $\bar{E}$ is the average carrier kinetic energy), $f_\mathrm{s}(\boldsymbol{k}, \boldsymbol{r}, t)$ satisfies the quasi-classical Boltzmann kinetic equation. In the opposite, quantum, range, radiation influences the scattering process. Generalized kinetic equations, which interpolate between the quasi-classical and quantum regimes, have also been derived [21.34].

There exist various methods of solving the quasi-classical Boltzmann equation. The relaxation-time method, variational method [21.35–37] for low electric fields, and displaced-Maxwell-distribution approximation [21.38] for high electric fields, were used in early studies. In the last four decades the Monte Carlo technique [21.39], which overcomes limitations inherent to these theories and allows one to calculate subtle details of the carrier distribution, has been applied to various semiconductors, including crystalline Si [21.19]. If $\hbar\omega \gg \bar{E}$, the kinetic and optical characteristics are calculated well using transition probabilities between carrier states, with the radiation quantum absorbed or emitted [21.40]. The most problematic is the intermediate range – generalized kinetic equations have been shown to recover the extreme ranges, but no working methods have been developed for solutions at $\hbar\omega \approx \bar{E}$, to the best of our knowledge. The relaxation-time approximation has proved to work well in many cases of scattering in Si. In this framework, the basic quantity is the relaxation-time tensor $\tau_\mathrm{s}(E)$, where s is the index indicating the conduction or valence band, and E is the carrier kinetic energy. For electron valleys, $\tau_\mathrm{c}(E)$ has the same symmetry as the respective effective-mass tensor – it is diagonal with principal values of, e.g., τ_l, τ_t, τ_t for $\langle 100 \rangle$ etc. For scalar holes, $\tau_{1,2}(E)$ can only be introduced in the isotropic-bands approximation. The mobility and the Hall factor for weak electric fields in the relaxation-time approximation are given by

$$\begin{aligned} \mu_\mathrm{e}(\omega) &= \frac{q}{3} \left\langle \frac{\tau_\mathrm{l}/m_\mathrm{l}}{1 - \mathrm{i}\omega\tau_\mathrm{l}} + \frac{2\tau_\mathrm{t}/m_\mathrm{t}}{1 - \mathrm{i}\omega\tau_\mathrm{t}} \right\rangle , \\ r_\mathrm{e} &= \frac{3 \left\langle 2\tau_\mathrm{l}\tau_\mathrm{t}/m_\mathrm{l}m_\mathrm{t} + (\tau_\mathrm{t}/m_\mathrm{t})^2 \right\rangle}{\langle \tau_\mathrm{l}/m_\mathrm{l} + 2\tau_\mathrm{t}/m_\mathrm{t} \rangle^2} ; \end{aligned} \tag{21.18}$$

$$\begin{aligned} \mu_\mathrm{h}(\omega) &= \frac{q}{1+\beta} \left\langle \frac{\tau_1/m_1}{1 - \mathrm{i}\omega\tau_1} + \frac{\beta\tau_2/m_2}{1 - \mathrm{i}\omega\tau_2} \right\rangle , \\ r_\mathrm{h} &= \frac{(1+\beta) \left\langle (\tau_1/m_1)^2 + \beta\,(\tau_2/m_2)^2 \right\rangle}{\langle \tau_1/m_1 + \beta\tau_2/m_2 \rangle^2} , \end{aligned} \tag{21.19}$$

where the angular brackets indicate averaging with the weight $-E^{3/2} f_0'(E)$, $\beta = (m_{\mathrm{d}2}/m_{\mathrm{d}1})^{3/2}$ is the density ratio of light holes to heavy holes, and the option for a nonparabolic band is retained.

Lattice Scattering

Deformational phonons – longitudinal, transverse acoustical (LA, TA) and optical (LO, TO) – mediate carrier–lattice scattering in Si. The phonon modes are

Table 21.4 Parameters of the phonon modes in crystalline Si

Mode	Energy (K)				Sound velocity (cm/s)

[a] After [21.9]

Table 21.5 Deformation-potential parameters [21.41]

T (K)	Ξ_u (eV)	$\Xi_d + 1/3\Xi_u - a$ (eV)	$\lvert b\rvert$ (eV)	$\lvert d\rvert$ (eV)
80	8.6 ± 0.2	3.8 ± 0.5	2.4 ± 0.2	5.3 ± 0.4
295	9.2 ± 0.3	3.1 ± 0.5	2.2 ± 0.3	–

presented in Table 21.4, where **q** is a point in the phonon BZ. The points Δ and S correspond to the scattering process, where the electron transits between the bottoms of two perpendicularly (f) and parallel (g) oriented valleys, respectively. The phonon energies are precise at the points Γ and X, as determined by neutron-scattering techniques [21.42], but uncertain at Δ and S, since in this case only estimation and fitting methods were available.

The rigid- and deformable-ion lattice models have been used to obtain the carrier–phonon interaction for electrons [21.43] and holes [21.44]. A deformation-potential theory of the interaction with long-wavelength phonons, which takes the crystal symmetry and band structure fully into account in a phenomenological manner, has been developed. This theory deduces two constants, Ξ_u, Ξ_d, for the conduction band [21.45] and four, a, b, d, d_{opt}, for the valence band [21.46, 47], which are presented in Table 21.5. The deformation-potential theory has been used to calculate the acoustic scattering-limited mobility in n-Si [21.48] and p-Si [21.49]. Later, optical-phonon scattering, along with an approximate valence-band spectrum instead of (21.5), were taken into account [21.18, 19].

The matrix elements of electron–phonon interaction between wave functions of different valleys are not taken into account by the deformation-potential theory. For inter-valley transitions, other than the three marked in Table 21.4 by the superscript a, the matrix elements calculated at the valley-bottom wave vectors are zero [21.43, 50]. The actual scattering probabilities are never zero; for those forbidden by selection rules [21.43, 50] one should take into account the wave-vector offset at the final scattering state, which gives nominally small, but unknown values. Several inter-valley scattering models have been tried to fit the theoretical formulas to the mobility data in lightly doped n-Si: with one allowed TO and one forbidden TA phonon [21.51], one allowed TO phonon [21.52] and more involved combinations of the transitions [21.53, 54]. The scattering of electrons by long-wavelength optical phonons, regarded as a cause of drift-velocity saturation at high electric fields [21.38], is forbidden in Si [21.43]. In n-Si, by all accounts, the cause may be the allowed g-phonon (Table 21.4) scattering [21.54].

Impurity Scattering

There are two types of impurity scattering – by ionized and neutral impurities. The latter is the dominant impurity scattering for uncompensated, light or moderate shallow-impurity doping, at low T. In samples doped with deep impurities, neutral-impurity scattering may also show up. At elevated T, when shallow impurities are increasingly ionized, ionized-impurity scattering is the dominant impurity scattering and may compete with phonon scattering, depending on $N_{\text{d(a)}}$. Lastly, in heavily doped samples, where the impurities are ionized for all T, ionized-impurity scattering is dominant up to 300 K.

Early theories of impurity scattering were developed for carriers in parabolic bands, scattered by hydrogen-like centers. For neutral impurities the s-scattering cross section [21.55] and a cross section that takes allowance of the scattered carrier's bound state [21.56] were adopted. For ionized centers, use was made of the Coulomb scattering cross section, cut off at a small angle depending on $N_{\text{d(a)}}$ [21.57], and the screened Coulomb potential cross section, calculated in the Born approximation [21.58–60]. These theories consider scattering by the donors and acceptors on an equal footing. The use of the Conwell–Weisskopf formula for $\tau_s(\varepsilon)$ declined towards the end of the 1950s, while the corresponding Brooks–Herring (BH) formula became widespread, mostly due the consistency of its derivation, even though none of the assumptions for its validity are completely satisfied. This formula was corrected [21.61], on account of the

band carrier's degeneracy, compensation and screening by carriers on impurity centers. The discrepancy between experiment and the BH formula, revealed during three decades of studies, have been thoroughly analyzed [21.62].

Modifications and developments made to overcome the drawbacks of the BH formula are worth mentioning. Taking the multi-valley band structure into account did not invalidate the relaxation-time method as such, but resulted in essentially different $\tau_l(E)$ and $\tau_t(E)$ [21.63, 64]. These formulas have also been discussed [21.65] in light of the scattering anisotropies measured in n-Si [21.66]. To overcome limitations of the Born approximation exact, although limited only to the standard band, phase-shift analysis was employed [21.67]. Including a non-Coulomb part of the impurity potential [21.68] made it possible to explain in part the difference in mobility of n-Si samples doped with different donors [21.25]. Lastly, Monte Carlo simulations of the impurity scattering, improving the agreement between theory and experiment for n-Si, have recently been reported [21.69]. The ionized-impurity scattering in p-Si was considered in the approximation of isotropic hole bands [21.70]. We are not aware of any theoretical papers on the subject, which used anisotropic energy spectra given by (21.26) in the case of p-Si.

Carrier–Carrier Scattering

Carrier–carrier scattering becomes important as n or p increases, along with increasing N_d^+ or N_a^-. The relaxation-time concept does not apply for this mechanism. Carrier–carrier collisions redistribute the carrier's energy in a chaotic manner that was presumed to cause a decrease in the net mobility due to other mechanisms [21.71]. For the standard band, the effects of electron–electron scattering were modeled using the variational method, which predicted about 30% reduction in the ionized-impurity scattering-limited mobility [21.72]; close results were obtained using another, quite different, method [21.73]. Hole–hole scattering and electron–hole scattering were also considered [21.74] in the standard band. Due to ignorance of the specific band-structure features, the results of these papers had limited relevance to Si. The effect of electron–electron scattering has been recast [21.75] for the multi-valley band structure using the generalized Drude approximation (GDA). At DC, the GDA corresponds to the zeroth-order approximation of the variational method, which highly overestimates [21.72] the effect considered.

Dielectric Constant

In Si the current carriers are well decoupled from the host electrons, so the Maxwell equations result in a unique decomposition of the dielectric constant

$$\varepsilon(\omega) = \varepsilon_L(\omega) + \varepsilon_C(\omega)\,,$$
$$\varepsilon_C(\omega) = \mathrm{i}\frac{4\pi\sigma(\omega)}{\omega}\,. \tag{21.20}$$

Here $\varepsilon_L(\omega)$ is the host contribution, which is indirectly influenced by the carriers. The direct effect of the carriers on the dielectric constant is the conductivity contribution $\varepsilon_C(\omega)$. As seen from (21.20), doped Si behaves at DC as a metal. The asymptote at high frequencies (IR for Si) is $\varepsilon_{C,s}(\omega) \approx -(\Omega_{pl,s}/\omega)^2$, where $s = $ e or h, and $\Omega_{pl,s}$ are the bare plasma frequencies given by

$$\Omega_{pl,e}^2 = \frac{4\pi q^2 n}{m_{ce}}\,, \quad \frac{1}{m_{ce}} = \frac{1}{3}\left\langle\frac{1}{m_l} + \frac{2}{m_t}\right\rangle,$$
$$\Omega_{pl,h}^2 = \frac{4\pi q^2 p}{m_{ch}}\,, \quad \frac{1}{m_{ch}} = \frac{1}{1+\beta}\left\langle\frac{1}{m_1} + \frac{\beta}{m_2}\right\rangle, \tag{21.21}$$

resulting from (21.18) and (21.20), irrespective of the scattering model. Due to this asymptote and (21.20) $\varepsilon_1(\omega)$ should become zero at some frequency $\omega_{pl,s}$ and doped Si should behave optically as a dielectric at $\omega < \omega_{pl,s}$ and as a metal at $\omega > \omega_{pl,s}$. True plasma frequencies are estimated roughly as $\omega_{pl,s} \approx \Omega_{pl,s}/n_L$, where $n_L = 3.42$–3.44 is the Si host refractive index in the IR. For the parabolic bands, m_{ce} has already been presented in Table 21.1, and $m_{ch} = (0.33$–$0.39)m_0$ using the data of Table 21.1, with the assumption that $m_{1,2} = m_{c1,2}$.

General formulas for $\varepsilon_C(\omega)$ are rather involved because of the averaging over E they contain, and so are rarely used. The Drude formula

$$\varepsilon_{C,s}(\omega)|_{\mathrm{Drude}} = \frac{\mathrm{i}}{\omega}\,\frac{\Omega_{pl,s}^2}{\gamma_s - \mathrm{i}\omega}\,, \tag{21.22}$$

where γ_s are adjustable phenomenological damping parameters, is often employed instead [21.76]. To match the behavior of $\varepsilon_C(\omega)$ at $\omega \to 0$ one should put $\gamma_s = 1/\tau_{0,s}$ in (21.22), where

$$\tau_{0,e} = \frac{m_{ce}}{3}\left\langle\frac{\tau_l}{m_l} + \frac{2\tau_t}{m_t}\right\rangle;$$
$$\tau_{0,h} = \frac{m_{ch}}{1+\beta}\left\langle\frac{\tau_1}{m_1} + \frac{\beta\tau_2}{m_2}\right\rangle \tag{21.23}$$

are the DC mobility relaxation times. Such an adjustment was shown to work poorly in n-Si [21.77]. On the

other hand, putting $\gamma_s = \gamma_{\infty,s}$ in (21.22), where

$$\gamma_{\infty,e} = \frac{m_{ce}}{3}\left\langle \frac{1}{m_l\tau_l} + \frac{2}{m_t\tau_t}\right\rangle;$$
$$\gamma_{\infty,h} = \frac{m_{ch}}{1+\beta}\left\langle \frac{1}{m_1\tau_1} + \frac{\beta}{m_2\tau_2}\right\rangle, \qquad (21.24)$$

allows one using the Drude formula to match *two* leading at $\omega \to \infty$ terms in the power series expansion of $\varepsilon_C(\omega)$ with respect to ω^{-1}. Thus (21.22) with the above adjustments may serve as an overall interpolation if the *high-frequency* relaxation time, $\tau_{\infty,s} = 1/\gamma_{\infty,s}$ turns out to be close to $\tau_{0,s}$. A Drude formula, empirically adjusted in IR has been devised for n-Si [21.78].

Using $\tau_{\infty,s}$ instead of $\tau_{0,s}$ in the mobility is a prerequisite for GDA at DC. As discussed above, the Boltzmann-equation-based formulas are valid in the range $\lambda \gg \lambda_q = hc/\bar{E}$. For nondegenerate carriers $\lambda_q(\text{cm}) \approx 1.4388/T$, while in Si for n or p up to $\approx 10^{20}\,\text{cm}^{-3}$ the carrier degeneracy (if present) stops much below 300 K, so the validity of the $\varepsilon_C(\omega)$ formulas considered is restricted to the far-IR and longer wavelengths. To properly describe $\varepsilon_C(\omega)$ in the near- and mid-IR range, ω-dependent GDA has been suggested [21.79]. In this approximation one replaces γ_s in (21.22) by an ω-dependent damping $\gamma_s(\omega)$, which is then determined by comparison of the first imaginary term in the expansion of the thus-generalized Drude formula, i. e., $(\Omega_{pl,s}/\omega)^2\gamma_s(\omega)/\omega$, with $\varepsilon_2(\omega)$ calculated using the methods of transition probabilities or perturbations for correlation functions.

In Si, unlike semiconductors with ionic bonds (e.g., $A^{III}B^{V}$), the elementary cell has no dipole moment and hence no quasi-classical optical-phonon contribution in $\varepsilon_L(\omega)$ is present. However, several weak IR absorption bands, attributed to two-phonon interaction of light with the Si lattice, are observed. Of these bands the most prominent is that peaked at 16.39 μm, which undergoes about a twofold increase in absorption upon increasing the temperature from 77 to 290 K. Comparable to that, the 9.03 μm absorption band, observed in pulled Si crystals, was attributed to Si−O bond stretching vibrations [21.80]. At $\lambda < 1.2\,\mu\text{m}$, where $\varepsilon_L(\omega)$ dominates the dielectric constant irrespective of the doping, $\varepsilon_{2L}(\omega)$ is accounted for by inter-band electronic transitions. The spectral bands of $\varepsilon_{2L}(\omega)$ correspond to the absorption of photons with energies close to the band gaps. Bare indirect-band-gap transitions, that necessitates lowest energy, is forbidden, but perturbation correction in the electron–phonon interaction to $\varepsilon_{2L}(\omega)$ suffices to describe the observed indirect absorption band. Due to the phonons the lowest fundamental absorption, although smaller than in direct bands, increases with increasing T. In principle, $\varepsilon_{2L}(\omega)$ may be calculated by the band-structure simulation route (e.g., [21.6, 7] and *Kleinmann* and *Phillips* [21.11]), especially with the present state-of-the-art theory – $\varepsilon_{1L}(\omega)$ is then calculated using the KKR (21.16). However, applications need fast modeling, and such formulas have been developed for Si [21.81–83]. There are a few distinct doping effects on $\varepsilon_L(\omega)$:

1. Effects on the lowest band edges, both direct and indirect: the Burstein–Moss shift with increasing $n(p)$ in heavily doped samples at the degeneracy due to filling of the conduction (valence) band below (above) E_F; band-gap shrinkage due to carrier–carrier and carrier–impurity interactions [21.84, 85] that work against the Burstein–Moss shift; and the formation of band tails because of the random potential of impurities [21.31].
2. Effects on higher edges, such as: E_1 (3.4 eV) – due to transitions between the highest valence band and the lowest conduction band along the Λ line in a region from $\pi/4a_0(1, 1, 1)$ to the L point on the BZ edge; and E_2 (4.25 eV) – due to transitions between the valence band at the X point and the conduction band at $2\pi/a_0(0.9, 0.1, 0.1)$ [21.7]. In this case [21.86], the electron–electron interaction plays a small role because carriers are located in a small region of the BZ, different from that where the transitions take place, and the effect of the electron–impurity interaction is calculated using standard perturbation theory.
3. Absorption due to direct inter-conduction-band (inter-valence-band) transitions specific to the type of doping. In n-Si this is a transition from the lowest conduction band to the band that lies higher at the Δ point but crosses the former at the X point, and which gives rise to a broad absorption band peaked around 0.54 eV [21.87] and tailing of the indirect gap at heavy doping [21.88]; the theory of this contribution to $\varepsilon_{2L}(\omega)$ has been developed [21.85]. In p-Si these transitions are those between the three highest valence bands [21.8]. Absorption due to the 1→2 transition has no energy threshold, and so resembles the usual free-carrier absorption; that due to the 1→3 and 2→3 transitions appears at $\hbar\omega = \Delta_{so}$. A high-energy threshold, above which the inter-valence-band absorption becomes negligible, exists due to the near congruency of all three valence sub-bands [21.8] at large well $\boldsymbol{k}$ (this is not accounted for by (21.5) and (21.6), which are valid at small $\boldsymbol{k}$). In contrast, with p-Ge, the manifestation of the inter-valence-band transitions in the

reflection, was proposed for p-Si [21.89], but fully reconciled later [21.85, 90]. Kane's theory of the inter-valence-band absorption [21.8] has also been revisited [21.90].

21.2 Electrical Properties

An extensive investigation of basic electrical properties was started 60 years ago, when polycrystalline Si containing B and P, was reported [21.91]. This seminal work was necessarily limited because neither single crystals nor the means for measuring below 77 K were then available. The first papers on single crystals were published five years afterwards. Since then, as techniques for fabricating quality single-crystalline silicon, such as the pulling, e.g., Czochralski (CZ), Teal–Little (TL), and floating-zone (FZ) techniques, became highly developed, many experiments on electrical properties have been published. A number of papers are considered below in historical retrospect. In the accompanying graphs additional, less cited, papers are referenced.

Though the physical mechanisms behind the electrical properties of crystalline Si have been studied and partially understood for a long time, the resulting formulas and procedures are too complicated and time-consuming to be used in electronics device modeling. In this connection, several useful, simplified but accurate, procedures for modeling mobility versus temperature, doping, injection level and electric field strength have been developed. For this issue we refer to items 2–4 in Sect. 21.2.3.

21.2.1 Ohm's Law Regime

Drift Measurements

1. The minority-carrier mobility as a function of N_d, N_a, T and ρ in n- and p-type samples is in the range 0.3–30 Ω cm [21.92]. The cited paper revealed for the first time the inapplicability, at least for holes, of the simple $T^{-1.5}$ lattice mobility law, and presented curves of ρ versus exhaustion concentration $N = |N_d - N_a|$ in the range $10^{14}\,\mathrm{cm}^{-3} \le N \le 10^{17}\,\mathrm{cm}^{-3}$.
2. Measurements of μ_e in p-type and μ_h in n-type Si on 11 single crystals ranging in ρ from 19 to 180 Ω cm [21.93]. In the purest crystals, in the range 160–400 K, μ_e and μ_h obeyed the dependencies $T^{-2.5\pm0.1}$ and $T^{-2.7\pm0.1}$, respectively. The conductivity of some of these crystals, measured from 78 to 400 K, provided independent evidence for the temperature dependencies of the mobility quoted above.
3. Room-temperature drift and conductivity plus Hall-effect measurements [21.94] of μ_e and μ_h versus resistivity on an unprecedentedly large number of samples cut from CZ crystals. The largest ρ was above 200 Ω cm. The values of μ_e and μ_h obtained from both experiments in the purest crystals were reported and compared with those obtained by other authors.

Resistivity and Galvanomagnetic Measurements

1. Room-temperature $\mu^{H}_{e(h)}$ as a function of $\rho_{e(h)}$ [21.95]. The crystals used were grown from Dupont hyper-pure material, with ρ of 0.01–94 Ω cm for n-type and 0.025–110 Ω cm for p-type samples. Curves of $\mu^{H}_{e(h)}$ versus $\rho_{e(h)}$ were calculated using the BH and combined-mobility [21.71] formulas for $m_{e(h)} = m_0$ and compared with experimental curves.
2. The first extensive experimental study of electrical conductivity and the Hall effect in TL silicon [21.96]. The properties were measured at temperatures of 10–1100 K on six arsenic-doped n-type samples, and one undoped, plus five boron-doped, p-type samples, covering the range from light ($N = 1.75\times10^{14}$ and $3.1\times10^{14}\,\mathrm{cm}^{-3}$) to heavy ($N = 2.7\times10^{19}$ and $1.5\times10^{19}\,\mathrm{cm}^{-3}$) doping. Compensation by unknown acceptors (donors) occurred in four lightly and moderately doped n(p)-type samples. A deviation of the lattice mobility from the $T^{-1.5}$ dependence was reported for both electrons and holes. Curves of $\mu^{H}_{e(h)}$ against $\rho_{e(h)}$ at 300 K were computed in the same way as by Debye and Kohane, but incomplete ionization of impurity centers was additionally taken into account.
3. First systematic study of μ_e and μ_h versus N_d and N_a, respectively, at $T = 300$ K [21.97]. Measurements were taken with several group V and group III impurities up to 6×10^{19} and $6\times10^{18}\,\mathrm{cm}^{-3}$ for n- and p-Si, respectively. Impurity concentrations were obtained by radioactive tracers or from thermal neutron activation analysis; μ_e and μ_h were calculated from these data by considering the N_d^+ and N_a^- percentages. The combination with measured $\mu^{H}_{e(h)}$ resulted in $r_{e(h)}$ values in agreement with theory. A comparison with a BH-formula-based theory yielded semiquantitative agreement for μ^{H}_{e}, while measured values of μ^{H}_{h} proved to be much smaller than the theoretical values.

4. Galvanomagnetic effects in p-Si: ρ and R^{H} versus T and B [21.98] and MR [21.99]. Boron-doped samples cut from CZ crystals were used. In the first paper four samples, two with $\rho(300\,\mathrm{K}) = 35\,\Omega\,\mathrm{cm}$ and two with $\rho(300\,\mathrm{K}) = 85\,\Omega\,\mathrm{cm}$, were measured in the range 77–320 K. The dependence $\mu_{\mathrm{h}} \propto T^{-2.7\pm0.1}$ at $B = 0$, as observed by Ludwig and Watters, was typical of the results obtained on all the samples; r_{h} was observed to exhibit a weak linear decrease with T in the range 200–320 K, and to be almost entirely independent of B up to $B = 1.3\,\mathrm{T}$ in the temperature interval studied. The dependence of MR on the relative directions of current, fields and crystallographic axes was studied at 77 and 300 K as a function of B. Large values of longitudinal MR, as large as the transverse effects in some cases, were observed, contradicting the only calculations available at that time [21.17]. To obtain data sufficient for constructing a more satisfactory model, the above study was continued in the second paper on 10 more samples, with ρ of 0.15–115 Ω cm. Measurements of three MR coefficients were carried out at a number of temperatures in the range 77–350 K. The results showed a marked dependence of the band structure and scattering anisotropies on the temperature, yet no definite model of these effects was arrived at.
5. A comparative study of mobility in pulled and FZ crystals [21.100]. The question of the dependence of the intrinsic mobility on temperature was recast. The authors found that in FZ, contrary to pulled crystals, $\mu_{\mathrm{e}}^{\mathrm{H}}$ followed the $T^{-1.5}$ law in the range 20–100 K, although $\mu_{\mathrm{h}}^{\mathrm{H}}$ still displayed a different, viz. T^{-2}, variation with temperature. It was argued that such a disagreement with the work of Morin and Maita was due to the large content, up to $10^{18}\,\mathrm{cm}^{-3}$, of oxygen impurities in the pulled crystals they used, which resulted in scattering that obscured the phonon scattering.
6. Solid analysis of electrical properties of n-Si with respect to: the ionized-impurity scattering in isotropic approximation [21.101], scattering anisotropies [21.66] and lattice scattering [21.51]. The measurements were made from 30 to 100–350 K using a set of P-doped, B-compensated, n-type samples of rather wide impurity content, yet in the range from light to moderate doping ($N_{\mathrm{d}} = 4.5\times10^{15}\,\mathrm{cm}^{-3}$ at most). The purest samples were cut from FZ crystals while others were from CZ crystals. These authors developed a sophisticated, but robust, method of determining N_{d} and N_{a} by analysis of the R^{H} versus T data. With this method, in the first paper they obtained curves of μ_{e} versus T in the range 30–100 K, which were used to test the BH formula. In comparing the formula with the data, correction to the observed μ_{e} because of the phonon-scattering contribution was necessary. The BH formula was shown to provide a good quantitative description of the data when $m_{\mathrm{e}} = 0.3m_0$ was used, provided that ion scattering was not too strong. When ion scattering was dominant, viz. in moderately doped samples at low T, they observed a discrepancy between the theory and data, which was attributed to electron–electron interaction. For the purpose of detecting scattering anisotropy, the MR coefficients were measured in the second paper on several relatively pure ($N_{\mathrm{d}} = 8.0\times10^{14}\,\mathrm{cm}^{-3}$ at most) samples. The results indicated that $\tau_{\mathrm{l}}/\tau_{\mathrm{t}} \approx 0.67$ and $\tau_{\mathrm{l}}/\tau_{\mathrm{t}} > 1$ for acoustic-phonon and ionized-impurity scattering, respectively. The inter-valley phonon scattering, important at higher T, proved to be isotropic. In the third paper lattice scattering was treated. A model assuming inter-valley scattering by two-phonon modes, in addition to the intra-valley acoustic-phonon scattering, was applied to the results of the electrical and MR measurements in the purest samples. By using the coupling constants with the phonon modes as fitting parameters, fairly good agreement was achieved between the model and experimental data on curves of μ_{e} versus T in the range 30–350 K, though one of the inter-valley phonon energies corresponded to a forbidden transition (Table 21.4).
7. Experimental verification of the anisotropic ion-scattering theory [21.102]. Measurements of saturated longitudinal MR and μ_{e} were made in fields up to 9 T at 78 K on a series of [111]-oriented phosphorus-doped samples with N_{d} in the range 2×10^{13}–$6\times10^{16}\,\mathrm{cm}^{-3}$. A quantitative analysis was made that involved combined relaxation times from impurity, intra-valley, and inter-valley lattice scattering. The data agreed very well with the theory [21.103]. In samples with $N_{\mathrm{d}} > 10^{16}\,\mathrm{cm}^{-3}$ the neutral-impurity scattering effect was observed.
8. Refined analysis of the Hall effect and mobility in n-Si [21.53]. μ_{e} and n, as determined from the high-field Hall effect, were numerically analyzed for a series of n-type samples doped with Sb, P, and As. The calculations were based on the general treatment for an anisotropic parabolic band [21.48]. Lattice-scattering parameters for the inter-valley and acoustic modes were determined from a comparison of the results between theory and experiment, using as many as four inter-valley phonons. The conclusions supported the two-phonon Long model. Ionized-impurity scattering was calculated from the BH formula and a newer theory [21.103] and compared with ex-

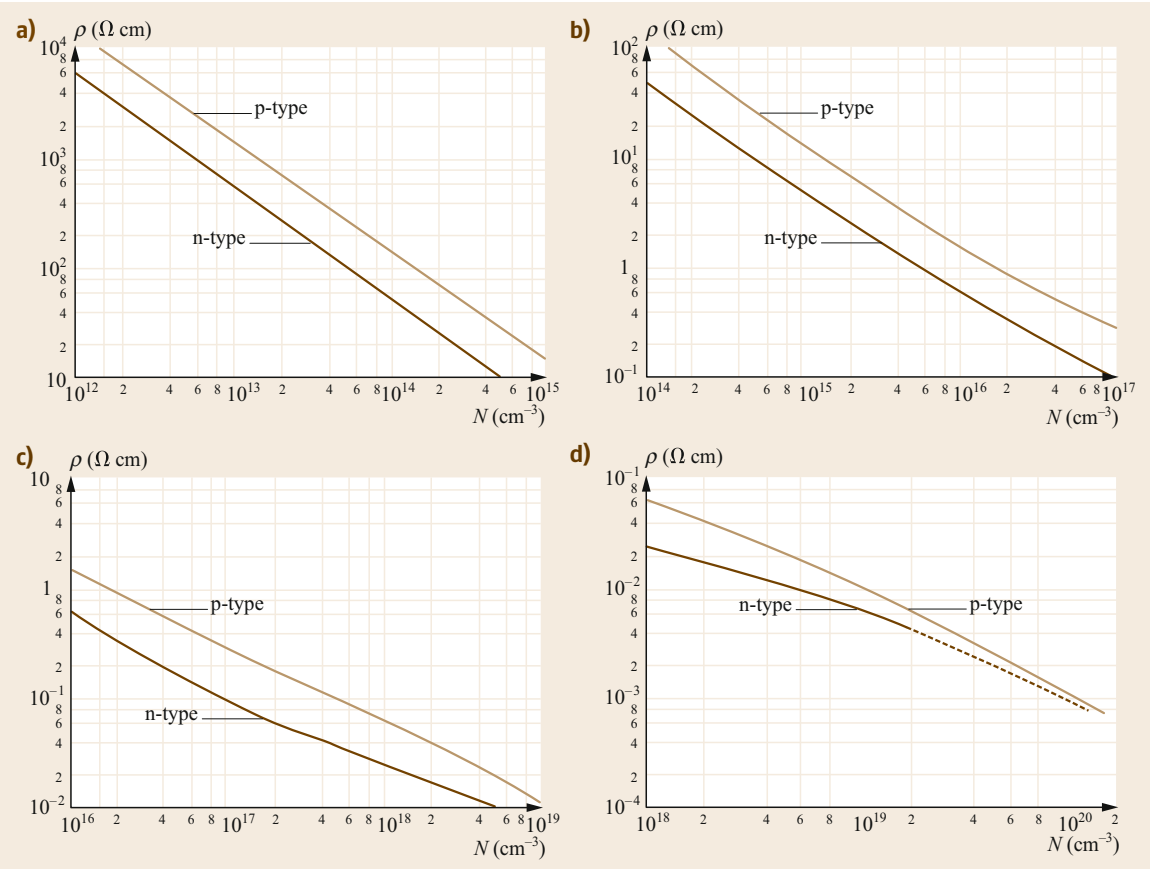

Fig. 21.5a–d Room-temperature resistivity of Si versus N (defined in the text) for overlapping ranges of doping: **(a)** light to moderate; **(b)** moderate; **(c)** moderate to heavy; **(d)** heavy. (After [21.24] with permission)

periment in favor of the latter. Neutral-impurity scattering proved to be temperature-dependent, unlike the available model [21.55].

9. The Hall factor in n-Si versus $N_I = N_d^+ + N_a^-$ [21.104]. The experimental value of r_e was obtained from the ratio of $R_e^H(0)$ to $R_e^H(\infty)$, determined by independent methods at 77 and 350 K over a wide range of N_I. Samples were cut from non-oxygenated ingots grown in vacuum, in which $R_e^H(0)$ was measured by the standard method (Sect. 21.2). Discs were then cut from the same samples, in proximity to Hall probes, and their total resistances (given by $BR_e^H(\infty)/d$ at $\mu_e B/c \gg 1$ (Sect. 21.2), where d is the disc width) were measured in fields up to $B = 3.5$ T. To check these results, standard measurements of R_e^H in pulsed fields (Sect. 21.2) up to $B = 15$ T were made. The values of r_e were calculated from theory [21.103]. Good agreement of experiment with theoretical calculations was obtained.

Minority Carriers – Miscellaneous

Minority carriers play a crucial role in silicon-based electronic devices such as bipolar junction transistors (BJTs) and solar cells, so their charge-transport parameters – concentration, recombination time, mobility and diffusion coefficient – are importany for device modeling. We do not present a literature overview nor graphical and tabular material here, as we do for the case of the majority carriers, and refer the reader directly to the review papers outlined in items 5 and 6 of Sect. 21.2.3.

Irvin Curves

The curves of $\rho(300\,\mathrm{K})$ versus N, over the entire range up to the solubility limit, compiled using published data [21.105, 106] are shown in Fig. 21.5a–d, with the high-doping range shown Fig. 21.6a–d. The resistivity decreases with increasing N since the conductivity is proportional to $n(p)$ while $n(p) = N$ at $T = 300$ K. However, at large N the decrease is slower than $\propto N^{-1}$

before 1965. For the Hall measurements the drift mobility was recalculated from the Hall value using the Hall factor for the standard band (Sect. 21.1.3). The dependencies of $\mu_{e(h)}$ on N, $N_{d(a)}$ and on N_I at low T are more physical and allow comparison with available theories. Examples of such dependencies obtained by different authors are presented in Fig. 21.8a–e. Several phenomenological expressions for $\mu_{e(h)}(N, 300\,K)$ have been given in the literature (Sect. 21.2.3) in agreement with experimental data on charge transport in Si. We consider here two of them, for obvious reasons of space. The first [21.108] reads

$$\mu(N_i) = \mu_{min} + \frac{\mu_{max} - \mu_{min}}{1 + (N_i/N_{ref})^{\alpha}}\,, \qquad (21.25)$$

where $i = a, d$, and the other fitting parameters are given in Table 21.6, the electron column of which corresponds to a later best fit for Si:P [21.109], while the hole column is due to *Caughey* and *Thomas* [21.108]. The particular case of (21.25) with $\mu_{min} = 0$, $\alpha = 0.5$, $N_{ref} = 10^{17}\,cm^{-3}$ [21.111] has also proved useful. The second expression for Ohm's mobility versus impurity concentration,

$$\mu(N_i) = \frac{\mu_0}{\sqrt{1 + \frac{(N_i/N_{eff})S}{N_i/N_{eff}+S}}}\,, \qquad (21.26)$$

where N_{eff} and S are fitting parameters, follows from the weak electric field limit of the more general phenomenological expression (21.31) for v_d versus E and N_i. The best-fit parameters for (21.26) can be found

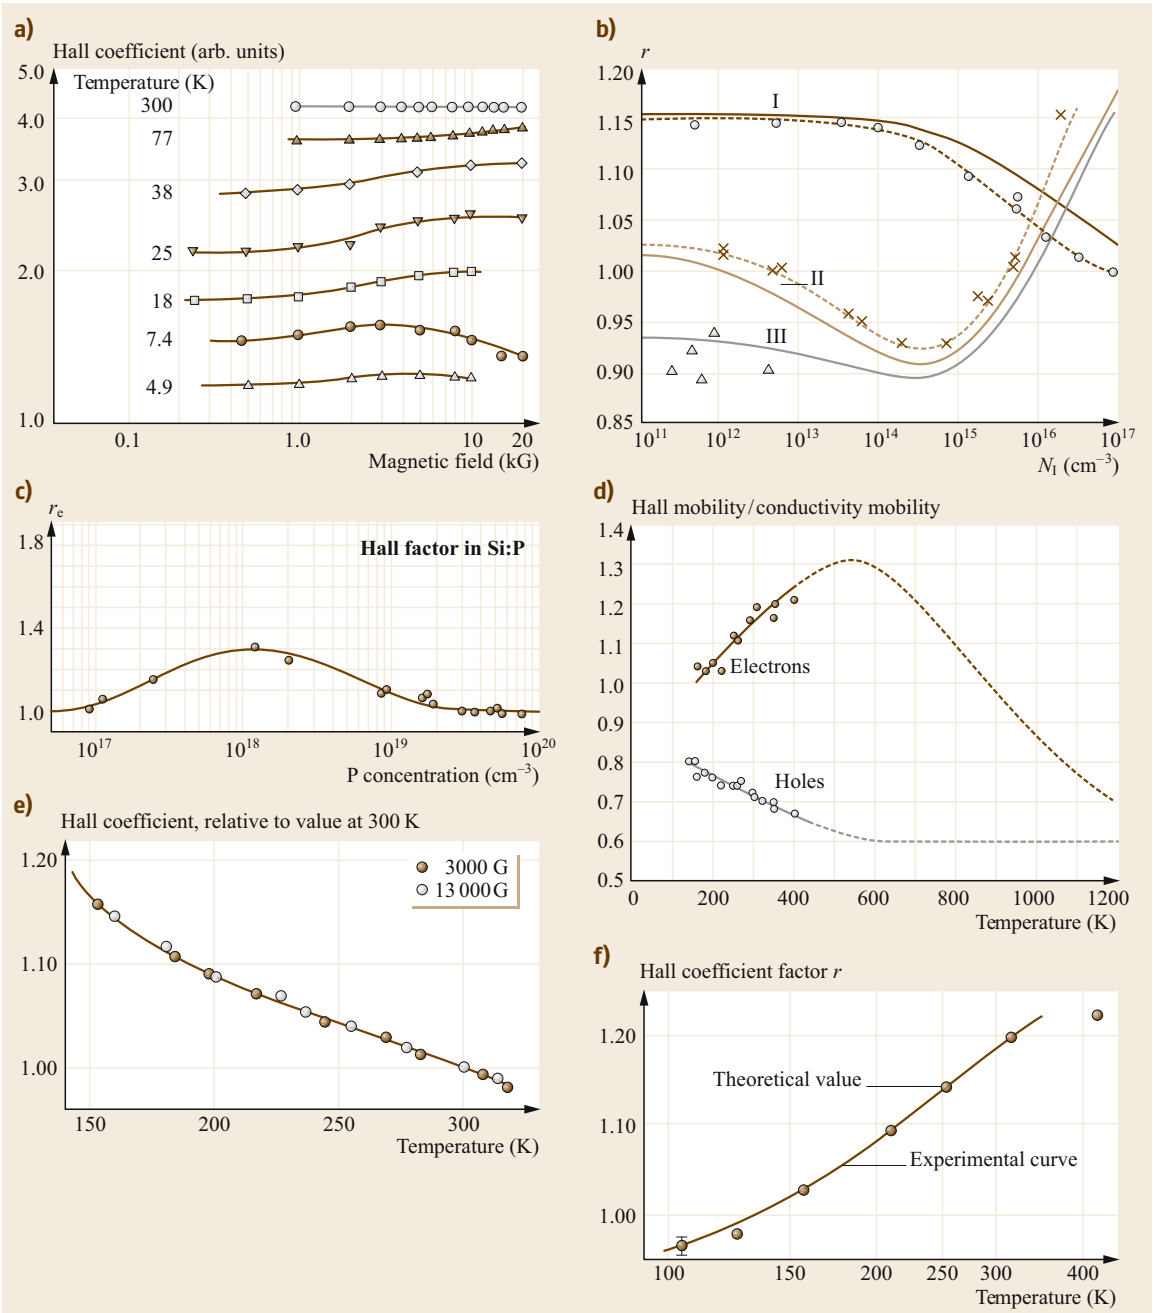
in Table 21.7. Fits to (21.25) and (21.26) are used in Fig. 21.8a–c. Physically, μ_{max} in (21.25) and μ_0 in (21.26) are $\mu_{e,hL}(300\,K)$, the intrinsic mobility (see below) at room temperature. Experimental data on this parameter due to different authors are presented in Table 21.8. Figure 21.8d shows a comparison between the mobility of holes, as minority and majority carriers, plotted against the concentration of majority impurities. At the same concentration the minority-hole mobility is strikingly larger than the majority-hole mobility. This effect may be due to the difference between scattering by attractive and repulsive centers as well as to hole–hole interaction. The variation of $\mu(N, 300\,K)$ with shallow donor and acceptor species, noted in Sect. 21.1.4, is shown in Table 21.9. As can be seen, the effect – the larger $E_{d(a)}$ the lower $\mu_{e(h)}$ – is not drastic but quite noticeable. At low temperatures the impurity-scattering-limited mobility depends on the density of ionized centers, as predicted by the BH formula (or its modifications), e.g., for electrons

$$\mu_{eI} = \frac{\eta T^{3/2}}{N_I(\ln b - 1)}\,,$$
$$\eta = \frac{2^{7/2}k_B^{3/2}\varepsilon'^2}{\pi^{3/2}q^3 m^{*1/2}}\,, \qquad (21.27)$$

where m^* is an adjusted effective mass, $\varepsilon' = \varepsilon(0)$ is the static dielectric constant and



$$b = \frac{24\pi m\varepsilon'(k_B T)^2}{n' q^2 h^2}\,,$$
$$n' = n + (n + N_a)\left(1 - \frac{n + N_a}{N_d}\right). \qquad (21.28)$$

For compensated n-Si $n \ll N_a$ at sufficiently low T, so $N_I = 2N_a$ and $n' = N_a(N/N_d) = N_I(1-K)/2$, where K is the compensation ratio. Thus, disregarding the weak logarithmic dependence, μ_{eI}^{-1} proves to be linear with N_I. Such dependence is seen in the experimental data shown in Fig. 21.8e.

The Hall coefficient for lightly compensated n-Si as a function of B is shown in Fig. 21.9a. The curve for $T = 300\,K$ shows no visible variation when sweeping from low to high fields, which means that either the high-field regime is not attained or $r_e = 1$. The transition between the two regimes is clearly seen with $r_e < 1$, at the lower indicated values of T. The data below 20 K were obtained by sweeps of the photo-Hall coefficient, so the decrease of R_e^H at high B is fictitious, due to the field dependence of the photo-carriers lifetime [21.53]. Figure 21.9b,c display the dependence of r_e on the impurity concentration for light to moderate and high doping, respectively. Figure 21.9a,b are in qualitative agreement with the inequality $r_e < 1$ at

Table 21.10 Si samples. (After [21.96])

$T = 77\,\mathrm{K}$ for comparable concentrations. The overall observed behavior of $r_e(N)$ at $T = 300\,\mathrm{K}$, as shown in Fig. 21.9c, viz. $r_e \approx 1$ on both the moderate and heavy doping sides and a maximum in between at which $r_e > 1$, is deduced from (21.23) using knowledge of the anisotropy of the mass and relaxation-time tensors. Compared to these, results for the Hall effect for holes are not available, to our knowledge.

Hall Effect and Mobility Versus Temperature

The dependencies of $r_e(T)$ and $r_h(T)$ for samples 131, 130 and 159, 127 from Table 21.10 are shown in Fig. 21.9d. The temperature dependence of R_h^H relative to its value at $T = 300\,\mathrm{K}$ for another p-type sample is shown in Fig. 21.9e. Since, in the considered temperature range, p is constant with T, the dependence is fully congruent to $r_h(T)$ – in this regard the lower curve in

(After [21.51] with permission) ◀

Fig. 21.9d and the curve in Fig. 21.9e are in agreement. There is good quantitative agreement between experiment and theory for $r_e(T)$ using an exact effective-mass tensor, as shown in Fig. 21.9f. On the contrary, the Hall effect and MR in p-Si are poorly understood [21.98, 99] as the energy spectra of holes is much more complicated than (21.5) and (21.6), even for energies well above 200 K [21.8].

The $\mu_{e,h}(T)$ curves have been the subject of extensive, but to our opinion not exhaustive, studies. As discussed in Sect. 21.2, these dependencies reflect the scattering mechanisms. The basic question is that of temperature dependence due to lattice scattering, which can be measured on technologically pure, very lightly doped and negligibly compensated samples. Since such samples were not available in early studies, researchers tried to apportion the intrinsic $\mu_{e,h}(T)$ from the drift measurements, as shown in Fig. 21.10a, or from conductivity and Hall measurements combined with calculations, as shown in Fig. 21.10b. In practice the intrinsic $\mu_{e,h}(T)$ is described by the phenomenological best-fit equation

$$\mu_{e,hL}(T) = AT^{-\gamma} \,, \tag{21.29}$$

where A and γ may vary with the carrier and measurement type, fitting interval and sample quality. Different drift measurements, in the ranges 150–300 K [21.92], and 160–400 K [21.93], resulted in very different values of A and γ for both electrons and holes. The first measurements of the Hall effect and conductivity against temperature [21.96] gave the same γ for holes as that obtained by Prince, but a drastically larger γ for electrons, as the n-type samples with the lowest N_d used were inappropriate for that purpose – one sample (131, Table 21.10), though lightly doped, was compensated ($K \approx 0.57$) and the other (130, Table 21.10) was doped in excess of 10^{15} cm^{-3}. Therefore, Morin and Maita numerically extracted the ionized-impurity scattering mobility portion (21.27) and (21.28) and then determined γ. This procedure seems unreliable in view of the inapplicability of the BH formula with strong compensation, neglect of scattering by neutral impurities and of the spectrum and scattering anisotropies. Analogously, using (21.29) for a high-resistivity p-type Si sample [21.99], fitting to $\mu_h(T)$ resulted in the same γ as that obtained by Ludwig and Waters while fitting to $\mu_h^H(T)$ (Fig. 21.10e) resulted in an even larger γ. Using high-purity samples, for which the $\mu_e(T)$ and $\mu_h(T)$ values are presented in Fig. 21.10c, made it possible to determine a γ for $\mu_e(T)$ in agreement with that obtained by Prince, but failed to fit $\mu_h(T)$ to (21.29) [21.100]. *Long* did not fit using (21.29) and calculated $\mu_{eL}(T)$ using a realistic electron spectrum and a specific inter-valley electron–phonon scattering model (Sect. 21.1.4), and compared the calculation to experiment [21.51], with excellent agreement, as can be seen in Fig. 21.10d. The validity of the model [21.51] was confirmed by an independent study [21.53]. The calculation of $\mu_{eL}(T)$ was revisited on the basis of the Monte Carlo method and extended inter-valley scattering models [21.113]; the results are displayed in Fig. 21.11a along with the experimental data and fit line. We are unaware of analysis for $\mu_{hL}(T)$ comparable to that done for $\mu_{eL}(T)$, taking both the realistic hole spectrum [21.8] and full hole–phonon scattering into consideration. Another analysis [21.70] greatly simplified the problem by using relaxation-time equalization ($\tau_1(E) = \tau_2(E)$), resulting from the isotropic approximation adopted for the hole spectra (21.5), but proved insufficient to account for both Ohm's mobility and hot-holes phenomena [21.18]. The results of calculations based on the relaxation-time method, using only one isotropic but nonparabolic heavy-hole band [21.18], are displayed in Fig. 21.11b along with the experimental data and fit line. The best-fit parameters of (21.29) obtained by different authors are given in Table 21.14.

The effect of doping on mobility is shown in Fig. 21.12. In doped samples $\mu_{e,h}(T)$ increases with decreasing T up a maximum at some T_{max} (the lower the sample's purity the larger T_{max}) and then starts to decrease. This behavior is due to competition be-

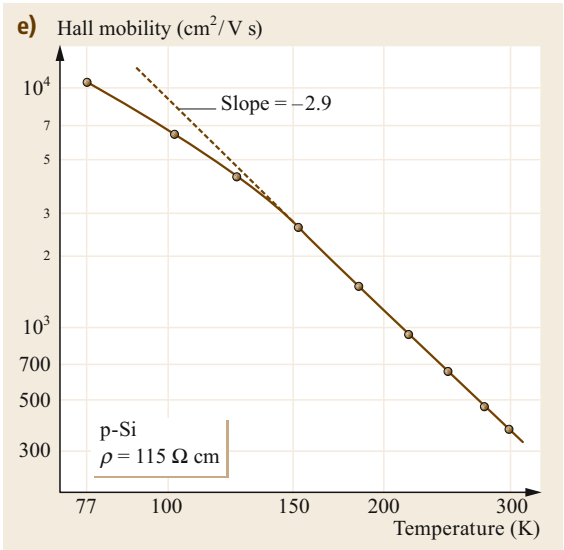

Fig. 21.10 (continued)

tween lattice scattering, which weakens with decreasing T (21.29), and impurity scattering, which strengthens with decreasing T, (21.27) and (21.28). In heavily doped samples scattering by impurities, while dominating the mobility, ceases to depend notably on T ((21.27) and (21.28) do not hold in this case), which results in an overall weak dependence of the observed $\mu_{e,h}(T)$ on T. These types of behavior are clearly seen in Fig. 21.12a,b. The evolution of T_{max} with the impurity content for lightly doped, differently compensated, n-Si is readily traced in Fig. 21.12c. The compensation is crucial for the rate of downturn of the mobility, as follows from (21.27) and (21.28) and is confirmed by the curves for samples C and D (Table 21.11) in Fig. 21.12c. Figure 21.12d summarizes the information on $\mu_{e,h}(T)$ for doped Si. For estimations of the combined-scattering mobility, e.g., for electrons, the Mattisen rule $\mu_e^{-1}(T) = \mu_{eL}^{-1} + \mu_{eI}^{-1}$, where μ_{eL} and μ_{eI} are given by (21.29) and (21.27) and (21.28), respectively, is used [21.100, 101]. The formula, consistently derived for nondegenerate carriers in the standard band, is

$$\mu_e(T) = \mu_{eL} + \mu_{eL}x^2 \times \left[\mathrm{Ci}(x)\cos x + \left(\mathrm{Si}(x) - \frac{\pi}{2}\right)\sin x\right], \quad x = \sqrt{6\frac{\mu_{eL}}{\mu_{eI}}}, \tag{21.30}$$

where $\mathrm{Ci}(x)$ and $\mathrm{Si}(x)$ are integral cosine and sine, respectively, and μ_{eL} is due to acoustic-phonon scat-

tering (with $\gamma = 1.5$) [21.71], which proved more appropriate for quantitative analysis. The comparison of (21.30) and the expression for $\mu_e^H(T)$, derived under the same conditions, with the corresponding experimental curves, using $\eta = 8.6\times10^{17}\,\mathrm{K}^{-1.5}\,\mathrm{cm}^2\,\mathrm{V}^{-2}\,\mathrm{s}^{-1}$ (21.27) for an effective isotropic band mass of $m^* = 0.3m_0$, is shown in Fig. 21.13. Good quantitative agreement between the theory and experiment is observed except for the samples SM3 and SM2, in which the ionized-impurity scattering is strongest (to avoid confusion the data points for SM2 are not shown but they are as discrepant with respect to the observed mobility curve as those shown for SM3). The generalization of (21.30) to the case with spectrum and scattering anisotropies [21.103] was employed to calculate $r_e(T)$ [21.65] and to extract N_a from the mobility data [21.53]. Dakhoskii numerically explained why the above isotropic approximation [21.101] worked well, but presented no graphs of mobility versus T. Norton et al. presented graphically calculated $\mu_e(T)$ only for Si:P6, the purest of their samples. No analysis for $\mu_h(N,T)$ comparable to that done for $\mu_e(N,T)$, i. e., taking both the realistic hole spectrum and hole–phonon and hole–impurity scatterings into account, exists to our knowledge in the literature. Success of modeling based on empirically adjusted phenomenological expressions (items 2–4 in Sect. 21.2.3), though valuable for the device community, cannot be considered as such from the viewpoint of solid-state and semiconductors theories.

21.2.2 High-Electric-Field Effects

The group of effects associated with the carrier transport in high electric fields is traditionally called *hot-carrier phenomena*. This name was borrowed from the displaced-Maxwell-distribution method, where an effective parameter is the carrier temperature, which becomes much higher than that of the lattice, as if the field heats the carriers [21.38]. Not too much work has been published on hot-carrier phenomena in Si, but most

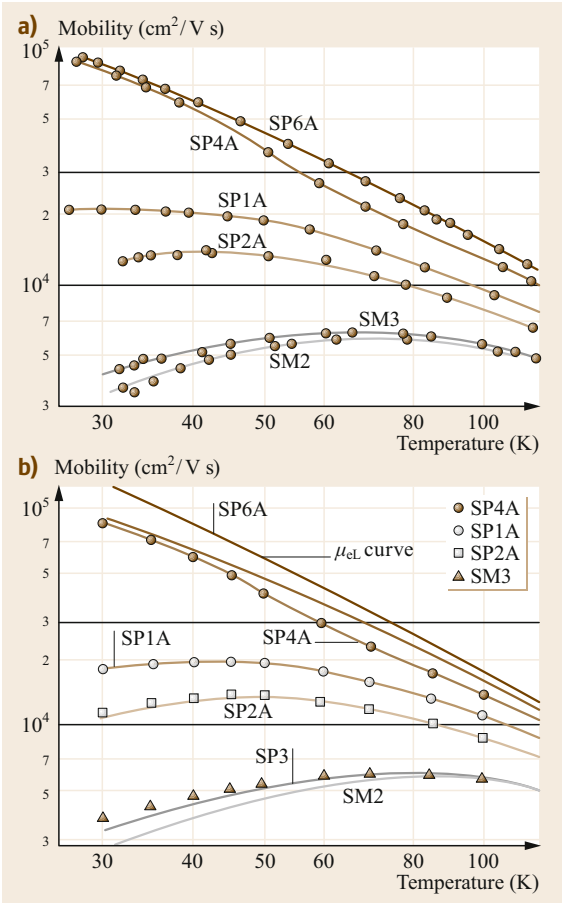

Fig. 21.13a,b Comparison of the theoretical results on $\mu_e(T)$ and $\mu_e^H(T)$ (*symbols*) with the experimental data (*full lines*). The indicated samples are those from Table 21.12. (After [21.101] with permission)

of the existing work was overviewed in the two referencess cited below, and in item 3 in Sect. 21.2.3:

1. The electron drift velocity [21.113]. Experimental results for electrons in Si obtained using a time-of-flight technique were presented for $8\,\mathrm{K} \le T \le 300\,\mathrm{K}$ and $\boldsymbol{E}$ in the magnitude range 1.5×10^4–$5\times10^4\,\mathrm{V/cm}$, oriented along the ⟨111⟩, ⟨110⟩ and ⟨100⟩ crystallographic directions. At 8 K the dependence of the transit time upon sample thickness allowed a measurement of the valley repopulation time when the electric field is ⟨100⟩ oriented. These experimental results were interpreted with Monte Carlo calculations in the same ranges of T and $\boldsymbol{E}$. The model included the many-valley structure of the conduction band of Si, acoustic intra-valley scattering with the correct momentum and energy relaxation and correct equilibrium phonon population, several inter-valley scatterings, and ionized-impurity scattering.
2. Hole drift velocity [21.18]. Drift velocities for holes in high-purity Si, were measured by a time-of-flight technique with $\boldsymbol{E}$ in the amplitude range from 3×10^4–$5\times10^4\,\mathrm{V/cm}$ along the ⟨100⟩, ⟨110⟩, and ⟨111⟩ directions, and at $8\,\mathrm{K} \le T \le 300\,\mathrm{K}$. The Ohm's mobility is theoretically interpreted on the basis of a two-band model consisting of a spherical parabolic and a spherical nonparabolic band, and relaxation-time approximation. The low-T Ohm's mobility proved to be strongly influenced by the nonparabolic structure of the heavy-hole band. The high-field region, $E = |\boldsymbol{E}| \ge 10^3\,\mathrm{V/cm}$, was analyzed using a single, warped heavy-hole band model and a Monte Carlo technique. Anisotropy of the hot-hole drift velocity due to warping of the valence band was measured. Optical- and acoustic-phonon scattering were found to have comparable rates.

Impact ionization phenomenon are different in appearance and are not considered here in detail; see item 7 in Sect. 21.2.3.

Drift Velocity – Electric-Field Relationship

As the field strength $\boldsymbol{E}$ overcomes some limit (which depends on the lattice temperature, doping and type of carrier) the drift velocity (Sect. 21.2.3) becomes a sub-linear function of $\boldsymbol{E}$, i. e., the mobility starts to decrease with increasing $\boldsymbol{E}$. As revealed by the early study for n-Si [21.116], in the range 10^3–$10^5\,\mathrm{V/cm}$, n does remain constant, but the mobility decreases appreciably, as seen in Fig. 21.14. Further studies obtained, in addition, the following patterns [21.18, 19, 113]:

1. Drift velocity $\boldsymbol{v}_d(\boldsymbol{E})$ is anisotropic in the orientation of $\boldsymbol{E}$ relative to the crystallographic axes: different values of $\boldsymbol{v}_d$ are obtained for the same E for $\boldsymbol{E}$ along different high-symmetry directions ⟨111⟩, ⟨110⟩ and ⟨100⟩. For less-symmetric directions $\boldsymbol{v}_d$ is not even parallel to $\boldsymbol{E}$, which is known as the Sasaki–Shibuya effect [21.38]. The $\boldsymbol{v}_d$–$\boldsymbol{E}$ relation depends strongly on T, as seen from Fig. 21.15a,b for the ⟨111⟩ and ⟨100⟩ directions. The anisotropy becomes stronger as T decreases, as seen from Fig. 21.16a,b. For electrons, the curves of $\boldsymbol{v}_d$ versus $\boldsymbol{E}$ for different T (Fig. 21.15a) tend to join together at some value of $\boldsymbol{E}$, which increases with T, even though such a rejoining is not reached at all considered T. For holes (Fig. 21.15b), this tendency is much weaker and the rejoining field is much higher than for electrons.
2. For electrons at the highest $\boldsymbol{E} \| \langle 111 \rangle$, a region where $\boldsymbol{v}_d$ is independent of E (saturation) is obtained

Table 21.13 Weakly compensated n-Si samples [21.53]

Sample	N_d (cm^{-3})	N_a (cm^{-3})	E_d (meV)	m^*/m_0	ρ_{300} (Ω cm)

Table 21.14 Parameters of the best fit of the intrinsic mobility to (21.29)

Carriers	γ						$A(10^8\,K^\gamma cm^2V^{-1}s^{-1})$			
Electrons	1.5[a]	2.6[b]	2.5[c]	–	1.5[e]	2.42[f]	5.5[a]	40[b]	21[c]	14.3[f]
Holes	2.3[a]	2.3[b]	2.7[c]	2.7–2.9[d]	2.0[e]	2.20[f]	2.4[a]	2.5[b]	23[c]	1.35[f]

[a] After [21.92], [b] after [21.96], [c] after [21.93], [d] after [21.99], [e] after [21.100] at $T \le 100$ K, [f] after [21.19]

(Fig. 21.15a). For holes, this type of saturation is not approached for all available $\boldsymbol{E}$ (Fig. 21.15b).

3. Ohm's law is reached at $T > 45$ and 100 K for electrons and holes, respectively, and the results for mobility are in agreement with those obtained by standard techniques for the linear regime. At $T < 45$ K for electrons, and $T < 100$ K for holes, even at the lowest $\boldsymbol{E}$, $\boldsymbol{v}_d$ is not linear with $\boldsymbol{E}$. At low temperatures the mobility is as high as $5\times10^5\,cm^2/(V\,s)$ at $E = 1.5$ V/cm for electrons ($T = 8$ K), and $3.5\times10^5\,cm^2/(V\,s)$ at $E = 3$ V/cm for holes ($T = 6$ K). A negative differential mobility (NDM) was found with $\boldsymbol{E}\|\langle100\rangle$ at $T < 40$ K for electrons (Fig. 21.16a). The field at which $\boldsymbol{v}_d$ reaches the maximum before the NDM region (NDM threshold), decreases with decreasing T. For holes, a net low-field saturation region of $\boldsymbol{v}_d$ (50 V/cm $< \boldsymbol{E} <$ 150 V/cm at $T = 6$ K) shows up for $\boldsymbol{E}\|\langle111\rangle$, $\langle110\rangle$ and $\langle100\rangle$ (see top of Fig. 21.16b). This effect gradually disappears as T increases, and at $T > 38$ K it is no longer visible.

For electrons, the anisotropy is due to a repopulation of the valleys: when $\boldsymbol{E}\|\langle111\rangle$ the six valleys (Fig. 21.3b) are equally oriented with respect to $\boldsymbol{E}$ and all of them give the same contribution to $\boldsymbol{v}_d$. When, for example, $\boldsymbol{E}\|\langle100\rangle$, two valleys exhibit the effective mass m_l in the direction of the field, while the remaining four exhibit the transverse mass $m_t < m_l$. Electrons in the transverse valleys respond with a higher mobility, are heated to a greater extent by the field and transfer electrons to the two longitudinal, *colder* and slower valleys, which results in a lower $\boldsymbol{v}_d$ than for $\boldsymbol{E}\|\langle111\rangle$, as seen, e.g., in Fig. 21.16a. For holes, the anisotropy is due to the two warped and degenerate valence sub-

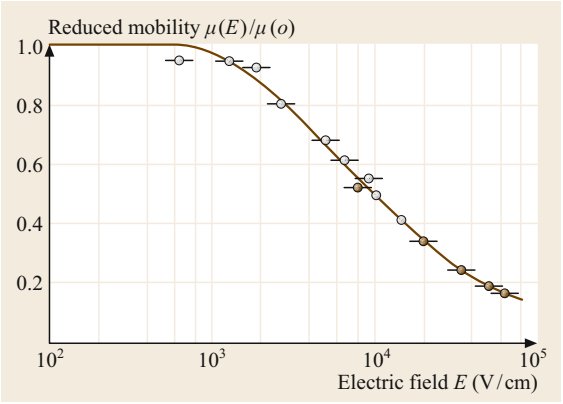

Fig. 21.14 Variation of reduced mobility with electric field applied to a 70 Ω cm n-Si sample along the direction $\langle111\rangle$. The electron concentration is assumed to be constant. (After [21.24] with permission)

bands (Fig. 21.3c) resulting in different effective masses for holes with different $\boldsymbol{k}$, and in the lowest and highest $\boldsymbol{v}_d$ for $\boldsymbol{E}\|\langle110\rangle$ and $\boldsymbol{E}\|\langle100\rangle$, as seen in Fig. 21.16b. A summary of the curves of $\boldsymbol{v}_d$ versus $\boldsymbol{E}$ is presented on Fig. 21.16c.

Anisotropy becomes stronger as T decreases, since a lower T leads to less-effective relaxation effects. In particular, at $T \approx 45$ K the repopulation of electron valleys may be so rapid with increasing $\boldsymbol{E}\|\langle100\rangle$ that NDM occurs with $\boldsymbol{E}$ in the range 20–60 V/cm. NDM was observed via oscillations of the current [21.132], and in the I–V [21.128, 132, 133] and $\boldsymbol{v}_d$–$\boldsymbol{E}$ [21.113, 134, 135] characteristics. Whether the curves of electron $\boldsymbol{v}_d$ versus $\boldsymbol{E}$ for $\boldsymbol{E}\|\langle100\rangle$ and $\boldsymbol{E}\|\langle111\rangle$ join together at the high-field limit is still an open point. Theoretical considerations [21.136] seem to indicate that a small

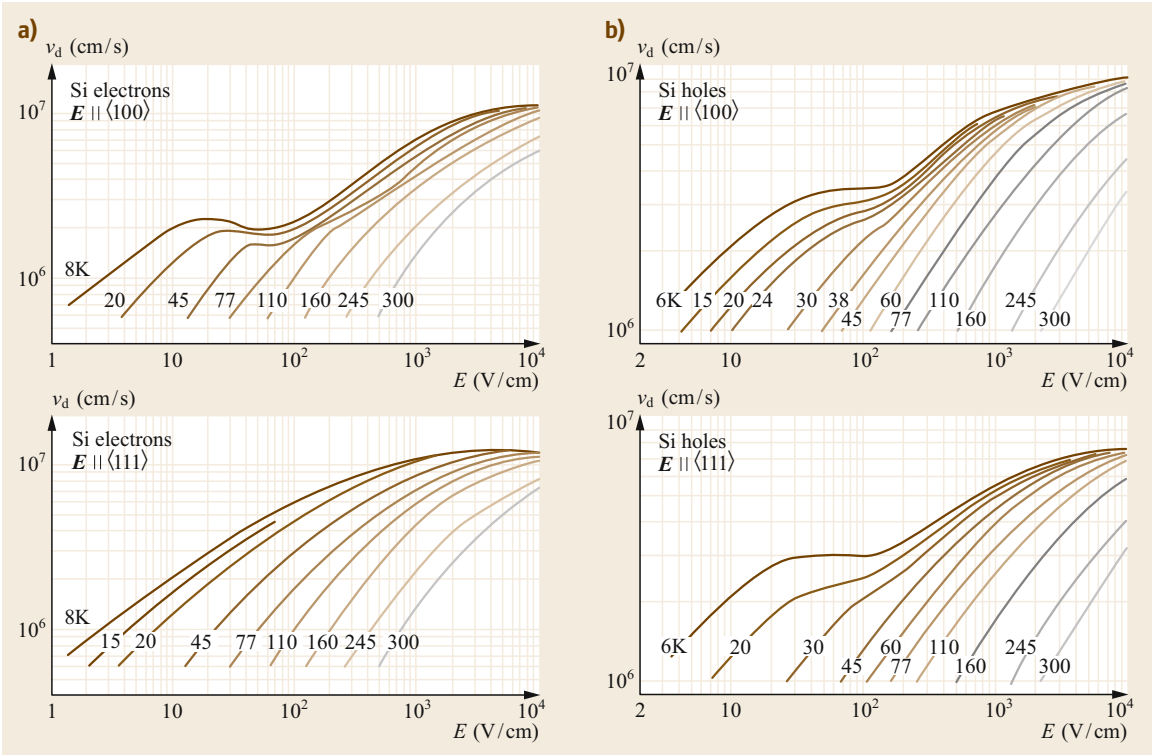

Fig. 21.15 Carriers' drift velocity for E, applied along two indicated directions, measured at different indicated T by the time-of-flight method: **(a)** Electrons. (After [21.117] with permission); **(b)** Holes. (After [21.18] with permission)

difference ($\approx 5\%$) between the two curves should remain. However, this difference is comparable to experimental error and merging of the two curves has been claimed at several temperatures in the experimental results [21.113, 118]. In the case of holes, both theoretical and experimental results [21.18] indicate that, up to the highest fields attained (5×10^4 V/cm), no merging occurs. The aforementioned anomalous behavior of the curves of $\boldsymbol{v}_d$ versus $\boldsymbol{E}$ for holes at low temperatures ($T < 38$ K) – that these curves tend to *saturate* at intermediate field strengths and then rise again – has been explained [21.18, 117] by a nonparabolic distortion of the heavy-hole spectrum.

A general tendency of $\boldsymbol{v}_d(\boldsymbol{E})$ to saturate at the highest fields is an important phenomenon which was considered from the very beginning of the hot-electron investigations [21.137–139]. The original explanation [21.138] for this behavior was based on a rough physical model, in which it was assumed that the carriers emit an optical phonon as soon as they reach the energy $\hbar\omega_0$ of the phonon that limits the drift velocity by the saturation value $v_s \approx \sqrt{\hbar\omega_0/m^*}$ [21.138]. For electrons, inter-valley instead of optical phonons should be considered (Sect. 21.2.3). Subsequent calculations [21.140, 141] showed, that the Shockley formula should be considered only as a rough evaluation, since at very high electric field the transport process depends on many factors including several phonon dispersion curves, phonon emission and absorption, and nonparabolic band corrections. Good agreement between the Monte Carlo calculations and the experimental data for high-purity n-Si is seen in Fig. 21.17a. In the case of holes the saturation was neither predicted theoretically, nor found experimentally. A nearly saturated drift velocity was observed [21.122] only at room temperature, and the saturation should occur, by extrapolation, at $\boldsymbol{E} \geq 2 \times 10^5$ V/cm with v_{sh} around 10^7 cm/s (Fig. 21.16c).

Empirically adjusted formulas for $v_d(E)$ have been proposed for varying N_i and $T = 300$ K [21.142]

$$v_d = \frac{\mu_0 \boldsymbol{E}}{\sqrt{1 + \frac{S(N_i/N_{ref})}{N_i/N_{ref}+S} + \frac{(E/E_1)^2}{E/E_1+F} + \left(\frac{E}{E_2}\right)^2}}, \quad (21.31)$$

and for $N_i = 0$ and varying T [21.108]

$$v_d = v_m \frac{E/E_c}{[1 + (E/E_c)^\beta]^{1/\beta}} ; \quad (21.32)$$

the best-fit parameters are presented in Table 21.7. Also a formula was suggested [21.19] for the electron satu-

Holes, $T = 300$ K: *full* – time-of-flight [21.118], *dashed* – time-of-flight [21.119], *double-dot-dashed* – time-of-flight [21.120], *cross-dashed* – $I(V)$ in space-charge-limited current (SCLC) regime [21.121], *dot-dashed* – $I(V)$ [21.122], *arrow* – extrapolated value of v_{sh} [21.122]. Electrons, $T = 300$ K: *full* – time-of-flight [21.118], *long-dash-dot* – time-of-flight [21.119], *dashed* – time-of-flight [21.120], *double-dot-dash* – $I(V)$ in the SCLC regime [21.123], *dots* – $I(V)$ [21.124], *dash-crossed* – $I(V)$ [21.125], *dashed arrow* – v_{se} from $I(V)$ in avalanche diodes [21.126, 127]. Electrons, $T = 77$ K: *full* – time-of-flight [21.118], *dashed* – $I(V)$ [21.128], *dash-dot* – $I(V)$ [21.129], *dotted* – $I(V)$ [21.130, 131]. (After [21.19] with permission)

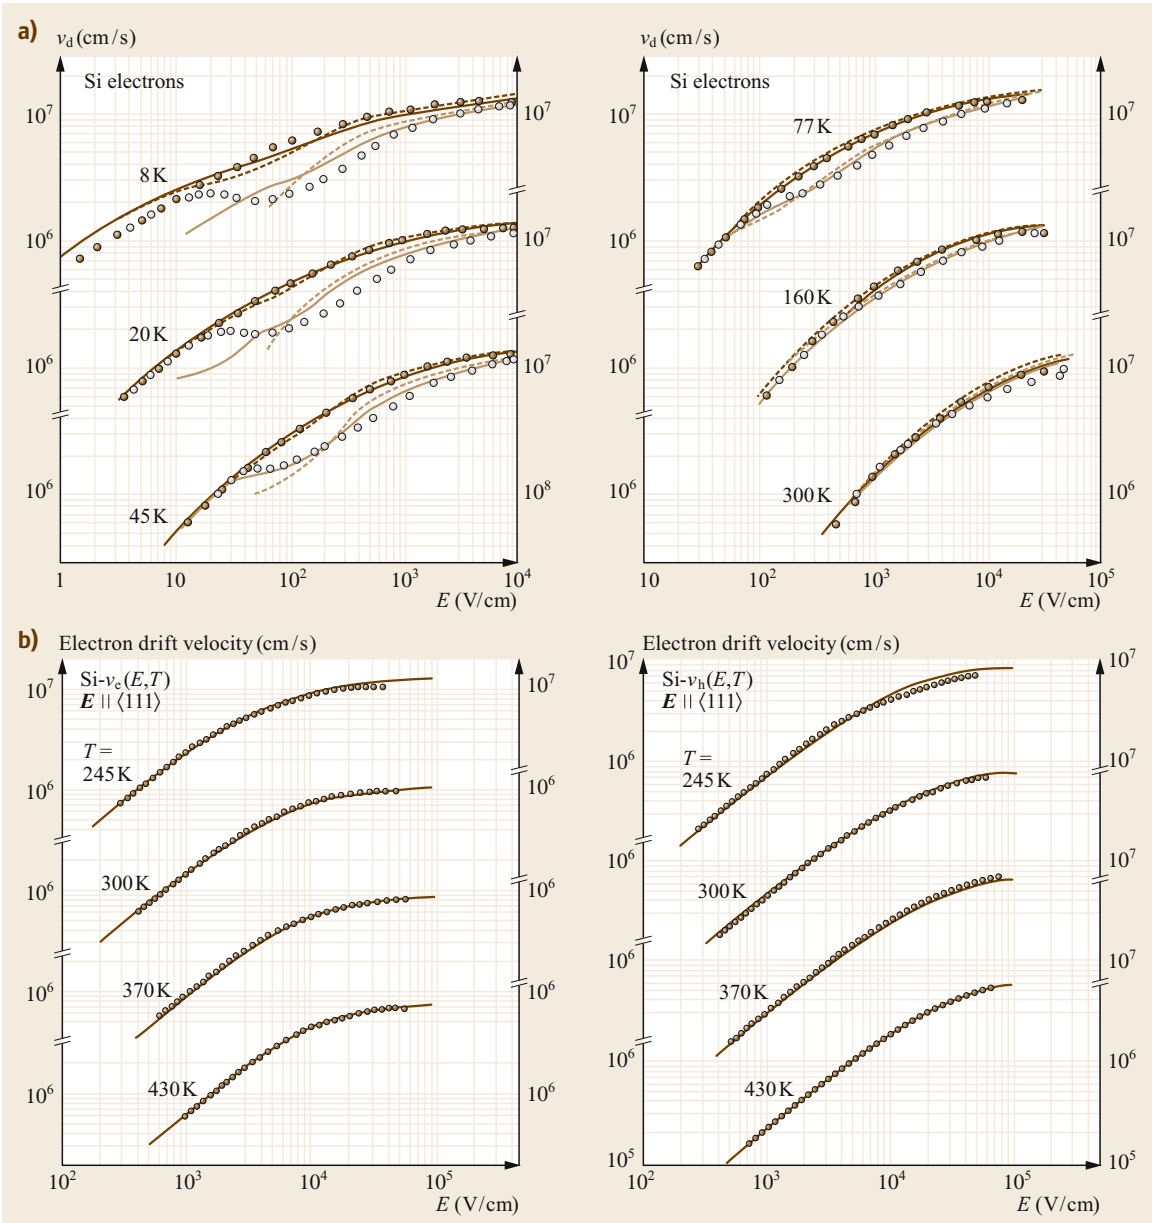

Fig. 21.17a–c Measured versus simulation results on drift velocity in Si: **(a)** $v_{de}(E)$ at different indicated temperatures. *Circles* indicate experimental data by time-of-flight method, *solid circle* – $E \| \langle 111 \rangle$ and $E \|$ *open circle* – $\langle 100 \rangle$, and lines Monte Carlo simulations results neglecting impurity scattering, *full* and *broken* – using six lowest and three allowed inter-valley phonons (Table 21.4), respectively. For $T \leq 45$ K, the theoretical curves which refer to the $\langle 100 \rangle$ direction are interrupted, as it was not possible to reach a sufficient precision in the simulated v_d. (After [21.113, 115] with permission); **(b)** The $v_{de}(E)$ and $v_{de}(E)$, for $E \| \langle 111 \rangle$, in high-purity Si at four different T. *Solid circle* – the experimental data [21.118] and *lines* are the best-fit curves obtained with (21.32) using the parameters listed in Table 21.7. (After [21.19] with permission); **(c)** $v_{se}(T)$ obtained experimentally with different techniques and numerically fitted. *Solid circle* – time-of-flight [21.113, 115, 118, 143], *open circle* – $I(V)$ in avalanche diodes [21.126, 127], *open triangle* – $I(V)$ in the SCLC regime [21.123]; the latter data have been normalized to 9.6×10^6 cms^{-1} at 300 K; *line* represents the best fitting curve of (21.33). (After [21.19] with permission)

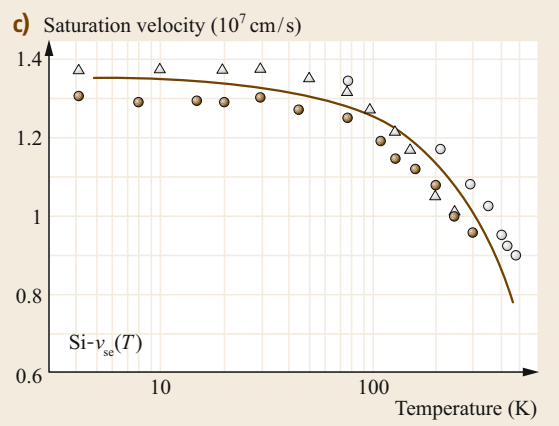

Fig. 21.17 (continued)

rated drift velocity as a function of temperature

$$v_{se}(T) = \frac{2.4\times10^7\,\mathrm{cm/s}}{1+0.8\times\exp\left(\frac{600\,\mathrm{K}}{T}\right)}. \qquad (21.33)$$

The applicability of (21.32) and (21.33) is clearly demonstrated by Fig. 21.17b,c, respectively.

Hot-Carrier Diffusion

Knowledge of diffusion processes is useful for a better understanding of charge-transport phenomena and correct simulation of high-frequency devices. At low fields the diffusion coefficient D is related to the mobility by the Einstein relation (Sect. 21.1.3). At high fields it becomes a field-dependent tensor, which describes the diffusion with respect to $\boldsymbol{E}$ depending on its direction in the crystallographic frame. The difference between diffusion parallel to and perpendicular to $\boldsymbol{E}$ is greater than the variations caused by changes in the crystallographic direction. Therefore, investigations set out to determine the field dependence of both the longitudinal ($D_\parallel$) and transverse ($D_\perp$) components of the diffusivity tensor with respect to $\boldsymbol{E}$ irrespective of its orientation in the crystal.

The longitudinal diffusion coefficient can be measured by the Haynes–Shockley or time-of-flight [21.120] technique by observing the difference between the fall and rise times of the current pulse. This difference is caused by the spread of the carriers traveling across the sample and is simply related to $D_\parallel$ [21.144]. Analogously, $D_\perp$ can be obtained by observing the spread of the current perpendicular to the direction of the field. The current is originated by a point excitation on one surface of a Si wafer and is collected on the opposite surface by several electrodes of appropriate geometry [21.145]; this technique is sometimes called *geometrical* [21.19]. Finally, both

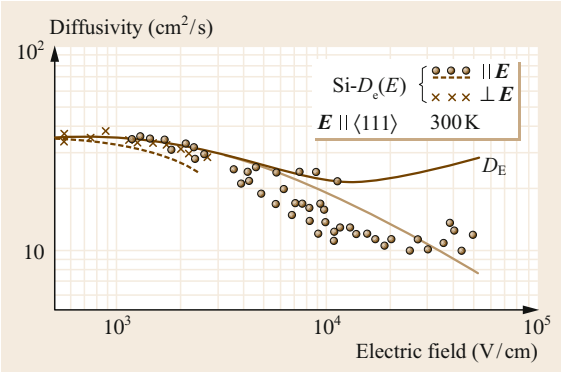

Fig. 21.18 Diffusion coefficients of electrons versus E in Si at $T = 300$ K: *solid circle* – $D_\parallel$, time-of-flight data [21.113, 115]; *dashed* – $D_\parallel$, noise data [21.146]; *crosses* – $D_\perp$, the geometrical technique data [21.145]; *full lines* – the Monte Carlo computed $D_\parallel$ and D_E [21.113, 115]. (After [21.19] with permission)

$D_\parallel$ and $D_\perp$ have been related to noise measurements, parallel and perpendicular respectively to the current direction [21.146].

Figure 21.18 shows some experimental results on the field dependence of $D_\parallel$ and $D_\perp$ for electrons in Si at room temperature with $\boldsymbol{E}\|\langle111\rangle$. The data obtained by the noise measurements are in a reasonable agreement with the time-of-flight results, although the former cover a narrower range of $\boldsymbol{E}$, just outside Ohm's region. As $\boldsymbol{E}$ increases $D_\parallel$ decreases to about one third of its low-field value ($\approx 36\,\mathrm{cm^2/s}$), which is in substantial agreement with theoretical Monte Carlo computations for the nonparabolic band [21.113]. The results for transverse diffusion showed that, as $\boldsymbol{E}$ increases, $D_\perp$ also decreases, but to a lesser extent than $D_\parallel$. There exists a hypothesis of validity to extrapolate the Einstein relation outside the linear region by $D_E = \frac{2\bar{E}}{3q}\mu(E)$. As seen from Fig. 21.18, this yields a qualitative interpretation of $D_\perp$ for not too high fields. As far as $D_\parallel$ is concerned, the diffusion process seems much more complex than pictured by the Einstein relation. For holes, the dependence of $D_\parallel$ on $\boldsymbol{E}$ was found to be similar to that for electrons [21.19].

Impact Ionization

Impact ionization is an important charge-generation mechanism. It occurs in many silicon-based devices, either determining the useful characteristic of the device or causing an unwanted parasitic effect. The breakdown of a silicon p-n diode is caused by impact ionization if its breakdown voltage is larger than about 8 V. The operation of such devices as thyristors, impact avalanche transit time (IMPATT) diodes and trapped plasma avalanche-triggered transit (TRAPATT) diodes

is based on avalanche generation, the phenomenon that results from impact ionization. The avalanche generation also plays an increasing role in degradation due to hot-carrier effects and bipolar parasitic breakdown of metal–oxide–semiconductor (MOS) devices, the geometrical dimensions of which have been scaled down recently.

The ionization rate is defined as the number of electron–hole pairs generated by a carrier per unit distance traveled in a high electric field, and is different for electrons and for holes. Impact ionization can only occur when the particle gains at least the threshold energy for ionization from the electrical field. This can be derived from the application of the energy and momentum conservation laws to the amount $E_i \approx 1.5E_g$ (assuming that the effective masses of electron and hole are equal). A large spread of experimental values for E_i exists, with a breakdown field of order of 3×10^5 V/cm. For more detailed consideration we refer the reader to the review article [21.147] noted in Sect. 21.2.3.

21.2.3 Review Material

The following materials may be recommended for further reading:

1. Electrical properties of Si [21.24]. Summary of papers on the subject that were published over a decade until 1965 are overviewed. Miscellaneous properties, such as piezoresistance and high-electric-field mobility, were also presented.
2. Electron mobility and resistivity in n-Si versus dopant density and temperature [21.148]. An improved model for computing μ_e as a function of N_d and T in uncompensated n-Si was formulated. The effects of electron–electron interaction on conventional scattering processes, as well as their anisotropies were incorporated empirically. The model was verified to ±5% of the mobility measured on wafers doped by phosphorous in the range $10^{13}-10^{19}\,\mathrm{cm}^{-3}$.
3. Bulk charge-transport properties of Si [21.19]. Review of knowledge on the subject with special emphasis on application to solid-state devices. Most attention was devoted to experimental findings at room temperatures and to high-field properties. The techniques for drift-velocity measurements and the principles of Monte Carlo simulation were overviewed. Empirical expressions were given, when possible, for the most important transport quantities as functions of T, $N_{d(a)}$ and E.
4. Semi-empirical relations for the carrier mobilities [21.149]. From a review of different publications on $\mu_{e,h}$ in Si, the authors proposed an approximated calculation procedure, analogous to that of Li and Thurber, which permits a quick and accurate evaluation of $\mu_{e(h)}$ over a wide range of T, $N_{d(a)}$ and $n(p)$. The proposed relations are well adapted to device simulation since they allow short computation times.
5. Minority-carrier recombination in heavily doped silicon [21.150]. A review of understanding of the recombination of minority carriers in heavily doped Si. A short phenomenological description of the carrier recombination process and lifetime was provided and the main theories of these were briefly reviewed with indications for their expected contributions in heavily doped Si. The various methods used for measuring the minority-carrier lifetime in heavily doped Si were described and critically examined. The insufficiency of existing theories to explain the patterns of lifetime versus doping was clearly demonstrated.
6. Minority-carrier transport modeling in heavily doped silicon emitters [21.110]. The experimental and theoretical efforts that addressed such important issues as: (i) the incomplete understanding of the minority-carrier physics in heavily doped Si, (ii) the lack of precise measurements for the minority-carrier parameters, (iii) the difficulties encountered with the modeling of transport and recombination in nonhomogeneously doped regions, and (iv) problems with the characterization of real emitters in bipolar devices, were reviewed with the goal of being able to achieve accurate modeling of the current injected into an arbitrarily heavily doped region in a silicon device.
7. Impact ionization in silicon: a review and update [21.147]. The multiplication factor and the ionization rate were revisited. The interrelationship between these parameters together with the multiplication and breakdown models for diodes and MOS transistors were discussed. Different models were compared and test structures were discussed to measure the multiplication factor accurately enough for reliable extraction of the ionization rates. Multiplication measurements at different T were performed on a BJT, and yielded new electron ionization rates at relatively low electric fields. An explanation for the spread of existed experimental data on ionization rate was given. A new implementation method for a local avalanche model into a device simulator was presented.

21.3 Optical Properties

21.3.1 Diversity of Silicon as an Optical Material

In *dielectric*-like material $n > k$ ($\varepsilon_1 > 0$), where for transparency and opacity it is necessary that $n \gg k$ ($\varepsilon_1 \gg \varepsilon_2$, Table 21.15) and $n \approx k$ ($\varepsilon_1 \ll \varepsilon_2$, Table 21.16), respectively. In *metallic*-like material $n < k$ ($\varepsilon_1 < 0$), where for good reflectivity and bad reflectivity it is necessary that $n \ll k(|\varepsilon_1| \gg \varepsilon_2)$ and $n \approx k(|\varepsilon_1| \ll \varepsilon_2)$, respectively, Table 21.16. Since in Si ε depends on the wavelength and carrier concentration, it may exhibit all these types of optical behavior ranging from dielectric-like to metallic-like. For example, $\langle 111 \rangle$ undoped Si ($n = 2.3 \times 10^{14}\,\mathrm{cm}^{-3}$) at $\lambda = 0.62\,\mu\mathrm{m}$ behaves as a transparent dielectric, as $\varepsilon_1 = 15.254$ and $\varepsilon_2 = 0.172$ at that wavelength, while it is an opaque dielectric at $\lambda = 0.295\,\mu\mathrm{m}$, where $\varepsilon_1 = 2.371$ and $\varepsilon_2 = 45.348$. For heavily doped Si ($n = 10^{20}\,\mathrm{cm}^{-3}$), $n = 1.911$ and $k = 8.63$ at $\lambda = 16.67\,\mu\mathrm{m}$, so it behaves as a good metallic reflector while at $\lambda = 2\,\mu\mathrm{m}$, where $n = 3.47$ and $k = 6.131 \times 10^{-3}$ it is a transparent dielectric.

21.3.2 Measurements of Optical Constants

Various methods are used to measure the dielectric constant of single-crystalline Si including transmission, reflection, and ellipsometric methods. For a smooth opaque sample, the quantity of interest is the complex reflection amplitude ρ_r (at normal incidence) defined by

$$\rho_\mathrm{r} = -\frac{\sqrt{\varepsilon}-1}{\sqrt{\varepsilon}+1}\,, \quad |\rho_\mathrm{r}|^2 = \frac{(n-1)^2+k^2}{(n+1)^2+k^2} = R_0\,,$$
$$\psi = \arctan\frac{2k}{n^2+k^2-1} = \arg(\rho_\mathrm{r})\,, \quad \mathrm{mod}\ (\pi)\,. \tag{21.34}$$

The Fresnel reflectance spectrum $R_0(\omega)$ is measured using reflectometry. The KKR analysis also applies to the causal function

$$\ln(\rho_\mathrm{r}) = \frac{1}{2}\ln R_0 + \mathrm{i}\psi$$

that gives

$$\psi(\omega) = \frac{1}{2\pi}\int_0^\infty \ln\left|\frac{\omega+\Omega}{\omega-\Omega}\right| \frac{\mathrm{d}}{\mathrm{d}\Omega}\ln R_0(\Omega)\mathrm{d}\Omega\,. \tag{21.35}$$

With the $\psi(\omega)$ retrieved in this way, the last two relations in (21.34) are simultaneously solved to yield the n and k spectra. The KKR method requires, in principle, data over an infinite ω range, which are supplied by measurements over a confined range and an appeal to simple models for high and low frequencies. This limitation is avoided using optical measurements on smooth slabs.

For a slab of thickness d, the reflectance and transmittance at normal incidence are given by

$$R = R_0\frac{1-2T_0\cos 2\varphi + T_0^2}{1-2R_0T_0\cos 2\chi + R_0^2T_0^2}\,,$$
$$T = T_0\frac{1-2R_0\cos 2\psi + R_0^2}{1-2R_0T_0\cos 2\chi + R_0^2T_0^2}\,,$$
$$T_0 = \mathrm{e}^{-\alpha d}\,, \tag{21.36}$$

where $\varphi = 2\pi nd/\lambda$ is the optical-path phase, $\chi = \varphi + \psi$ and $\alpha = 4\pi k/\lambda$ is the power attenuation coefficient. The parameter αd characterizes the slab's opacity. At $n > k$ ($\varepsilon_1 > 0$, (21.17)), i. e., in the optically dielectric range, α is referred to as *absorption coefficient*. In the optically metallic range that exists for doped Si in the IR, where $k > n$ ($\varepsilon_1 < 0$, (21.17)), α^{-1} is the skin depth multiplied by a factor ≈ 1. If the dispersion of the optical constants is disregarded, R and T are periodic in $1/\lambda$ (21.20). For nonopaque slabs, these interference effects show up at $nd/\lambda > 1$. For thick slabs ($nd/\lambda \gg 1$), even small fluctuation of n or/and λ causes changes in φ of the order 2π. Therefore, if such factors as bulk defects, source incoherence and low spectral resolution are present in an experiment, then the averages of R and T over φ, given by

$$\langle R\rangle = R_0\left(1 + T_0\langle T\rangle\right),$$
$$\langle T\rangle = T_0\frac{1-2R_0\cos 2\psi + R_0^2}{1-R_0^2T_0^2}\,, \tag{21.37}$$

are more appropriate than (21.36). This *multiple-reflection* approximation [21.151] has proved effective in countless studies. The apparent absorbance of the slab in the multiple-reflection approximation is calculated by

$$\langle A\rangle = 1 - \langle R\rangle - \langle T\rangle$$
$$= \frac{(1-R_0)(1-T_0) - 4R_0T_0\sin^2\psi}{1-R_0T_0}\,. \tag{21.38}$$

Equation (21.38) at $k \ll n$ is extensively used in silicon-wafer thermometry [21.152, 153]. Given $\langle R\rangle$, $\langle T\rangle$ and d, (21.37) builds up a system of two equations for the two unknowns n and k. Thus, measurement of

the reflection and transmission on the same slab of known thickness allows one to retrieve the optical constants. This R–T measurement method [21.154] is greatly simplified at $2k \ll n^2 + k^2 - 1$. Under this low-loss condition the above system can be solved analytically for T_0 and R_0. The calculated T_0 directly yields k, and n is then found using the calculated R_0. The R–T technique is the best method at $\alpha d \leq 1$, while at $\alpha d \gg 1$, where solving the aforementioned system becomes an ill-conditioned problem, the KKR analysis is more reliable. In two last decades, spectroscopic ellipsometry has gained wide recognition for being more precise than photometric methods. In ellipsometry, the ratio of reflectance for s- and p-polarized radiation, and the relative phase shift between the two, are both measured at large angles of incidence [21.155].

The measured results are affected by the structural atomic-scale properties of the samples. These properties are defined by polishing processes – mechanical or chemical – that affect the surface damage and roughness, the properties of the surface native oxide, the growth mechanism of the measured layer, grain boundaries, and the quality of the cleaved surface. Since Si samples may be optically inhomogeneous, retrieving the optical constants from measurements may become a complicated inverse electromagnetic problem [21.156, 157], which is why some of the reported data for ε disagree by up to 30%. A detailed list of publications on the subject can be found in [21.158, 159]. Emphasis on these effects should be especially considered when transmission measurement is done for a wavelength range in which the absorption coefficient is large and thin samples are therefore required.

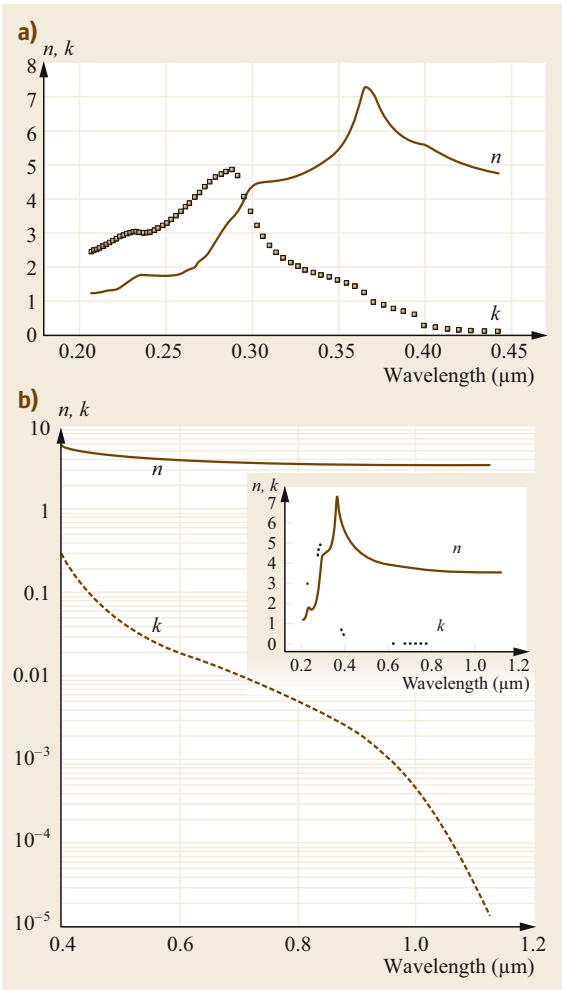

Fig. 21.19 Refractive index n and the extinction coefficient k versus wavelength, using Adachi and Geist models in the wavelength ranges: **(a)** 0.2–0.45 μm, **(b)** 0.4–1.127 μm. *Inset* – the complete range from 0.2 to 1.127 μm

21.3.3 Modeling of Optical Constants

A method for calculating ε_1 and ε_2 and then n, k and α for photon energies of 0–6 eV ($\lambda > 0.2\,\mu$m) has been reported [21.82]. The calculated data are in excellent agreement with experimental data for the wavelength range 0.2–4 μm [21.156, 160]. The model is based on the KKR (Sect. 21.1.3) and takes into account the dependence of ε on the energy-band structure. It considers the effect of indirect-band-gap and inter-band transitions as well as the electron (conduction bands) and hole (valence bands) density of states. The fundamental absorption (generation of electron–hole pair) edge energy of 1.12 eV corresponds to the indirect tran-

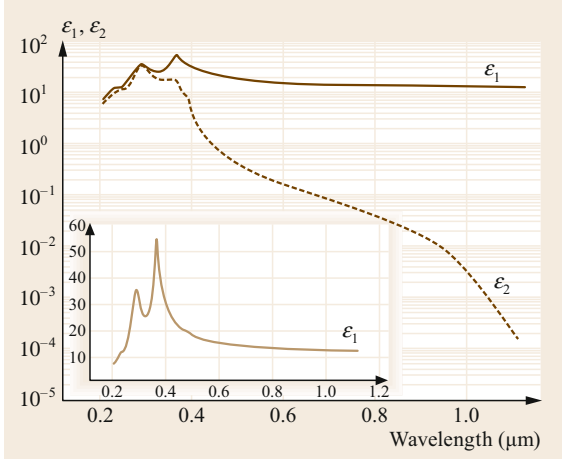

Fig. 21.20 Real ε_1 and imaginary ε_2 parts of dielectric constant versus wavelength, using Adachi and Geist models. *Inset*: real dielectric constant ε_1 versus wavelength

[a] Values calculated using an empiricial fit [21.78], [b] values calculated using GDA [21.79]

sition from the highest valence band to the lowest conduction band. Sharp changes in the optical constants are obtained at wavelengths around 0.367, 0.29 and 0.233 µm, which correspond to the energy-band critical points of 3.38, 4.27 and 5.317 eV, respectively. An additional analytical model for calculating the n and k values for the wavelength range 0.4–1.127 µm has been developed [21.158]. The model is based on measured k and n data [21.161–163], where the calculated values are within ±10% of the measured values. Using Adachi and Geist models we have calculated and plotted n, k, ε_1 and ε_2 for the wavelength range 0.2–1.127 µm, as seen in Figs. 21.19 and 21.20.

In the IR range the lattice and free carriers, which arise from doping, give additive contributions. The free-carrier contribution to the dielectric function when the radiation quantum is much smaller than the mean electron energy, $\hbar\omega \ll \bar{E}$, is considered using the semiclassical Drude approximation (DA, Sect. 21.1.4), which leads to the simple formula

$$\varepsilon = \varepsilon_\mathrm{L} - \frac{n_\mathrm{L}^2\omega_\mathrm{p}^2}{\omega(\omega + \mathrm{i}\gamma)}\,,$$

$$\gamma = \frac{1}{\tau}\,, \qquad (21.39)$$

Table 21.16 (continued)

Energy (eV)	Wavenumber (cm^{-1})	Wavelength (μm)	n HW[a]	n GDA[b]	k HW[a]	k GDA[b]

[a] Values calculated using an empiricial fit [21.78], [b] values calculated using GDA [21.79]

where τ is the phenomenological relaxation time, ω_p is the electron plasma frequency given by

$$\omega_p = \sqrt{\frac{4\pi q^2 N}{\varepsilon_L m_c}} \,. \tag{21.40}$$

Here N denotes the carriers' concentration, $m_c \approx 0.26 m_0$ for electrons (Table 21.1) and $m_c = (0.33–0.39) m_0$ for holes (Sect. 21.1.4).

Advanced GDA, which extrapolates the free-carrier contribution to the range of $\hbar\omega > \bar{E}$ was also considered [21.79]. In Tables 21.15 and 21.16 we tabulated the values of n and k for practical use at two extreme electron concentrations: 10^{16} and $10^{20}\,cm^{-3}$. The results placed in the columns headed by the abbreviation HW were obtained using DA (21.22), (21.39) and (21.40) and the empirically adjusted τ versus N fit [21.78]. The columns of theoretical values calculated by us using GDA are headed by the corresponding abbreviation. A disagreement between the theory and the empirical fit notable at heavy doping has been discussed in detail [21.79]. The dependencies of n and k on wavelength in the range at carrier concentration of $10^{16}–10^{20}\,cm^{-3}$ in steps of $10\,cm^{-3}$ are shown in Fig. 21.21.

21.3.4 Electric-Field and Temperature Effects on Optical Constants

It has been known for many years that the optical absorption spectrum of Si can also be affected by external electric fields (the Franz–Keldysh effect). The Franz–Keldysh effect, which alters the α spectrum of crystalline Si, is field-induced tunneling between valence- and conduction-band states. In recent years, the generic term *electroabsorption* has been adopted for $\Delta\alpha$ versus E effects. The effect of electric field on the refractive index is shown in Fig. 21.22 [21.164]. Sharp changes occur around the wavelengths correspond to the band-gap transition.

The temperature dependence of the refractive index of high-purity damage-free Si, for photon energies less than 3 eV in the temperature range 300–500 K is given by [21.162]

$$\frac{\Delta n}{\Delta T} \approx 1.3 \times 10^{-4} n \quad (\mathrm{K}^{-1}) \,. \tag{21.41}$$

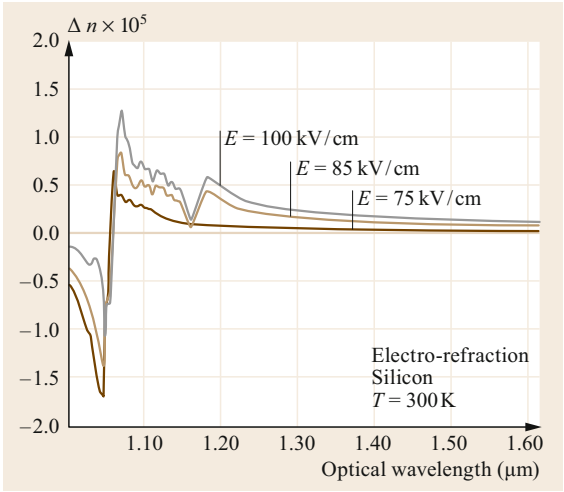

Fig. 21.22 Refractive index change versus wavelength at various electric fields (after [21.164])

22. Silicon-Germanium: Properties, Growth and Applications

Yaser M. Haddara, Peter Ashburn, Darren M. Bagnall

Silicon-germanium is an important material that is used for the fabrication of SiGe heterojunction bipolar transistors and strained Si metal-oxide-semiconductor (MOS) transistors for advanced complementary metal-oxide-semiconductor (CMOS) and BiCMOS (bipolar CMOS) technologies. It also has interesting optical properties that are increasingly being applied in silicon-based photonic devices. The key benefit of silicon-germanium is its use in combination with silicon to produce a heterojunction. Strain is incorporated into the silicon-germanium or the silicon during growth, which also gives improved physical properties such as higher values of mobility. This chapter reviews the properties of silicon-germanium, beginning with the electronic properties and then progressing to the optical properties. The growth of silicon-germanium is considered, with particular emphasis on the chemical vapour deposition technique and selective epitaxy. Finally, the properties of polycrystalline silicon-germanium are discussed in the context of its use as a gate material for MOS transistors.

Silicon-germanium ($Si_{1-x}Ge_x$) alloys have been researched since the late 1950s [22.1], but it is only in the past 30 years or so that these layers have been applied to new types of transistor technology. $Si_{1-x}Ge_x$ was first applied in bipolar technologies [22.2, 3], but more recently has been applied to metal-oxide-semiconductor (MOS) technologies [22.4–7]. This has been made possible by the development of new growth techniques, such as molecular-beam epitaxy (MBE), low-pressure chemical vapour deposition (LPCVD) and ultra-high-vacuum chemical vapour deposition (UHV-CVD). The key feature of these techniques that has led to the development of $Si_{1-x}Ge_x$ transistors is the growth of epitaxial layers at low temperatures (500–700 °C). This allows $Si_{1-x}Ge_x$ layers to be grown without disturbing the doping profiles of structures already present in the silicon wafer. $Si_{1-x}Ge_x$ layers can be successfully grown on silicon substrates even though there is a lattice mismatch between silicon and germanium of 4.2%.

The primary property of $Si_{1-x}Ge_x$ that is of interest for bipolar transistors is the band gap, which is smaller than that of silicon and controllable by varying the

germanium content. Band-gap engineering concepts, which were previously only possible in compound semiconductor technologies, have now become viable in silicon technology. These concepts have introduced new degrees of freedom in the design of bipolar transistors that have led to dramatic improvements in transistor performance. In $Si_{1-x}Ge_x$ heterojunction bipolar transistors (HBTs), the $Si_{1-x}Ge_x$ layer is incorporated into the base and the lower band gap of $Si_{1-x}Ge_x$ than Si is used to advantage to dramatically improve the high-frequency performance. $Si_{1-x}Ge_x$ HBTs have been produced with values of cut-off frequency, f_T, approaching 300 GHz [22.8], a value unimaginable in silicon bipolar transistors. Values of gate delay well below 10 ps can be achieved in properly optimised $Si_{1-x}Ge_x$ HBTs [22.9]. In $Si_{1-x}Ge_x$ MOS field-effect transistors (MOSFETs), the $Si_{1-x}Ge_x$ layer is incorporated in the channel and is used to give improved values of mobility. Initially, strained $Si_{1-x}Ge_x$ layers on silicon substrates were used to give improved hole mobility in p-channel transistors [22.7], but more recently thin, strained silicon layers on relaxed SiGe virtual substrates have been used to give improvements in both electron and hole mobility [22.4–6].

In this chapter, the properties of single-crystal silicon-germanium will first be outlined, followed by a description of the methods used for growing silicon-germanium layers. The properties and applications of polycrystalline silicon-germanium are also discussed later in the article.

22.1 Physical Properties of Silicon-Germanium

Silicon and germanium are completely miscible over the full range of compositions and hence can be combined to form $Si_{1-x}Ge_x$ alloys with the germanium content, x, ranging from 0 to 1 (0–100%). $Si_{1-x}Ge_x$ has a diamond-like lattice structure and the lattice constant is given by Vegard's rule:

$$a_{Si_{1-x}Ge_x} = a_{Si} + x\,(a_{Ge} - a_{Si})\ , \qquad (22.1)$$

where x is the germanium fraction and a is the lattice constant. The lattice constant of silicon, a_{Si}, is 0.543 nm, the lattice constant of germanium, a_{Ge}, is 0.566 nm and the lattice mismatch is 4.2%.

When a $Si_{1-x}Ge_x$ layer is grown on a silicon substrate, the lattice mismatch at the interface between the $Si_{1-x}Ge_x$ and the silicon has to be accommodated. This can either be done by compression of the $Si_{1-x}Ge_x$ layer so that it fits to the silicon lattice or by the creation of misfit dislocations at the interface. These two possibilities are illustrated schematically in Fig. 22.1. In the former case, the $Si_{1-x}Ge_x$ layer adopts the silicon lattice spacing in the plane of the growth and hence the normally cubic $Si_{1-x}Ge_x$ crystal is distorted. When $Si_{1-x}Ge_x$ growth occurs in this way, the $Si_{1-x}Ge_x$ layer is under compressive strain and the layer is described as *pseudomorphic*. In the second case, the $Si_{1-x}Ge_x$ layer is unstrained, or relaxed, and the lattice mismatch at the interface is accommodated by the formation of misfit dislocations. These misfit dislocations generally lie in the plane of the interface, as shown in Fig. 22.1, but dislocations can also thread vertically through the $Si_{1-x}Ge_x$ layer.

22.1.1 Critical Thickness

There is a maximum thickness of $Si_{1-x}Ge_x$ that can be grown before relaxation of the strain occurs through the formation of misfit dislocations. This is

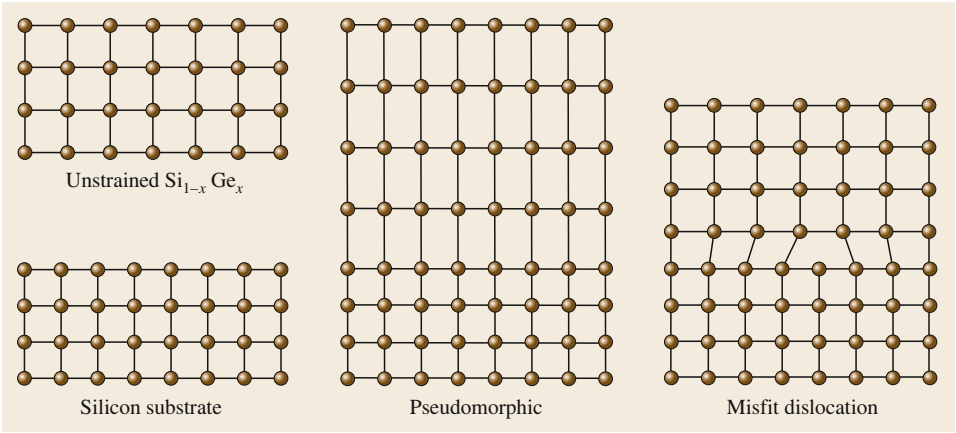

Fig. 22.1 Schematic illustration of pseudomorphic $Si_{1-x}Ge_x$ growth and misfit-dislocation formation

known as the critical thickness of the $Si_{1-x}Ge_x$ layer, and depends strongly on the germanium content, as shown in Fig. 22.2. The original calculations of critical layer thickness were made by *Matthews* and *Blakeslee* [22.10, 11] on the basis of the mechanical equilibrium of an existing threading dislocation. However, measurements of dislocation densities in $Si_{1-x}Ge_x$ showed, in many cases, no evidence of misfit dislocations for $Si_{1-x}Ge_x$ layers considerably thicker than the Matthews–Blakeslee limit. These results were explained by *People* and *Bean* [22.12] who calculated the critical thickness on the assumption that misfit-dislocation generation was determined solely by energy balance. The discrepancy between these two types of calculation can be explained by the observation that strain relaxation in $Si_{1-x}Ge_x$ layers occurs gradually. Layers above the People–Bean curve can be considered to be completely relaxed, whereas layers below the Matthews–Blakeslee curve can be considered to be fully strained. These fully strained layers are termed *stable* and will not relax during any subsequent high temperature processing. Layers lying between the two curves are termed *metastable*; these layers may be free of dislocations after growth, but are susceptible to relaxation during later high-temperature processing.

In practice, a number of additional factors influence the critical thickness of a $Si_{1-x}Ge_x$ layer. Of particular importance to both $Si_{1-x}Ge_x$ HBTs and $Si_{1-x}Ge_x$ MOSFETs, is the effect of a silicon cap layer, which has been shown to increase the critical thickness of the underlying $Si_{1-x}Ge_x$ layer. Figure 22.3 shows a comparison of the calculated critical thickness as a function of germanium percentage for stable $Si_{1-x}Ge_x$ layers with and without a silicon cap. It can be seen that the critical thickness is more than doubled by the presence of the silicon cap.

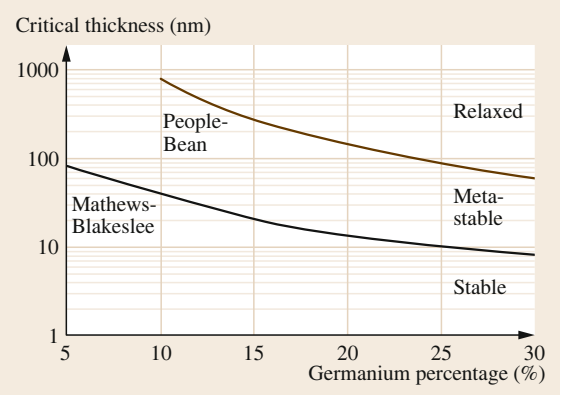

Fig. 22.2 Critical $Si_{1-x}Ge_x$ thickness as a function of germanium percentage. (After *Iyer* et al. [22.2], copyright 1989 IEEE)

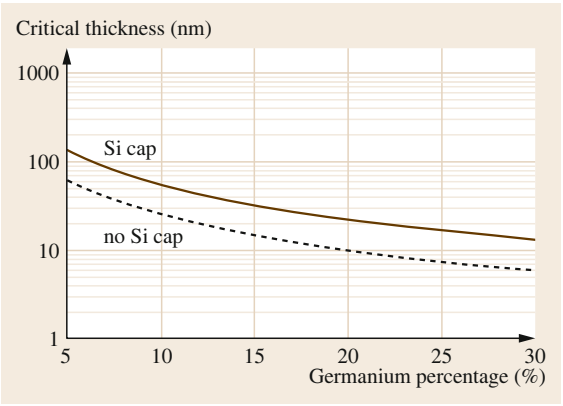

Fig. 22.3 Critical thickness as a function of germanium percentage for stable $Si_{1-x}Ge_x$ layers with and without a silicon cap. (After *Jain* et al. [22.13], copyright 1992 Elsevier)

The presence of misfit dislocations in devices is highly undesirable, since they create generation/recombination centres, which degrade leakage currents when they are present in the depletion regions of devices. Threading dislocations are also highly undesirable, as they can lead to the formation of emitter/collector pipes in $Si_{1-x}Ge_x$ HBTs. When designing $Si_{1-x}Ge_x$ devices, it is important that the $Si_{1-x}Ge_x$ thickness is chosen to give a stable layer, so that dislocation formation is avoided. A base thickness below the silicon cap curve in Fig. 22.3 will ensure a stable layer, which will withstand ion implantation and high-temperature annealing without encountering problems of relaxation and misfit-dislocation generation.

Considerable research has been done on the oxidation of $Si_{1-x}Ge_x$ [22.14, 15]. Both silicon and germanium oxidize so that it is possible to form a mixed oxide ($SiO_2 + GeO_2$). Si oxidation is more favorable [22.16] so that as long as the Si flux arriving at the oxidizing interface is sufficient Si will replace Ge in the oxide, no Ge oxide remains, and a Ge-rich layer forms at the oxide/$Si_{1-x}Ge_x$ interface. However, oxidation at low temperature [22.17], high pressure [22.16], or with high Ge content in the $Si_{1-x}Ge_x$ layer [22.18], produces a mixed oxide and the Ge pile-up is reduced or eliminated. *Rabie* et al. [22.19] have developed a kinetic model describing the details of the oxidation process. Given the process conditions, the model predicts oxide thickness and composition as well as the profile of Si/Ge in the SiGe layer.

The pile-up of germanium makes it difficult to achieve low values of interface state density in oxidised $Si_{1-x}Ge_x$ layers. Even when the pile-up is suppressed, the interface state density is still roughly two orders of magnitude higher than it is for Si. This is likely due to

the higher fraction of Si atoms in suboxide states and strain relaxation during the oxidation process [22.20]. In some experiments, good oxide quality and low interface trap and fixed charge densisties were achieved and the Ge pile-up suppressed by oxidation at very low temperatures [22.21]. Nonetheless, most practical process flows do not involve direct oxidation of $Si_{1-x}Ge_x$ layers, particularly in $Si_{1-x}Ge_x$ MOS technologies. In $Si_{1-x}Ge_x$ MOSFETs, a silicon cap is often included above the $Si_{1-x}Ge_x$ layer that can be oxidised to create the gate oxide. Alternatively, there has been considerable recent work exploring the deliberate use of the Ge-rich layer by oxidizing SiGe on SOI. This has been proposed for applications in fully depleted MOSFETs and for photonics applications (see [22.22] and references therein).

22.1.2 Band Structure

$Si_{1-x}Ge_x$ alloys have a smaller band gap than silicon partly because of the larger lattice constant and partly because of the strain. Figure 22.4 shows the variation of band gap with germanium percentage for strained and unstrained $Si_{1-x}Ge_x$. The bandgap of strained Si depends on the type as well as magnitude of strain and is therefore strongly affected by the substrate. The data shown in Fig. 22.4 are for SiGe on (100) Si. For strained SiGe on Ge the bandgap would be an increasing function of Ge fraction over almost the entire range from Si to Ge. It can be seen that the effect of strain is considerable. For 10% germanium, the reduction in band gap compared with silicon is 92 meV for strained $Si_{1-x}Ge_x$, compared with 50 meV for unstrained $Si_{1-x}Ge_x$. The variation of band gap E_G with germanium content for unstrained $Si_{1-x}Ge_x$ can be described by the following empirical equation

$$E_G(x) = \begin{cases} 1.17 - 0.47x + 0.24x^2\,, & x < 0.85 \\ 5.88 - 9.58x + 4.43x^2\,, & x > 0.85 \end{cases} \quad (22.2)$$

The transition at $x = 0.85$ is due to the conduction band minima switching from the [100] direction associated with Si to the [111] direction associated with Ge. For strained $Si_{1-x}Ge_x$ the appropriate equation is

$$E_G(x) = 1.17 - 0.94x + 0.34x^2 \quad (22.3)$$

This equation is valid over the entire range of Ge fraction.

In addition to strain, heavy doping will also result in significant bandgap narrowing. Figure 22.4 contains data showing the bandgap of SiGe layers doped with

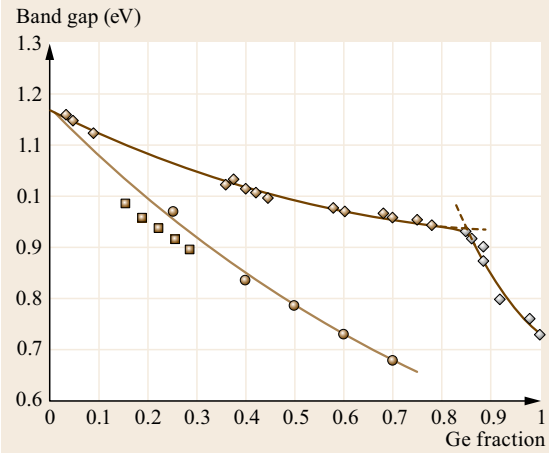

Fig. 22.4 Band gap as a function of germanium percentage for unstrained (*diamonds* [22.1]), strained undoped (*circles* [22.23]), and strained heavily doped $Si_{1-x}Ge_x$ (*squares* [22.24]). The *lines* are empirical best fits corresponding to (22.2) and (22.3). Data from [22.1] and [22.24] were corrected to 90 K using the methodology of [22.25]

B in the range of $4.3-5.8\times10^{19}$ cm^{-3}. These data were obtained by fitting measured device characteristics from a Si/SiGe HBT.

From the graph, we note that the effect of strain is significantly more than that of doping. For example, at 25% Ge the bandgap is reduced by approximately 97 meV due to strain and a further 50 meV due to heavy doping. The narrowing due to strain increases with increasing Ge fraction. The narrowing due to doping does not appear to be significantly affected by Ge fraction. A theoretical model for bandgap narrowing is discussed below (see Sect. 22.1.8).

The band alignment for compressively strained $Si_{1-x}Ge_x$ on unstrained silicon is illustrated schematically in Fig. 22.5. This band alignment is referred to as *type I*, and the majority of the band offset at the heterojunction interface occurs in the valence band, with only a small offset in the conduction band. Different band alignments can be obtained by engineering the strain in the substrate and the grown layer in different ways. For example, *type II* band alignments can be obtained by growing tensile-strained silicon on top of unstrained $Si_{1-x}Ge_x$. This arrangement gives large conduction- and valence-band offsets and is used in strained silicon MOSFETs.

Figure 22.6 shows the variation of valence-band offset, ΔE_V, conduction-band offset, ΔE_C, and band-gap narrowing, ΔE_G, with germanium content. Once again, it should be emphasized that this is for SiGe on (100)

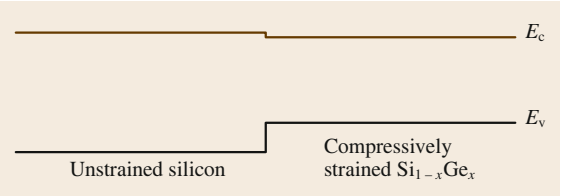

Fig. 22.5 Schematic illustration of the band alignment obtained for a compressively strained $Si_{1-x}Ge_x$ layer grown on an unstrained silicon substrate

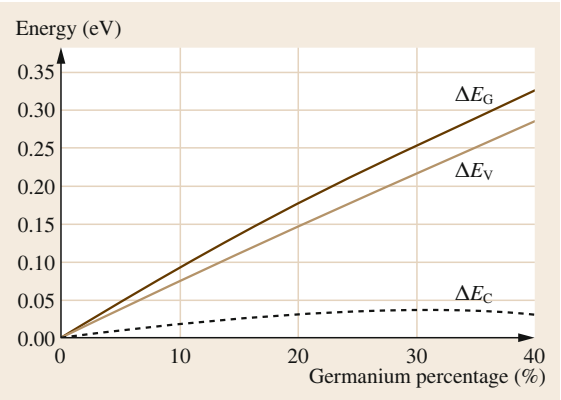

Fig. 22.6 Valence- and conduction-band offsets as a function of germanium percentage for strained $Si_{1-x}Ge_x$ grown on unstrained silicon. (After *Poortmans* et al. [22.26], copyright 1993 Elsevier)

Si and that the behavior would be different for other substrates. It can be seen that the majority of the band offset occurs in the valence band. For example for 10% germanium, the valence-band offset is 0.073 eV, compared with 0.019 eV for the conduction-band offset. The conduction-band offset can therefore be neglected for most practical purposes.

22.1.3 Dielectric Constant

The dielectric constant of $Si_{1-x}Ge_x$ can be obtained by linear interpolation between the known values for silicon and germanium [22.26] using the following equation

$$\varepsilon(x) = 11.9(1 + 0.35x) \,. \qquad (22.4)$$

22.1.4 Density of States

While the density of states in the conduction band in $Si_{1-x}Ge_x$ is generally assumed to be the same as that in silicon, there is some evidence in the literature to suggest that the density of states in the valence band is considerably smaller. *Manku* and *Nathan* [22.27, 28] have calculated the *E–k* diagram for strained $Si_{1-x}Ge_x$ and shown that the density-of-states hole mass is significantly lower, by a factor of approximately three at 30% germanium. There is some experimental evidence to support this calculation. For example, freeze-out of holes in p-type $Si_{1-x}Ge_x$ has been reported to occur at higher temperatures than in p-type silicon [22.29] and enhancements in the majority-carrier, hole mobility have been reported for p-type $Si_{1-x}Ge_x$ [22.30]. Using the calculated values of hole density of states of *Manku* and *Nathan* [22.27, 28], the hole concentration can be calculated as a function of Fermi-level position. These results are shown in Fig. 22.7 for $Si_{1-x}Ge_x$ with four different germanium contents. It can be seen that the Fermi level moves deeper into the valence band as the germanium concentration increases. Figure 22.8 shows the ratio of the calculated density of states in the valence band for $Si_{1-x}Ge_x$ to that for silicon as a function of germanium content. It is clear that the density of states in the valence band for $Si_{1-x}Ge_x$ is significantly lower than that for silicon at germanium contents of practical interest.

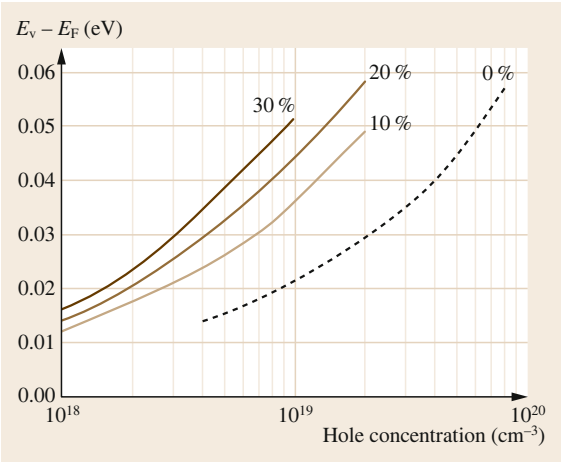

Fig. 22.7 Fermi-level position as a function of hole concentration for $Si_{1-x}Ge_x$ with four different germanium concentrations. (After *Iyer* et al. [22.2], copyright 1989 IEEE)

22.1.5 Majority-Carrier Mobility in Strained $Si_{1-x}Ge_x$

Values of in-plane and out-of-plane low-field mobility in strained $Si_{1-x}Ge_x$ grown on (100) Si have been calculated by *Fischetti* et al. [22.31], and are shown in Fig. 22.9. There is some uncertainty in the chosen values of alloy scattering parameters used in the calculations, but nevertheless the results are representative of current understanding. These results show a large

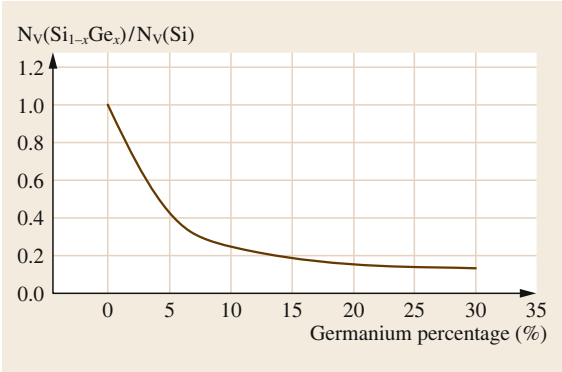

Fig. 22.8 Ratio of density of states in the valence band for $Si_{1-x}Ge_x$ to that for Si as a function of germanium percentage. (After *Poortmans* [22.29], copyright 1993 University of Leuven)

enhancement of low-field hole mobility for $Si_{1-x}Ge_x$ compared with unstrained silicon, but only a modest enhancement of low-field electron mobility. These results indicate that strained $Si_{1-x}Ge_x$ channels can be used to significantly improve the mobility of p-channel MOSFETs, but little benefit is obtained for n-channel MOSFETs. For this reason, industry focus has moved away from channels realised in $Si_{1-x}Ge_x$ to channels realised in tensile-strained silicon, as discussed below.

22.1.6 Majority-Carrier Mobility in Tensile-Strained Si on Relaxed $Si_{1-x}Ge_x$

Tensile-strained silicon can be produced by growing a thin silicon layer on top of a relaxed $Si_{1-x}Ge_x$ virtual substrate. Figure 22.10 shows a typical virtual substrate for a surface-channel MOS transistor. A graded $Si_{1-x}Ge_x$ layer is grown on top of the silicon substrate with the Ge content varying from 0 to 30%. Misfit dislocations will form in this layer, but the majority of dislocations will be in the plane of the $Si_{1-x}Ge_x$ layer and only a small percentage will propagate vertically to the surface of the layer. A 30%-relaxed $Si_{1-x}Ge_x$ buffer is then grown followed by a thin tensile-strained $Si_{1-x}Ge_x$ layer in which the channel is fabricated. The key to any virtual substrate growth process is the minimisation of dislocation propagation to the surface of the wafer.

Figure 22.11 shows typical values of effective electron mobility obtained from measurements on n-channel MOS transistors for a $Si_{1-x}Ge_x$ virtual substrate with 30% Ge [22.6]. For the surface-channel strained Si device, the effective mobility is enhanced by 80% compared with the Si control transistor due to the tensile strain in the $Si_{1-x}Ge_x$ layer.

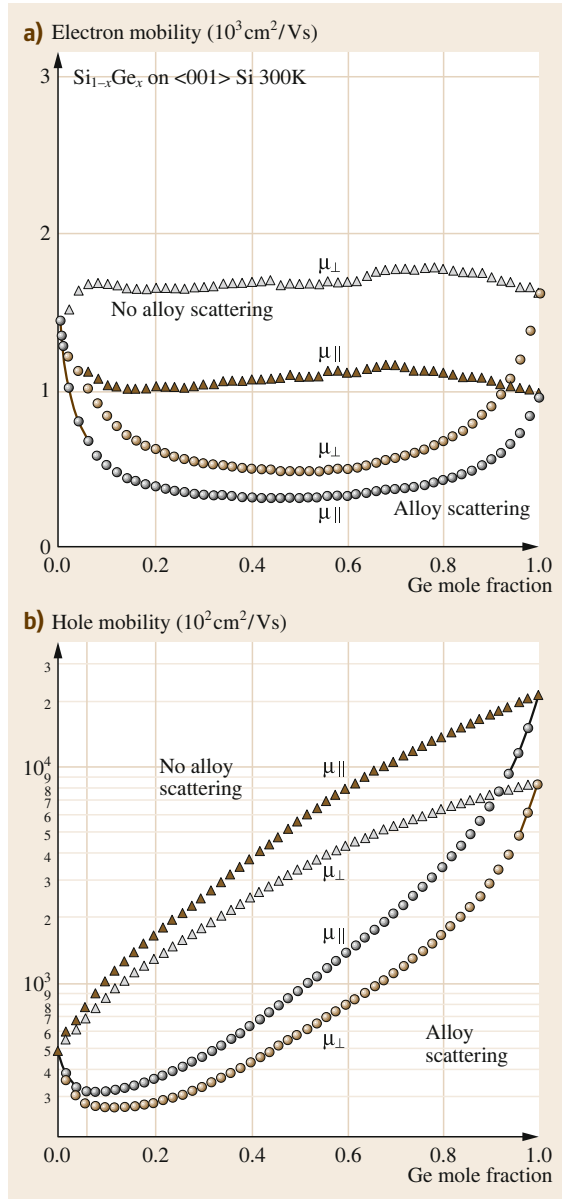

Fig. 22.9a,b Calculated 300 K electron **(a)** and hole **(b)** in-plane and out-of-plane low-field mobilities in strained $Si_{1-x}Ge_x$ grown on (100) Si. (After *Fischetti* and *Laux* [22.31], copyright 1996 American Institute of Physics)

Enhanced hole mobility can also be obtained in tensile-strained Si grown on a $Si_{1-x}Ge_x$ virtual substrate, though higher germanium contents are needed to obtain a significant mobility enhancement. Figure 22.12 shows typical values of effective hole mobility in strained Si for Ge contents between 35 and 50% [22.32]. The effective mobility of the strained Si

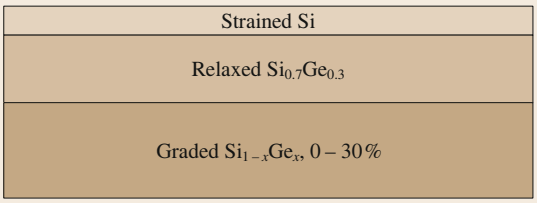

Fig. 22.10 Schematic illustration of a typical tensile-strained Si layer grown on top of a $Si_{1-x}Ge_x$ virtual substrate

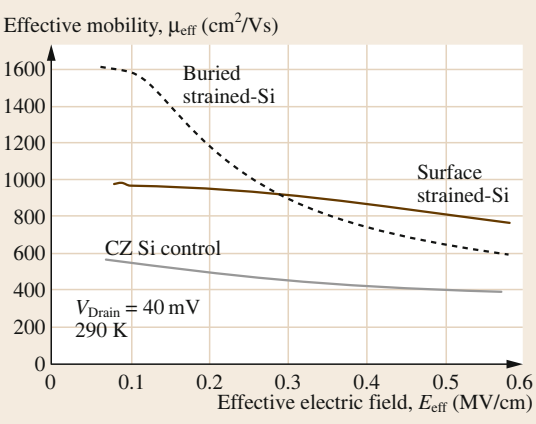

Fig. 22.11 Effective electron mobility as a function of effective electric field for strained Si MOSFETs fabricated on a 30% $Si_{1-x}Ge_x$ virtual substrate. (After *Welser* et al. [22.6], copyright 1994 IEEE)

device is enhanced by 100% compared with the Si control device.

22.1.7 Minority-Carrier Mobility in Strained $Si_{1-x}Ge_x$

$Si_{1-x}Ge_x$ HBTs are minority-carrier devices and hence values of the minority-carrier mobility of more interest than the majority-carrier mobility. Unfortunately very few measurements of minority-carrier mobility have been made in $Si_{1-x}Ge_x$. *Poortmans* [22.29] inferred values of minority-carrier mobility from measurements on $Si_{1-x}Ge_x$ HBTs and found an enhancement in mobility compared with silicon by a factor of 1.2–1.4 for base doping concentrations in the range 5×10^{18}–5×10^{19} cm^{-3}. Given the scarcity of measured data on minority-carrier mobility and density of states in $Si_{1-x}Ge_x$, the most reliable way of calculating the expected gain improvement in a $Si_{1-x}Ge_x$ HBT is to use data directly obtained from measurements on $Si_{1-x}Ge_x$ HBTs. The gain enhancement in a $Si_{1-x}Ge_x$ HBT is determined by the ratio of the product $N_C N_V D_{nb}$ in

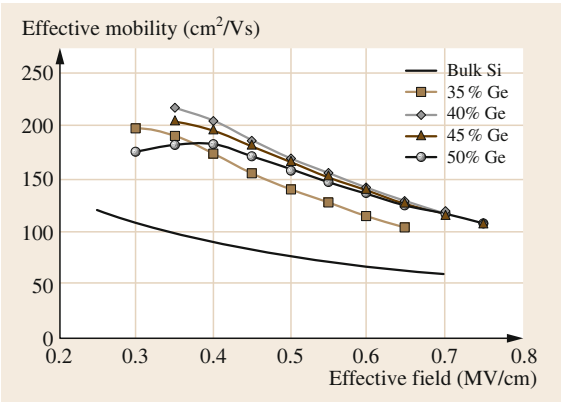

Fig. 22.12 Effective hole mobility as a function of effective electric field for strained Si MOSFETs fabricated on a $Si_{1-x}Ge_x$ virtual substrate with Ge contents in the range 35–50%. (After *Leitz* et al. [22.32], copyright 2002 IEEE)

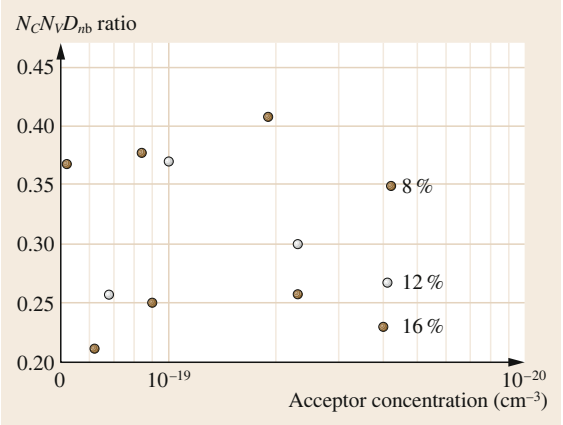

Fig. 22.13 Measured values of the ratio of $N_C N_V D_{nb}$ in $Si_{1-x}Ge_x$ to that in Si as a function of acceptor concentration. (After *Poortmans* [22.29], copyright 1993 University of Leuven)

$Si_{1-x}Ge_x$ and Si, together with the band-gap narrowing due to the strained $Si_{1-x}Ge_x$. Figure 22.13 shows a graph of this $N_C N_V D_{nb}$ ratio as a function of acceptor concentration for three values of germanium content. It can be seen that for germanium contents of practical interest, in the range 11–16%, this ratio has a value of around 0.25.

22.1.8 Apparent Band-Gap Narrowing in $Si_{1-x}Ge_x$ HBTs

In $Si_{1-x}Ge_x$ HBTs, the apparent band-gap narrowing is often quoted, which combines the effect of the band-gap reduction and the effect of high doping. *Poortmans* et al. [22.26] have developed a theoretical approach that

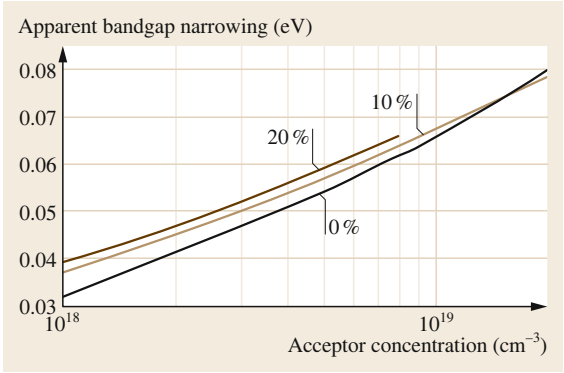

Fig. 22.14 Apparent band-gap narrowing as a function of acceptor concentration for $Si_{1-x}Ge_x$ with three different germanium concentrations. (After *Poortmans* et al. [22.26], copyright 1993 Elsevier) ▶

has been shown to be in reasonable agreement with experiment. Figure 22.14 shows the apparent band-gap narrowing in $Si_{1-x}Ge_x$ as a function of acceptor concentration for three values of germanium content. At low acceptor concentrations, the apparent band-gap narrowing in $Si_{1-x}Ge_x$ is slightly higher than that in silicon, but at acceptor concentrations in the range $1-2\times 10^{19}\,cm^{-3}$, the apparent band-gap narrowing is approximately the same. This latter doping range is the base doping range that is of practical interest for $Si_{1-x}Ge_x$ HBTs. This is reasonably close to experimental data such as that reported by [22.24] (see Sect. 22.1.2 and Fig. 22.4).

22.2 Optical Properties of SiGe

Interest in the optical properties of SiGe stems from the desire to design silicon-based optoelectronic devices as well as the usefulness of many optical techniques in material analysis. The optical properties of bulk SiGe provides an important starting point for any attempt at in-depth understanding, however, nearly all real applications of SiGe involve the use of thin, strained layers. Beyond this, the formation of SiGe quantum structures within silicon devices has remained one of the most promising methods by which device engineers hope to improve the largely unimpressive optical behaviour of silicon that is brought about by its indirect band gap. The growth of quantum wells, quantum wires and quantum dots in the Si/SiGe system has been extensively explored [22.33–38]. However, there has as yet been little success at using Si/SiGe quantum structures to produce efficient silicon-based light emitters, although there have been impressive attempts [22.38]. Perhaps the most promising devices based on SiGe quantum wells are near-infra-red photodetectors in which the SiGe can be used to enhance sensitivity at the optical-communications wavelengths [22.39–43]. More futuristic applications of SiGe quantum wells include devices based on transitions between the confined energy levels in quantum wells. Devices based on these *inter-subband* transitions include quantum-well infrared photodetectors (QWIPs) [22.44, 45] and quantum cascade lasers [22.46–48].

22.2.1 Dielectric Functions and Interband Transitions

A range of 1 μm-thick $Si_{1-x}Ge_x$ films grown by MBE on Si(100) substrates have been studied by spectroscopic ellipsometry to yield their complex dielectric functions at room temperature [22.49]. Both the real (ε_1) and imaginary (ε_2) parts of the measured dielectric function for Ge compositions of 0, 0.2, 0.4, 0.6, 0.8 and 1.0 are shown in Figs. 22.15a and 22.15b, respectively.

In Fig. 22.15b the absorption structures observed at 3.4 and 4.2 eV in the spectra shown for silicon originate from direct band-to-band transitions at various regions in the Brillouin zone of silicon. The structure seen around 3.4 eV is due to E_0', E_1 and $E_1+\Delta_1$ interband transition edges, whereas the structure at 4.2 eV is due to $E_2(X)$ and $E_2(\Sigma)$ edges [22.49]. The evolution of each of these transition edges for the full range of SiGe compositions is shown in Fig. 22.16.

The quadratic fits shown in Fig. 22.16 are as follows [22.49],

$$E_0'(x) = 3.337 - 0.348x + 0.222x^2\,, \qquad (22.5)$$

$$E_1(x) = 3.398 - 1.586x + 0.27x^2\,, \qquad (22.6)$$

$$E_1+\Delta_1(x) = 3.432 - 1.185x + 0.065x^2\,, \qquad (22.7)$$

$$E_2(X)(x) = 4.259 - 0.052x + 0.084x^2\,, \qquad (22.8)$$

$$E_2(\Sigma)(x) = 4.473 - 0.139x + 0.072x^2\,. \qquad (22.9)$$

22.2.2 Photoluminescence

The emission properties of semiconductor structures are of fundamental interest to scientists as well as being an important analytical technique for engineers. In general, the features of low-temperature photoluminescence spectra are very dependent on the specific conditions under which materials are grown and treated. This is because emission energies and emission rates are of-

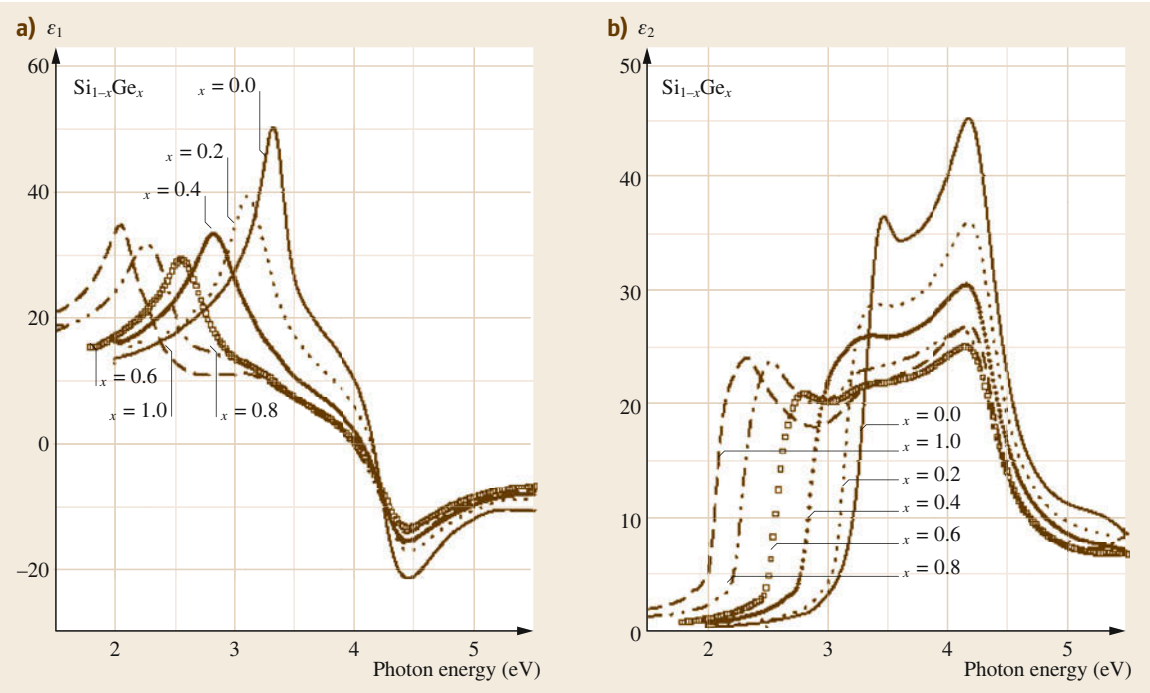

Fig. 22.15a,b Real (a) and imaginary (b) parts of the dielectric functions of relaxed $Si_{1-x}Ge_x$ alloys with composition x indicated in the legend. (After *Bahng* et al. [22.49], copyright 2001, American Physical Society)

ten sensitive to even small variations of impurity or defect densities, as well as variations in strain or composition. A brief examination of low-temperature photoluminescence spectra is nearly always sufficient to allow a simple qualitative assessment of material quality; alternatively, detailed analysis can permit a broad range of material or structural parameters to be assessed or determined. No two photoluminescence spectra are the same. In this section and the section that follows on photoluminescence studies of Si/SiSe quantum wells, we will present a range of spectra that represent most of the key features that have been observed.

Weber and *Alonso* [22.50] have provided a very useful study of the near-band-gap photoluminescence of bulk SiGe alloys. In their study bulk SiGe samples are cut from nominally undoped polycrystalline ingots prepared by a zone-levelling technique. Figure 22.17 shows the photoluminescence spectra for a range of compositions. Samples were excited using the 514 nm line of an argon ion laser and the sample temperature was 4.2 K.

Excitonic emission lines are a strong feature of photoluminescence spectra when the thermal energy of the semiconductor is less than the exciton binding energy. Each spectrum featured in Fig. 22.17, across the full range of SiGe compositions, show similar *excitonic* features.

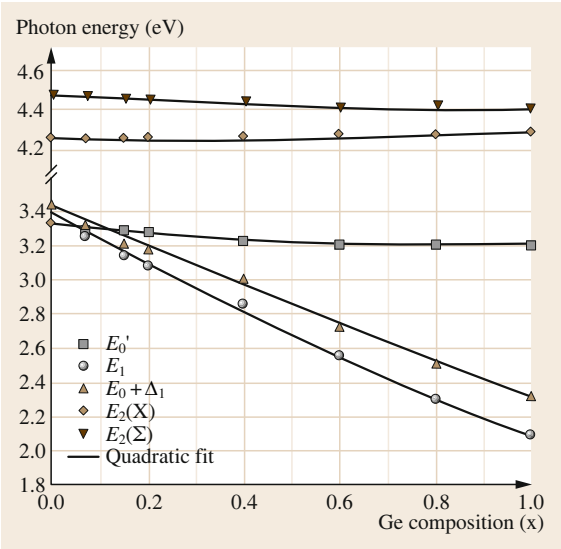

Fig. 22.16 Evolution of E_0', E_1, $E_1+\Delta_1$, $E_2(X)$ and $E_2(\Sigma)$ transition energies for relaxed $Si_{1-x}Ge_x$ with composition x. (After *Bahng* et al. [22.49], copyright 2001, American Physical Society)

In most spectra the most pronounced peak is the no-phonon (X^{NP}) line caused by the optical recombination of excitons bound to shallow impurities. In the

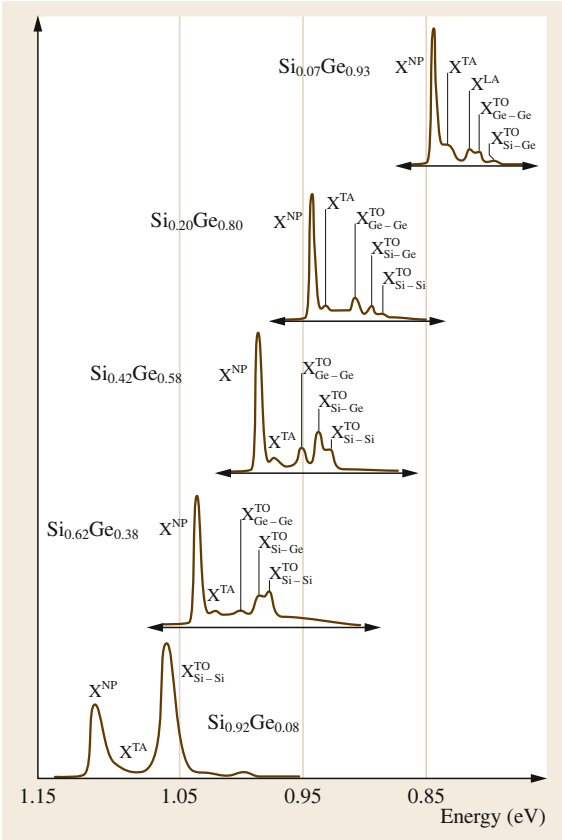

Fig. 22.17 Near-band-gap photoluminescence spectra for several bulk SiGe samples. (After *Weber* et al. [22.50], copyright 1989, American Physical Society)

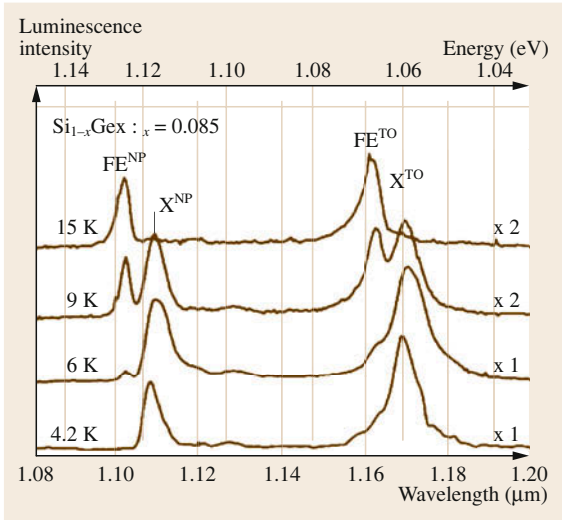

Fig. 22.18 Photoluminescence spectra of a bulk $Si_{0.915}Ge_{0.085}$ sample at different temperatures. (After *Weber* et al. [22.50], copyright 1989, American Physical Society)

case of the no-phonon line, momentum is conserved through interaction with the binding impurity. There are many candidate atoms for these shallow impurities and with B, P and As having binding energies of 4.2, 5.0 and 5.6 meV, respectively [22.51]. These bound energy states will tend to dominate luminescence spectra for doped samples and will always tend to be present in nominally undoped samples. The no-phonon line is accompanied by transverse-optical (X^{TO}) or transverse acoustic (X^{TA}) phonon replicas that are created as photon emission is accompanied by the momentum-conserving creation of lattice vibrations in Si–Si, Si–Ge or Ge–Ge bonds.

Figure 22.18 shows how the spectrum from a bulk $Si_{0.915}Ge_{0.085}$ sample develops with increasing temperature [22.50]. With increasing temperature the X^{NP} line thermalises to leave the free-exciton (FE^{NP}) line. Here, emission from nominally free excitons is greatly enhanced for the alloy samples by local fluctuations in composition that provide momentum-conserving scattering centres [22.52].

At higher temperatures the free-exciton line is also thermalised and all fine structure is lost, at temperatures around 25 K broad luminescence bands are commonly observed (Fig. 22.19) [22.50]. These deep luminescence bands are difficult to assign and have been ascribed to impurities, structural defects and, as in the case of the line presented in Fig. 22.19, potential wells formed by alloy fluctuations [22.50].

Weber and *Alonso* [22.50] use their data to provide analytical expressions for both the X^{NP} and L bands for bulk $Si_{1-x}Ge_x$ in the range $0 \le x \le 0.85$ as follows,

$$E_{gx}^{(x)}(x) = 1.155 - 0.43x + 0.206x^2 \text{ eV} , \quad (22.10)$$

$$E_{gx}^{L}(x) = 2.010 - 1.270x \text{ eV} . \quad (22.11)$$

At low temperatures narrow excitonic luminescence features are indicative of defect-free material, and in this way low-temperature photoluminescence becomes a good qualitative tool with which material quality can be assessed.

22.2.3 SiGe Quantum Wells

Figure 22.20 shows the first excitonic luminescence spectra from a Si/SiGe multiple quantum well grown by atmospheric-pressure CVD [22.35]. As we can see, many of the features seen in the photoluminescence spectra of quantum-well samples are similar to those seen from the bulk samples described in the previous section. Again, the most pronounced peak is the no-phonon (NP) line and this is accompanied by phonon

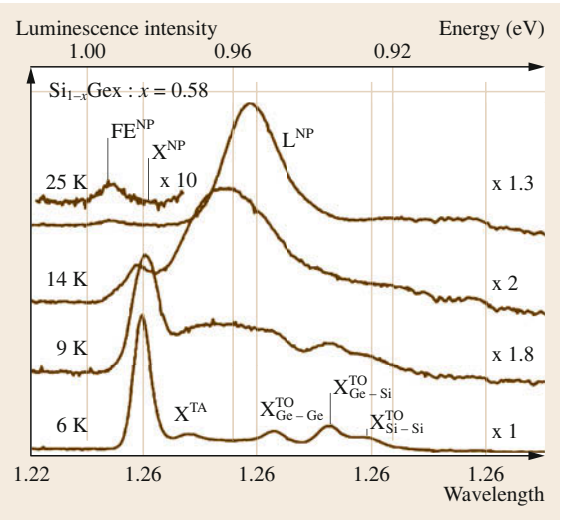

Fig. 22.19 Photoluminescence spectra of a bulk $Si_{0.42}Ge_{0.58}$ sample at different temperatures. (After *Weber* and *Alonso* [22.50], copyright 1989, American Physical Society)

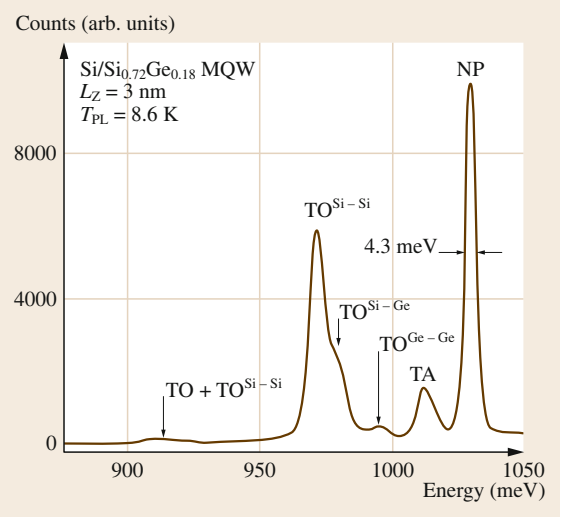

Fig. 22.20 Excitonic photoluminescence spectrum of a SiGe quantum well. (After *Grutzmacher* et al. [22.35], copyright 1993, AVS)

replicas, including, impressively, a two-phonon replica of the NP line $\left(\mathrm{TO} + \mathrm{TO}^{\mathrm{Si-Si}}\right)$. The most significant difference between bulk and quantum well spectra is the energy positions of the excitonic features as these are shifted by quantum confinement effects.

Robbins et al. [22.33], have provided one of the most detailed studies of near-band-gap photoluminescence from pseudomorphic SiGe layers and provide analytical expressions for all factors pertaining to the energy positions of the excitonic energy gap for $Si_{1-x}Ge_x$ quantum wells in the range $0 < x < 0.24$. The effects of alloying, confinement, band offsets, alignment type and exciton binding energy are all taken into account. Samples used in the study were grown by low-pressure CVD at 920 °C; a typical set of photoluminescence spectra are shown in Fig. 22.21.

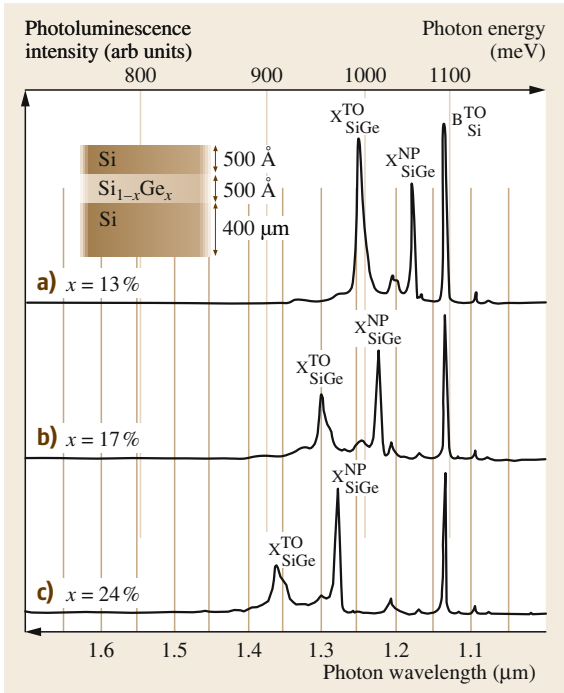

Fig. 22.21 4.2 K photoluminescence spectra from layers with the nominal structure shown in the *inset* (514 nm Ar-ion laser excitation). (After *Robbins* et al. [22.33], copyright 1992, American Physical Society)

The exciton band gap at 4.2 K is considered for thick (50 nm) strained layers (E_X^S) where the energies are not affected by quantum shifts. The following expression is derived

$$E_X^S(x) = 1.155 - 0.874x + 0.376x^2 \text{ eV}, \ (x < 0.25) \,. \tag{22.12}$$

Here the presence of strain is responsible for the differences from the expression obtained for bulk samples (22.10). An expression for the exciton binding energy $E_B^C(x)$ is theoretically derived for the cubic alloy and the following quadratic expression is fitted

$$E_B^C(x) \approx 0.0145 - 0.022x + 0.020x^2 \text{ eV}, \ (x < 0.25) . \quad (22.13)$$

A strain-corrected expression is also provided but this is found to modify (22.13) only slightly. Thus by adding (22.12) and (22.13) an expression for the band gap can be obtained

$$E_C - E_V \approx 1.17 - 0.896x + 0.39x^2 \text{ eV}, \ (x < 0.25) . \quad (22.14)$$

22.3 Growth of Silicon-Germanium

Over the past ten years and more there have been rapid developments in techniques for the growth of Si and $Si_{1-x}Ge_x$ epitaxial layers at low temperatures. This has been made possible by a number of changes in the design of epitaxy equipment and by improvements to growth processes. There are two main prerequisites for the growth of epitaxial layers at low temperature:

- Establishment of a clean surface prior to growth [22.53–56]
- Growth in an ultra-clean environment [22.57–59].

The removal of oxygen and carbon is the main problem in establishing a clean surface prior to growth. A clean silicon surface is highly reactive and oxidises in air even at room temperature. The secret of low-temperature epitaxial growth is therefore the removal of this native oxide layer and the maintenance of a clean surface until epitaxy can begin. Two alternative approaches to pre-epitaxy surface cleaning have been developed, as described below.

22.3.1 In situ Hydrogen Bake

The concept that underlies this surface clean is the controlled growth of a thin surface oxide layer, followed by its removal in the epitaxy reactor using a hydrogen bake. The controlled growth of the surface oxide layer is generally achieved using a Radio Corporation of America (RCA) clean [22.53] or a variant [22.54]. The oxide created by the RCA clean is removed in the reactor using an in-situ bake in hydrogen for around 15 min at a temperature in the range 900–950 °C. The temperature required to remove the native oxide depends on the thickness of the oxide, which is determined by the severity of the surface clean.

22.3.2 Hydrogen Passivation

An alternative approach to pre-epitaxy cleaning is to create an oxide-free surface using an ex-situ clean and then move quickly to epitaxial growth before the native oxide can grow. The aim of the ex-situ clean is to produce a surface that is passivated by hydrogen atoms bonded to dangling bonds from silicon atoms on the surface. When the wafers are transferred in the epitaxy reactor, the hydrogen can be released from the surface of the silicon very quickly using a low-temperature bake or even in the early stages of epitaxy without any bake. *Meyerson* [22.55] has reported that hydrogen desorbs at 600 °C at a rate of a few monolayers per second, so the hydrogen passivation approach allows epitaxial layers to be grown at low temperatures without the need for a high-temperature bake. The hydrogen-passivated surface is stable for typically 30 min after completion of the ex-situ cleaning [22.56].

22.3.3 Ultra-Clean Epitaxy Systems

Having produced a clean hydrogen-passivated silicon surface, it is clearly important to maintain the state of this surface in the epitaxy system. This necessitates the use of low-pressure epitaxy systems if epitaxial growth at low temperatures is required. Figure 22.22 summarises the partial pressures of oxygen and water vapour that need to be achieved in an epitaxy system if an oxide-free surface is to be maintained at a given temperature [22.57, 58]. This figure shows that epitaxial growth at low temperature requires low partial pres-

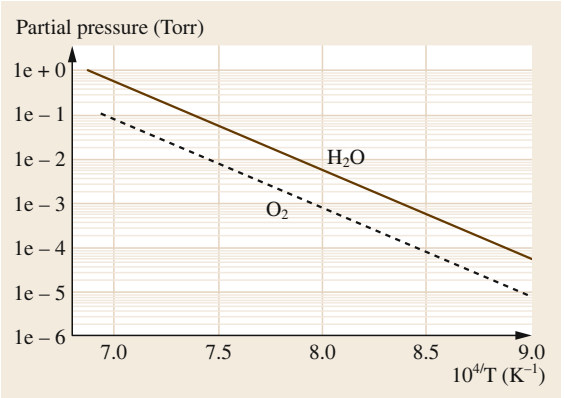

Fig. 22.22 Conditions for oxide formation in an epitaxy system. Note that 1 atm = 1.113 bar = 760 Torr = 1.113×10^5 Pa. (After *Smith* and *Ghidini* [22.57, 58], copyright Electrochemical Society 1984)

sures of oxygen and water vapour, which of course can be achieved by reducing the pressure in the epitaxy system. Research [22.59] has shown that a pressure below 30 Torr is needed to achieve silicon epitaxial growth below 900 °C.

22.3.4 $Si_{1-x}Ge_x$ Epitaxy

The growth of $Si_{1-x}Ge_x$ epitaxial layers can be achieved over a wide range of temperatures using low-pressure chemical vapour deposition (LPCVD) [22.59] or ultra-high-vacuum chemical vapour deposition (UHV-CVD) [22.61, 62]. The gas used to introduce the germanium into the layers is germane, GeH_4. The influence of germanium on the growth rate is complex, as illustrated in Fig. 22.23. At temperatures in the range 577–650 °C a peak in the growth rate is seen. At low germanium contents, the growth rate increases with germanium content, whereas at high germanium content, the growth rate decreases with germanium content. In the low-temperature regime it has been proposed that hydrogen desorption from the surface is the rate-limiting step. In $Si_{1-x}Ge_x$ this occurs more easily at germanium sites than at silicon sites and hence the growth rate increases with germanium content [22.44]. As the germanium content increases, the surface contains more and more germanium and less and less hydrogen. The rate-limiting step then becomes the adsorption of germane or silane. *Robbins* et al. [22.63] proposed that the sticking coefficient for germane or silane was lower at germanium sites. This would slow the adsorption rate as the germanium content increased and hence slow the growth rate.

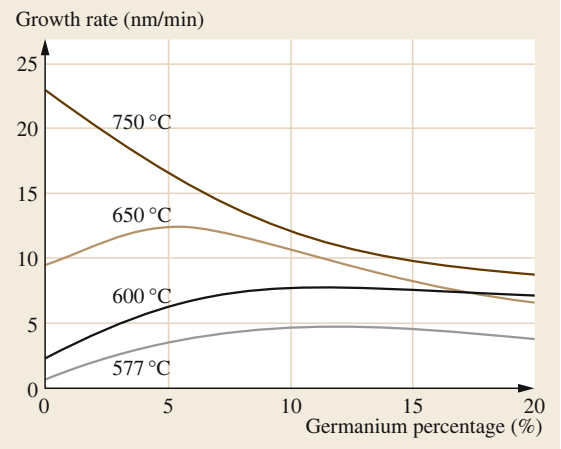

Fig. 22.23 Growth rate of $Si_{1-x}Ge_x$ as a function of germanium percentage for temperatures in the range 577–750 °C. (After *Racanelli* and *Greve* [22.60], copyright 1990, American Institute of Physics)

22.3.5 Selective $Si_{1-x}Ge_x$ Epitaxy

Selective epitaxy is the growth of a single-crystal layer in a window, with complete suppression of growth elsewhere, and can be achieved in a number of different ways. The most common method of achieving both selective Si and $Si_{1-x}Ge_x$ epitaxy is by introducing chlorine or HCl into the growth chamber. This can either be done by adding chlorine or HCl as a separate gas or by using a growth gas that contains chlorine, for example dichlorosilane, SiH_2Cl_2. With chlorine chemistry, selective growth of silicon and $Si_{1-x}Ge_x$ can be achieved to both silicon dioxide and silicon nitride.

Chlorine is reported to have two effects that lead to selective growth. First it increases the surface mobility of silicon and germanium atoms, so that atoms deposited on the oxide or nitride layer are able to diffuse across the surface to the window where the growth is occurring. Second it acts as an etch [22.59] and hence can remove silicon or germanium atoms deposited on the oxide or nitride. The strength of the etching action increases with chlorine content and, if the chlorine content is too high, etching of the substrate will occur instead of epitaxial growth.

A typical growth process for selective silicon epitaxy would use silane and a few percent of HCl [22.59]. The growth rate for this process is shown in Fig. 22.24, and compared with the growth rate for dichlorosilane and silane epitaxy. It can be seen that the activation energy for the silane-plus-HCl process is very similar to that for the dichlorosilane process, indicating that the growth mechanisms are similar. One disadvantage of chlorine-based growth processes over the silane

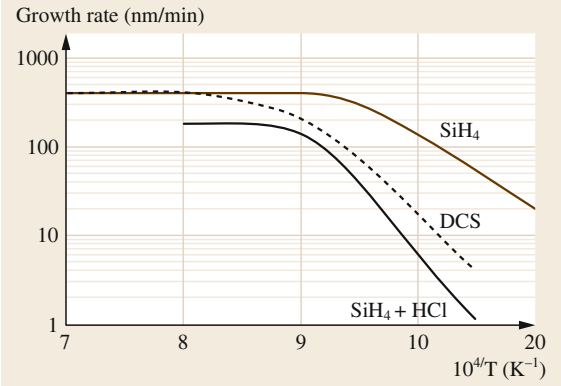

Fig. 22.24 Silicon growth rate as a function of reciprocal temperature for three different growth gases: 40 sccm of SiH_4, 80 sccm of dichlorosilane and 20 sccm of SiH_4 with 2 sccm of HCl. The hydrogen flow was 2 slm. (After *Regolini* et al. [22.59], copyright 1989 American Institute of Physics)

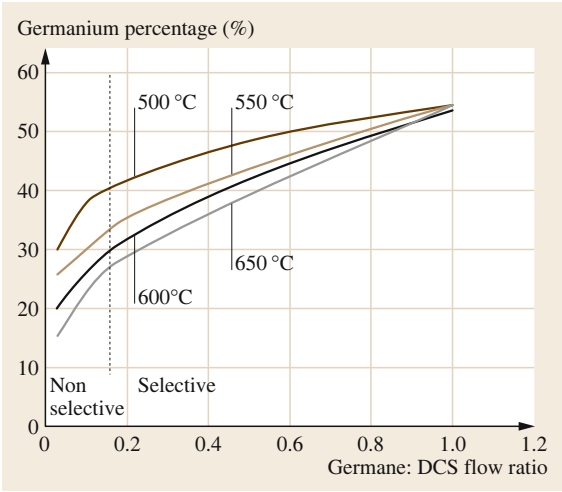

Fig. 22.25 Germanium percentage as a function of germane: dichlorosilane (DCS) flow ratio for temperatures in the range 500–650 °C showing the move from nonselective to selective growth as the proportion of germane in the gas flow increases. (After *Zhong* et al. [22.65], copyright 1990, American Institute of Physics)

process is a lower growth rate at low temperatures, as can clearly be seen in Fig. 22.24. It is also possible to grow silicon selectively using dichlorosilane and HCl [22.64].

Selective $Si_{1-x}Ge_x$ growth is generally easier to achieve than selective silicon growth, as illustrated in Fig. 22.25 [22.65] for $Si_{1-x}Ge_x$ growth using germane and dichlorosilane. The growth moves from nonselective to selective as the proportion of germane in the gas flow increases.

Arrhenius plots for $Si_{1-x}Ge_x$ growth using germane and dichlorosilane are shown in Fig. 22.26 for $Si_{1-x}Ge_x$ layers grown using germane and dichlorosilane and for two different HCl flows. It can be seen that the growth rate decreases and the activation energy increases with increasing HCl flow. The explanation proposed for this behaviour is that the limiting growth mechanism changes from hydrogen desorption from the growing surface to chlorine or HCl desorption from the surface [22.66]. This decrease in growth rate at high HCl flows is a disadvantage because it leads to increased growth times. High HCl flows can also cause surface roughening when the $Si_{1-x}Ge_x$ layer is heavily boron-doped [22.66]. These considerations demonstrate that the HCl flow should be chosen to be to the smallest value that is consistent with good selective epitaxy.

Silane can be used for selective silicon epitaxy if the growth is performed at a high temperature. This approach relies on the fact that nucleation on oxide is

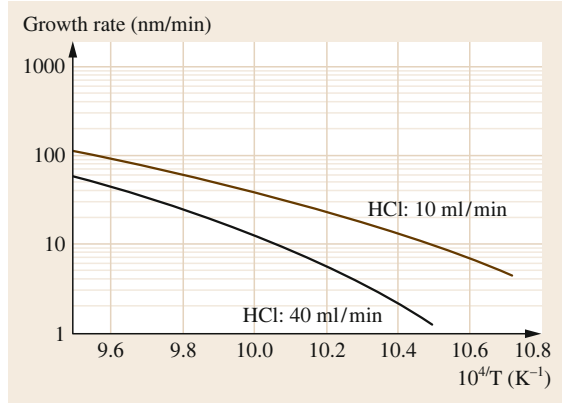

Fig. 22.26 Arrhenius plots for $Si_{1-x}Ge_x$ growth at two different HCl flow rates. The dichlorosilane and germane flow rates were fixed at 100 and 8 ml/min, respectively. (After *Kiyota* et al. [22.66], copyright 2002, IEEE)

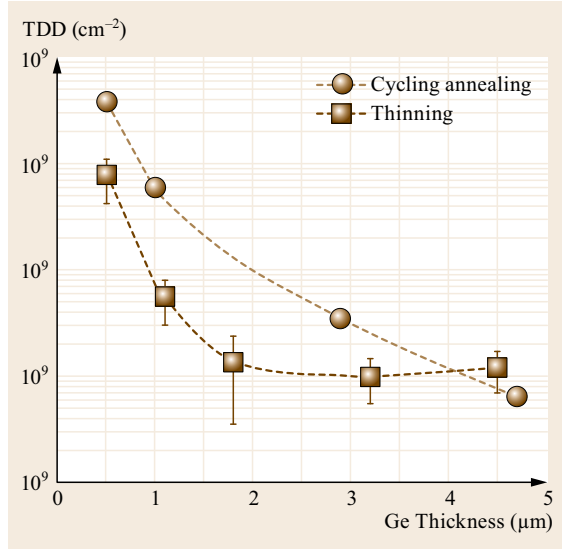

Fig. 22.27 Variation of TDD on Ge thickness for Ge grown on Si using cycling annealing at 800 °C versus Ge grown to 4.5 μm followed by thinning to the desired thickness. (Adapted from [22.67])

more difficult than that on silicon. This incubation time for growth on an oxide layer is relatively long at high temperatures but much shorter for growth at low temperatures. Selective silicon layers 1 μm thick can be grown using silane at a temperature of 960 °C [22.68], but the achievable layer thickness decreases with decreasing temperature. At 800 °C the maximum selective silicon layer thickness is around 130 nm, at 700 °C it is around 60 nm, and at 620 °C it is around 40 nm. Selective growth to silicon dioxide can be achieved using silane only, but not to silicon nitride.

22.3.6 Heteroepitaxial Ge on Si

The heteroepitaxial growth of Ge on Si has also garnered much recent interest for electronic and photonic applications. In almost all cases, a low temperature buffer layer is deposited to relieve misfit strain and allow two-dimensional (2-D) film growth. In the absence of such a buffer layer islands begin to form beyond thicknesses of several nm [22.69]. The LT buffer layer acts as a seed and allows the growth of thick Ge flat films. However, the density of threading dislocations becomes a problem for these layers. Several techniques have been explored to reduce the threading dislocation density (TDD). Cyclic annealing and thick film growth followed by etching to thin the layers have both produced good results bringing TDD to the order of $10^6\,\mathrm{cm}^{-2}$. Figure 22.27 shows the dependence on film thickness from these two techniques [22.67].

Ge layers on Si can be strain engineered for electronic and photonic applications. As-grown layers are compressively strained because of the lattice mismatch to the underlying Si substrate. However, cooling from a high growth temperature or a postanneal results in the Ge being tensile strained because of the difference in the thermal expansion coefficients of Ge and Si [22.70]. Tensile strained Ge is attractive because the strain reduces the direct bandgap of the Ge. N-type doping can then be used to fill the L conduction band valley to the level of the Γ valley, effectively making the Ge a direct bandgap material [22.67, 69, 70].

22.4 Polycrystalline Silicon-Germanium

In the past ten years there has been increasing interest in polycrystalline silicon-germanium for a number of applications that require polycrystalline material deposition at low temperature (around 600 °C). Examples of potential applications are thin film transistors, gates of MOS transistors and poly-SiGe emitters for SiGe HBTs.

In thin-film transistor technologies [22.71–73], polycrystalline silicon-germanium is compatible with the low-thermal-budget processing that is needed to produce thin-film devices for large-area electronics. The key physical property of polycrystalline silicon-germanium that makes it attractive is its lower melting point compared with silicon. This means that processes such as deposition, crystallisation, grain growth, and dopant activation will occur at a lower temperature than in silicon. Thus lower temperature processes can be used for poly-SiGe devices and hence it is preferable to poly-Si in applications with tight thermal-budget requirements.

In MOS transistors, polycrystalline silicon-germanium is attractive as a gate material for future generations of MOS transistor, since the germanium content in the silicon-germanium layer can be varied by 200–300 mV in the direction of a mid-gap gate [22.74–76]. This can be understood from Fig. 22.28, which compares the conduction- and valence-band energy levels in single-crystal silicon, silicon-germanium and germanium. Silicon and germanium have similar electron affinities (4.05 and 4.00 eV respectively), but germanium has a much smaller band gap (0.66 eV compared with 1.12 eV). The energy difference between the valence band and the vacuum level is therefore about 0.5 eV smaller in germanium than in silicon. In silicon-germanium, this energy difference can be varied by varying the germanium content. This allows the threshold voltage of p-channel MOS transistors to be tuned by varying the germanium content in the poly-$Si_{1-x}Ge_x$ gate.

Figure 22.29 shows values of work-function difference between the poly-$Si_{1-x}Ge_x$ gate and the n-type silicon substrate as a function of germanium content in a poly-$Si_{1-x}Ge_x$ gate [22.72]. The work function is defined as the difference in energy between the vacuum level and the Fermi level. In p^+ poly-$Si_{1-x}Ge_x$ the Fermi level is near the valence band and hence the work-function difference varies strongly with germanium content. In n^+ poly-$Si_{1-x}Ge_x$ the Fermi level is near the conduction band and hence the work-function difference varies little with germanium content.

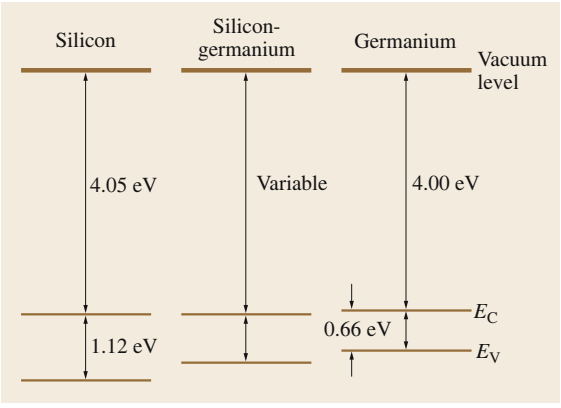

Fig. 22.28 Band-energy levels in silicon, silicon-germanium and germanium

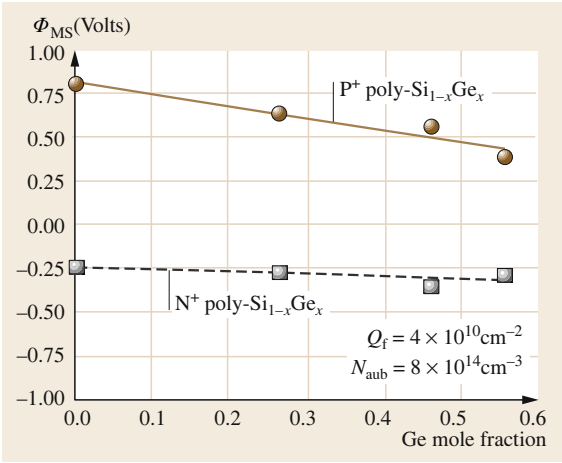

Fig. 22.29 Work-function difference between a poly-$Si_{1-x}Ge_x$ gate and an n-type substrate as a function of germanium content. (After *King* and *Saraswat* [22.72], copyright 1994, IEEE)

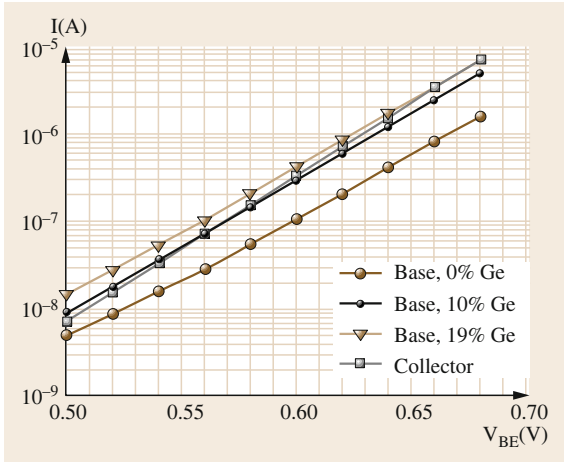

Fig. 22.30 Use of a poly-$Si_{1-x}Ge_x$ emitter to vary the base current of a $Si_{1-x}Ge_x$ HBT and hence give the best trade-off between gain and breakdown voltage BV_{CEO}. (After *Kunz* et al. [22.77], copyright 2003, IEEE)

In $Si_{1-x}Ge_x$ HBTs, poly-$Si_{1-x}Ge_x$ has potential as an emitter of a SiGe HBT [22.77]. In bipolar transistors, the breakdown voltage, BV_{CEO}, is inversely proportional to the gain [22.78] and hence transistors with a high gain have lower values of breakdown voltage. $Si_{1-x}Ge_x$ HBTs inherently have high values of the gain because the reduced band gap of the $Si_{1-x}Ge_x$ base enhances the collector current. The base current is unchanged by the $Si_{1-x}Ge_x$ base and hence the gain, which is the ratio of collector current to base current, is increased. The use of a poly-$Si_{1-x}Ge_x$ emitter instead of a poly-Si emitter provides a reduced band gap in the emitter, which enhances the base current, and thereby reduces the gain. Typical measured values of base current in a poly-$Si_{1-x}Ge_x$ emitter are shown in Fig. 22.30, where it can be seen that 19% germanium gives a factor of approximately four reduction in gain. A poly-$Si_{1-x}Ge_x$ emitter therefore allows the gain to be tuned to give the best trade-off between gain and breakdown voltage BV_{CEO}.

22.4.1 Electrical Properties of Polycrystalline $Si_{1-x}Ge_x$

Figure 22.31 shows the sheet resistance as a function of anneal temperature for boron- and phosphorus-doped $Si_{1-x}Ge_x$ for different germanium contents. For boron-doped poly-$Si_{1-x}Ge_x$ the sheet resistance decreases with increasing germanium content, with the decrease being large between 0 and 25% germanium and smaller between 25 and 50% germanium. In contrast, for phosphorus-doped poly-$Si_{1-x}Ge_x$ the sheet resistance increases with increasing germanium content, with the increase being small between 0 and 25% germanium and large between 25 and 50%. Similar behaviour is seen for arsenic-doped poly-$Si_{1-x}Ge_x$ where higher values of sheet resistance have been reported for poly-$Si_{1-x}Ge_x$ than for poly-Si [22.75].

The explanation for the sheet-resistance results in Fig. 22.31 can be found in Fig. 22.32, which shows the results of Hall measurements [22.72]. For boron-doped poly-$Si_{1-x}Ge_x$ both the activation and the Hall mobility increase with increasing germanium content, thereby explaining the decrease in sheet resistance with increasing germanium content. For phosphorus-doped poly-$Si_{1-x}Ge_x$ there is little change in activation and electron mobility at low germanium contents, but a sharp decrease in activation at germanium contents above 35%. This explains the sharp increase in sheet resistance seen in Fig. 22.31 for germanium contents between 25 and 50%. The decrease in activation at high germanium contents in the phosphorus-doped poly-$Si_{1-x}Ge_x$ may be due to increased segregation at grain boundaries. Boron does not generally segregate to grain boundaries [22.80], which may explain the different behaviour in boron- and phosphorus-doped poly-$Si_{1-x}Ge_x$.

Asafa et al. experimented with Ge-rich polycrystalline films grown by CVD and demonstrated that the electrical properties are very sensitive to the Ge fraction [22.81]. An increase in Ge fraction from 0.83 to 0.88 resulted in a sixfold increase in Hall mobility and decrease in resistivity. This was accompanied by a doubling of grain size resutling in more columnar grains.

23. Temperature-Insensitive Band-Gap III-V Semiconductors: Tl-III-V and III-V-Bi

Hajime Asahi

Thallium-containing III-V (Tl-III-V) and bismuth-containing III-V (III-V-Bi) alloy semiconductors were first proposed as novel functional semiconductors. They are alloys consisting of semiconductors (III-V) and semimetals (Tl-V, III-Bi), and are important materials for the fabrication of temperature-insensitive lasing wavelength laser diodes as well as long wavelength infrared (LWIR) optical devices. However, the growth conditions for alloys containing Tl and Bi are very strict and the growth windows are narrow. In this chapter, the expected properties of these semiconductors and the experimental results for the growth, characterization, and device applications are described.

References 554

Wavelength division multiplexing (WDM) technology is very important for an optical fiber communication system for increasing transport capacity and obtaining flexible network management. However, one of the problems encountered when using InGaAsP/InP laser diodes (LDs) in the WDM system is that the lasing wavelength fluctuates with ambient temperature variation mainly due to the temperature dependence of the band-gap energy. Therefore, LDs in WDM systems must be equipped with Peltier elements to stabilize the LD temperature.

To solve this problem, *Oe* et al. proposed the use of temperature-insensitive band-gap semiconductors as an active layer of LDs [23.1]. Such a temperature-insensitive band-gap property was observed in the II-VI semiconductor, HgCdTe, as shown in Fig. 23.1 [23.2]. HgCdTe is usually used for the long wavelength infrared (LWIR) detectors. CdTe is a semiconductor and HgTe is a semimetal. With the increase of HgTe composition, their band-gap energy decreases. At the CdTe-rich side of HgCdTe, the band-gap energy decreases with the increase of temperature, while at the HgTe-rich side of HgCdTe, the band-gap energy increases with the increase of temperature. Therefore, at a certain HgTe composition (0.48) region, the temperature-insensitive behavior is expected [23.3]. Similar behavior was also observed for HgCdSe, where the very small temperature dependence of refractive index was also confirmed [23.4].

The origin of this temperature-insensitive band-gap energy is considered as follows. Figure 23.2 shows the alloy composition dependence of the band structure for HgCdTe alloys [23.5]. At the CdTe side of HgCdTe, the Γ_6 band behaves as a conduction band and the Γ_8 band behaves as a valence band. Also in this composition region, the band-gap energy decreases with increasing temperature similar to usual semiconductors. With increasing HgTe composition, the Γ_6 band goes down and the band-gap energy decreases. By further increasing HgTe composition, the Γ_6 and Γ_8 bands cross and the band inversion occurs. After this band inversion, the Γ_6 band becomes a valence band and the Γ_8 light hole band forms a conduction band. The Γ_8 heavy hole band still behaves as a valence band and HgCdTe becomes a semimetal. Therefore, the energy difference between the two bands increases with increasing temperature so that the band-gap energy for HgCdTe semiconductors at the HgTe side composition increases with increasing temperature. At some intermediate alloy composition, we can observe the

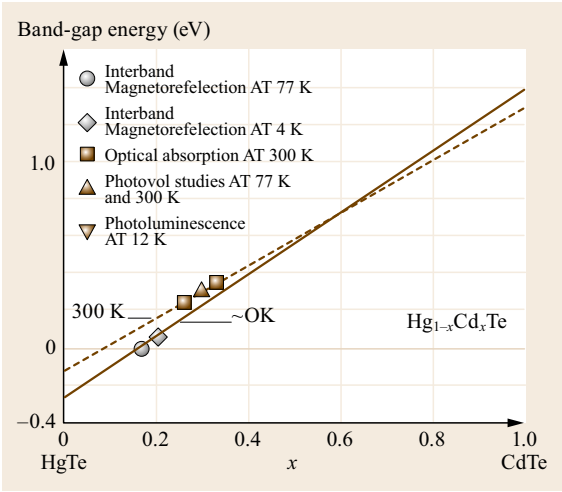

Fig. 23.1 Band-gap energy versus alloy composition for HgCdTe as a function of temperature. (After [23.2])

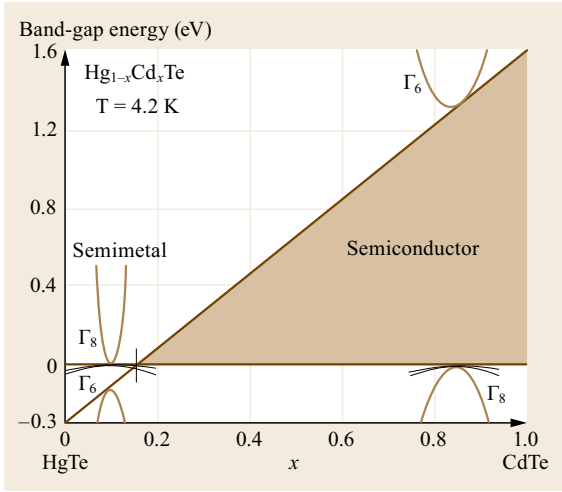

Fig. 23.2 Alloy composition dependence of the band structure for HgCdTe alloys. (After [23.5])

temperature-insensitive band-gap energy as shown in Fig. 23.1 [23.2].

From the above-mentioned discussion, the alloy semiconductor consisting of a semiconductor and a semimetal is expected to show the temperature-insensitive band-gap behavior. *Oe* et al. suggested GaAsBi and InGaAsBi alloys as new semiconductors showing temperature-insensitive band-gap energy for possible application to the temperature-stable lasing wavelength LDs [23.1]. *Asahi* et al. also proposed TlInGaAs and TlInGaP as new semiconductors showing temperature-insensitive band-gap energy [23.6, 7]. Similar to HgCdTe, it is also expected that these alloy semiconductors can be used for the LWIR detectors.

This chapter describes the expected properties of the Tl-III-V and III-V-Bi alloy semiconductors and the present status of their growth, characterization, and device applications.

23.1 Tl-III-V Alloy Semiconductors

Alloy semiconductor HgCdTe is widely used for LWIR focal-plane arrays (FPA). However, HgCdTe is a weakly bonded II-VI compound with material growth and processing problems dominated by native defects that limit FRA performance and yield [23.8]. *Van Schilfgaarde* et al. proposed thallium (TI)-based III-V ternary alloy semiconductors, TlInSb, TlInAs, and TlInP as the possible candidates for future LWIR detector materials [23.8–11]. Their theoretical calculations of TlSb, TlAs, and TlP showed that they have negative band gaps similar to HgTe (semimetal). Therefore, it is expected that TlInSb, TlInAs, and TlInP should exhibit LWIR band gaps. Furthermore, they are III-V materials and are compatible with the conventional III-V device fabrication technologies. Therefore, it was expected that these Tl-based alloys could overcome the difficulties encountered in the widely used LWIR semiconductor HgCdTe.

Interesting extensions of TlInSb, TlInAs, and TlInP alloys are quaternary alloys TlInGaP and TlInGaAs [23.6, 7, 12]. These quaternary alloys can be lattice matched to GaAs, InP, and InAs substrates. Lattice matching is very important to obtain good quality crystals. Furthermore, they are expected to have temperature-insensitive band-gap energies at some alloy compositions and they can be applied to the fabrication of temperature-insensitive lasing wavelength LDs [23.6]. Further extension is a quinary alloy semiconductor TlInGaAsN, which consists of a semiconductor GaInNAs and a semimetal TlAs and is also expected to be applicable to fabricate the temperature-stable lasing wavelength and temperature-stable threshold LDs [23.13] as discussed below.

23.1.1 Expected Properties of Tl-Based III-V Alloys

Figure 23.3 shows the expected relationships between the band-gap energy (E_g) and the lattice constant for

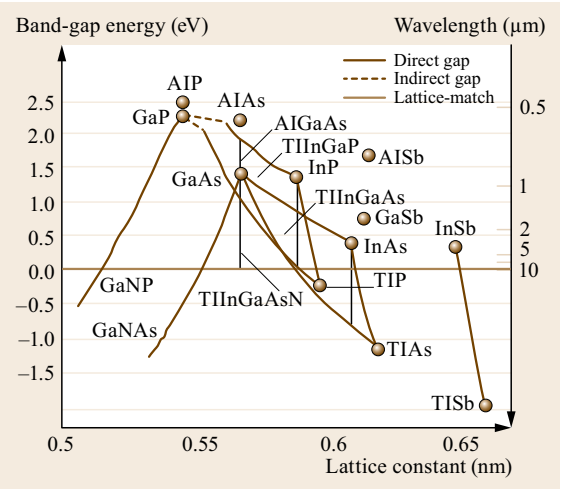

Fig. 23.3 Relationship for the band-gap energy versus alloy composition for Tl-III-V alloys as well as usual III-V semiconductors. (After [23.6, 12, 13])

Tl-based III-V alloys [23.6, 12, 13] based on the theoretical results for TlInSb, TlInAs, and TlInP by *van Schilfgaarde* et al. [23.8, 11]. The lines for TlGaAs and TlGaP were predicted by *Asahi* et al. [23.6]. The data for other III-V compound materials are also plotted in the figure for reference.

Van Schilfgaarde et al. [23.8–11] have theoretically calculated the lattice constant, cohesive energy, elastic constant, band-gap energy, effective mass, and electron mobility by the local density approximation first principle theory. They obtained the following results: (1) TlAs and TlP are formed in the zincblende structure, while TlSb is formed in the CsCl structure; (2) the lattice constants of TlSb (0.659 nm), TlAs (0.618 nm), and TlP (0.596 nm) are only 1.5−2% larger than those of InSb (0.648 nm), InAs (0.606 nm), and InP (0.587 nm), respectively; (3) the cohesive energies are about twice that of HgTe; therefore, bond strengths are higher; (4) TlSb, TlAs, and TlP are semimetals with negative band gaps of −1.60, −1.34, and −0.27 eV, respectively, similar to HgTe (−0.3 eV); (5) TlInSb, TlInAs, and TlInP exhibit a direct band gap of 0.1 eV (12.4 μm) at the Tl compositions of 0.09, 0.15, and 0.67, respectively. These properties are promising for application to LWIR detectors.

Thermodynamical properties of TlInP and TlInAs were theoretically estimated [23.14]. It was predicted that only low concentrations of Tl can be achieved in TlInP (< 5% at 350 °C) using gas-source molecular beam epitaxy (GSMBE). Although much less than 1% Tl was expected to be soluble in TlInAs, the error estimates in calculation indicated that obtaining 15% Tl is possible.

Quaternary alloys of TlInGaP and TlInGaAs proposed by *Asahi* et al. [23.6, 7] can be easily lattice matched to InP, GaAs, and InAs substrates as shown in Fig. 23.3. TlInGaP lattice matched to InP can cover the band-gap energy from 1.24 eV (0.92 μm at 0 K, InP) to less than 0.1 eV (12.4 μm, TlGaP), and over the whole lattice-matched composition the direct band-gap is expected to form. The addition of Al and As can further extend the energy (wavelength) range. TlInGaAs lattice matched to InP can cover from 0.75 eV (1.65 μm, InGaAs) to about 0 eV (TlGaAs). These quaternary alloys can be applied to LWIR detectors and emitters. They are expected to exhibit the temperature-insensitive band-gap energy behavior at some alloy compositions similar to HgCdTe [23.6]. This is because these semiconductors are alloys consisting of semiconductors (InGaP, InGaAs) and semimetals (TlP, TlAs). These temperature-insensitive band-gap energy characteristics are very promising for the fabrication of LDs whose wavelength does not change with or is insensitive to ambient temperature variation. The band lineup of lattice-matched TlInGaP/InP heterostructures was suggested to be type-I and the conduction band discontinuities are larger than the valence band offsets [23.6], also proved by the theoretical calculation [23.15].

Quinary alloy semiconductor TlInGaAsN was proposed by *Asahi* et al. to fabricate the temperature-stable lasing wavelength and temperature-stable threshold current TlInGaAsN/AlGaAs LDs [23.13]. TlInGaAsN is an alloy of a semiconductor InGaNAs and a semimetal TlAs as shown in Fig. 23.3. InGaNAs/AlGaAs heterostructures are widely studied to fabricate temperature-stable threshold current LDs in the wavelength range of 1 μm because of their large conduction band discontinuity [23.16]. However, there exists a long wavelength limit of 1.3 μm in this material system. This is because of the degradation of the crystal quality as well as the reduction of valence band offset with increasing N composition [23.17]. To overcome this problem, new alloy semiconductor TlInGaAsN/AlGaAs heterostructures were proposed [23.13].

As can be clearly seen in Fig. 23.3, much lower band-gap energy, therefore, longer wavelength, can be easily obtained for this new semiconductor compared with GaInNAs. TlInGaAsN/AlGaAs heterostructures also have a large conduction band discontinuity similar to GaInNAs/AlGaAs ones. Furthermore, TlInGaAsN is expected to have temperature-insensitive band-gap energy because it is an alloy of a semiconductor and a semimetal, similar to TlInGaAs. Therefore, the fabrication of temperature-stable lasing wavelength and temperature-stable threshold current LDs is expected by using TlInGaAsN/AlGaAs heterostructures.

23.1.2 Growth of Tl-III-V Alloys

The growth of Tl-based III-V alloys has been attempted by metal-organic vapor phase epitaxy (MOVPE) [23.18–20], gas source MBE (GSMBE) [23.6, 21–26], and solid source MBE (SSMBE) [23.27, 28].

In the MOVPE growth of TlInSb and TlInP, cyclopentadiethylthallium (CPTl) and trimethylindium (TMIn) were used as Tl and In precursors, and trimethylantimony (TMSb) or tertiarybutyldemethylantimony (TBDMSb) and phosphine (PH_3) as Sb and P precursors, respectively [23.18–20, 29]. The vapor pressure of CPTl is as low as about 3 Torr even at 120 °C. Therefore, high bubbler temperature and heated valves, and stainless delivery lines are needed.

In GSMBE or SSMBE growth, elemental Tl, In, and Ga were used as group III sources [23.6, 21–28]. Thermally cracked arsine (AsH_3), phosphine (PH_3), or elemental As and Sb were used as group V sources. Tl vaporizes from the melt state, which means that the controllability of the Tl flux is much better than that of Sb. The problem in using Tl metal is its ease of oxidation. The toxicity of Tl is known to be higher than that of As, so extreme care must be taken during treatment [23.6]. Tl-condensed surfaces should not be touched with bare hands and Tl flakes or vapors should not be inhaled: legal intake is documented to be at 600 mg. From this toxicity point of view, growth by MBE is much safer than that by MOPVE. In MBE, the solid Tl is used and is stored in the growth chamber, whereas in MOVPE, the Tl is supplied and vented as a form of metal organic (MO) gas. It is considered that there is no essential difference between GSMBE and SSMBE both in safety and growth mechanism, though growth conditions may be slightly different.

Growth of Tl-III-Sb Ternary Alloys

The growth of TlInSb was first conducted by *Choi* et al. [23.18]. They grew TlInSb layers with good surface morphology on GaAs and InSb substrates at 455 °C by low-pressure MOVPE. X-ray diffraction measurements showed resolved peaks of InSb and TlInSb. However, in contrast to the theoretical prediction, an increase in Tl incorporation led to a decrease in the lattice constant (higher diffraction angle). This was also observed by *Karam* et al. [23.20]. The latter obtained TlInSb with Tl composition of 0.1 (10%). Incorporation of Tl was also confirmed with Auger electron spectroscopy and Rutherford backscattering (RBS) measurements. Infrared transmission measurements showed a shift of the absorption edge toward longer wavelengths with increasing Tl composition for TlInSb [23.18, 20, 29].

Infrared photoconductors were fabricated from TlInSb/InSb grown on (100) semi-insulating GaAs substrates [23.20, 30, 31]. A clear shift of response to longer wavelength was observed. The cutoff wavelength extended to 11 μm at 300 K for the TlInSb (Tl composition of 6%) photoconductor [23.30]. The maximum detectivity was 7.6×10^8 cm $Hz^{1/2}$ W^{-1} at 77 K.

Growth of Tl-III-As Ternary Alloys

The growth experiments of TlInAs were conducted by GSMBE [23.25, 26, 32] and SSMBE [23.27, 28]. *Takenaka* et al. [23.25] confirmed the successful growth of TlInAs on InAs substrate at 430 °C by double crystal x-ray diffraction measurement (40 arcsec shift) as well as by reflection high-energy electron diffraction (RHEED) intensity oscillation measurement, where the oscillation period was reduced by the addition of Tl flux during the growth of InAs (1.3% reduction). *Lubyshev* et al. [23.28] also reported the growth of TlInAs with Tl composition of 0.6%. However, *Antonell* et al. [23.26, 32] and *Lange* et al. [23.27] reported that the incorporation of Tl into InAs was difficult. The growth of high Tl composition TlInAs has not been accomplished. The window for the appropriate growth conditions, especially substrate temperature, was narrow.

The growth of TlGaAs was conducted on GaAs substrates by SSMBE by *Lubyshev* et al. [23.28]. They reported the successful growth of TlGaAs with a Tl composition of 0.05 (diffraction peak separation of 1260 arcsec between TlGaAs and GaAs in the (400) double crystal x-ray diffraction (DCXRD)) and a second metal phase (Tl+Ga+As) on the surface. They observed that the growth of TlGaAs is easier than that of TlInAs.

Growth of Tl-III-P Ternary Alloys

TlInP growth was conducted on InP substrates by both MOVPE and GSMBE. *Razeghi* et al. [23.29] reported the successful growth of $(TlP_3)_x(InP)_{1-x}$ layers at 520 °C by MOVPE and observed clear photoresponse with onset wavelengths of 5.5 and 8.0 μm in infrared photoconductivity measurements for two samples (estimated compositions: $x = 0.6$ and 0.64), respectively. *Yamamoto* et al. confirmed the GSMBE growth of TlInP by the DCXRD measurement [23.21] and by the RHEED intensity oscillation measurement [23.22]. The growth temperature was about 450 °C and (2×4) RHEED patterns and specular surface morphology with SEM were observed [23.21]. With increasing Tl/(Tl+In) flux ratio, the XRD peak was shifted to lower diffraction angles, indicating the increase in Tl incorporation. On the other hand, *Antonell* et al. [23.26]

reported the difficulty of the growth of TlInP similar to TlInAs. Narrow growth window for the growth of these materials is probably the reason for this discrepancy.

TlGaP layers closely lattice matched to GaAs were successfully grown on GaAs substrates at about 450 °C by GSMBE [23.23]. However, TlGaP on GaAs showed the phase separation into three stable compositions: TlGaP nearly lattice matched to GaAs, GaP-like TlGaP and TlP-like TlGaP. However, by adjusting Tl and Ga fluxes, TlGaP layers without phase separation and nearly lattice matched to GaAs were grown. Photoconductance measurement on TlGaP showed the absorption in the 1.3 μm wavelength region, agreeing with the expected band-gap energies for the TlGaP lattice matched to GaAs. Furthermore, a small temperature variation of band-gap energy was observed as expected.

Growth of Tl-III-V Quaternary Alloys

Quaternary TlInGaP layers were successfully grown on InP substrates by GSMBE [23.22, 33, 34]. During growth, the RHEED pattern showed (2×4) reconstructions [23.22]. The DCXRD measurement showed a lower angle shift for the TlInGaP peak with increasing Tl flux [23.33, 34], agreeing with the increase of Tl composition. No phase separation was observed. The Tl composition obtained was less than 0.1. The increase of photoconductivity (PC) was observed in the longer wavelength region compared with the PC of InP [23.24], clearly indicating the formation of narrow band-gap semiconductors.

Quaternary TlInGaA layers were also successfully grown on InP substrates by GSMBE [23.25, 33, 34]. The growth temperature was 450 °C. The growth condition for alloys containing Tl was very strict. For example, the growth below 400 °C resulted in segregation of Tl, and the growth above 460 °C failed to incorporate Tl due to desorption of Tl atoms from the growing surface. During the growth at 450 °C, the RHEED pattern showed (2×2) reconstructions. The grown samples showed mirror surface and incorporation of Tl. With increasing Tl flux, the x-ray diffraction peak shifted toward lower angles and the Tl composition was increased (Fig. 23.4) [23.33]. It is considered that during the growth of TlInGaAs, the large part of incident Tl atoms is re-evaporated from the surface and only a small part of them is incorporated into films, very similar to the case of MBE growth of GaN under usual growth conditions [23.35].

Growth of TlInGaAsN Quinary Alloys

The growth of TlInGaAsN was conducted by GSMBE with thermally cracked AsH_3 and plasma-enhanced N_2 as As and N sources [23.36]. TlInGaAsN/GaAs quantum well (QW) structures were grown on GaAs (100) substrates. High Tl flux was needed for the incorporation of Tl into the films.

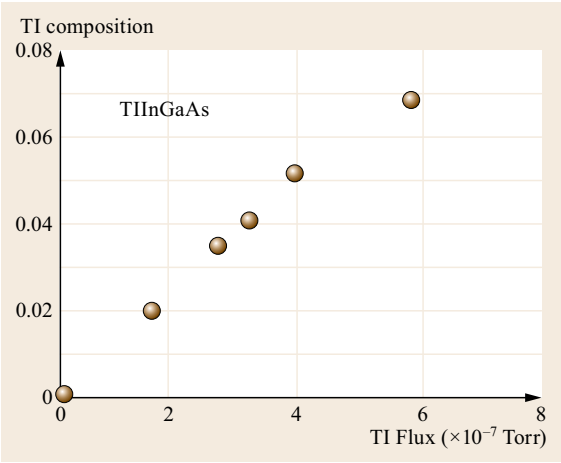

Fig. 23.4 Dependence of Tl composition in TlInGaAs on Tl flux during MBE growth. (After [23.33])

The TlInGaAsN/TlGaAsN QW samples having higher N concentration in the QWs showed higher Tl incorporation [23.37]. The addition of N species during growth induced the increase of Tl incorporation into TlInGaAs. This is considered due to the strong bonds of Tl–N.

23.1.3 Temperature Dependence of Physical Properties

TlInGaAs: Photoluminescence

Photoluminescence (PL) emission was observed from the grown TlInGaAs/InP samples in the temperature range of 10–300 K. With increasing Tl composition, the PL peak energy was shifted toward lower energy [23.38]. As the Tl composition increased, the temperature variation of the PL peak energy decreased and was much smaller than that of InAs, as shown in Fig. 23.5. It is noteworthy that the band-gap energy (≈ 0.8 eV) of TlInGaAs is larger than that (0.356 eV) of InAs. In general, the wider the band gap a material has, the larger is the variation of band-gap energy with temperature.

The temperature variation of as small as −0.03 meV/K was observed in Fig. 23.5, which corresponds to the wavelength variation of 0.04 nm/K. This value is much smaller than those of lasing wavelengths for the InGaAsP/InP Fabry–Pérot (FP) LDs (0.4 nm/K) as well as the InGaAsP/InP-distributed feedback (DFB) LDs (0.1 nm/K). The InGaAsP/InP

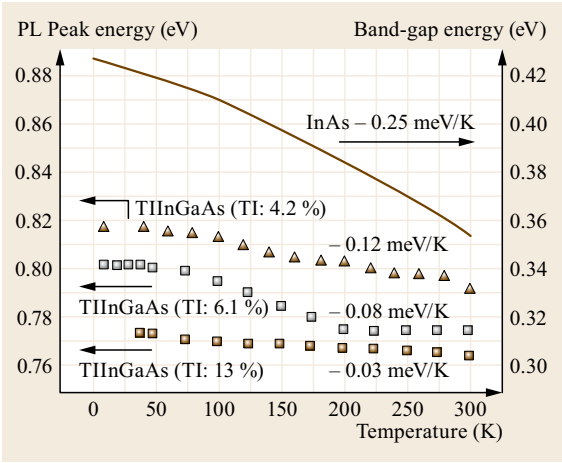

Fig. 23.5 Temperature variation of the PL peak energy for the TlInGaAs/InP DH samples as a function of Tl composition. (After [23.38])

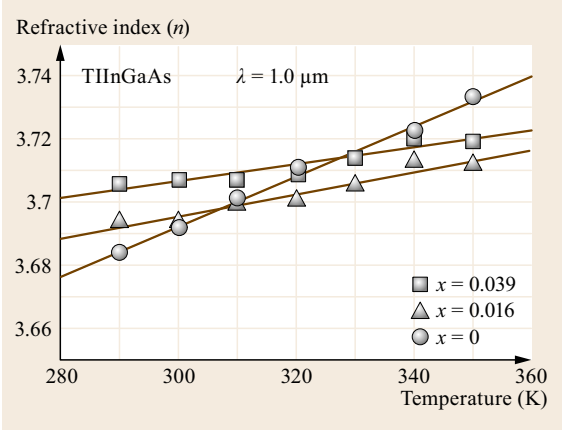

Fig. 23.6 Temperature variation of refractive indices for TlInGaAs (with different Tl composition x) and InGaAs at a wavelength of 1.0 μm. (After [23.39])

DFB LDs are presently used in the optical fiber communication systems. With further increase of Tl composition, real temperature-insensitive band-gap energy temperature dependence is expected.

TlInGaAs: Refractive Index and Band-Gap Energy

A spectroscopic ellipsometer (SE) was used to obtain the refractive indices of TlInGaAs in the photon energy range of 1.2–2.0 eV (above band-gap energy region) [23.39]. Optical reflectance and absorption measurements were carried out with a double-beam spectrometer in the wavelength range of 1700–2500 nm (below band-gap energy region) to determine the refractive indices n and the band-gap energies E_0 (E_g) of TlInGaAs, respectively [23.40].

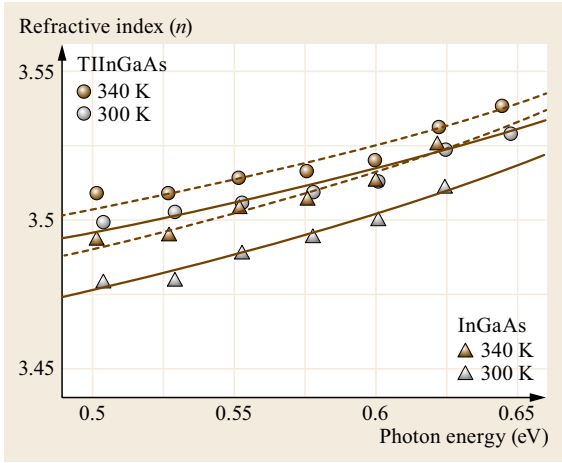

Fig. 23.7 Refractive index dispersions at $T = 300$ and 340 K. *Gray-colored circles* and *triangles* represent experimental refractive indices at 300 K and *brown-colored circles* and *triangles* represent those at 340 K for TlInGaAs (Tl = 0.043) and InGaAs, respectively. Solid and dashed lines represent the calculated results with the first-order Sellmeier equation. (After [23.40])

Table 23.1 Temperature coefficients of the direct-band edge E_0 and the refractive index $[n(\lambda \to \infty)]$ of InGaAs and TlInGaAs. (After [23.40])

Material	dE_0/dT (10^{-4} eV/K)	$n^{-1}(dn/dT)$ (10^{-5} K^{-1})	Ref.
InGaAs	−3.48		[23.41]
	−3.5	9.8	[23.40]
TlInGaAs	−2.1	5.0	[23.40]

At the energies above band gap, the refractive index n increases with photon energy [23.39]. However, the temperature variation of n for TlInGaAs (Tl = 0.039) greatly decreases as compared to InGaAs, as can be seen in Fig. 23.6 at the wavelength of 1.0 μm.

The photon energy dependencies of n at the energies below band gap for TlInGaAs (Tl = 0.043) and InGaAs at 300 and 340 K together with the calculated results by the first-order Sellmeier equation are shown in Fig. 23.7 [23.40]. The value of n of TlInGaAs is greater than that of InGaAs. The n value increases with increasing temperature. However, the temperature variation of n of TlInGaAs is remarkably smaller than that of InGaAs. Therefore, the temperature variation of n decreases with the increase of Tl composition at the photon energy both above and below E_g.

Table 23.1 [23.40] summarizes the temperature coefficients of the E_0 edge, dE_0/dT, and those of the

refractive index, $n^{-1}(dn/dT)$, for TlInGaAs (Tl = 0 and 0.043), together with those from [23.41]. Table 23.1 shows that the TlInGaAs alloy, although the Tl composition is limited to small value, exhibits temperature stability not only in the E_0 edge but also in n.

TlInGaAsN: Photoluminescence and Electroluminescence

TlInGaAsN/GaAs and InGaAsN/GaAs double quantum well (DQW) LEDs with GaAs layers as barrier layers were fabricated [23.36]. Reduction in the temperature variation of electroluminescence (EL) peak energy was observed in the temperature range of 288–328 K by the addition of Tl into InGaAsN/GaAs DQW layers; −0.62 meV/K for the InGaAsN/GaAs DQW and −0.53 meV/K for the TlInGaAsN/GaAs DQW. By replacing GaAs barrier layers with TlGaAs barrier layers, further reduction was obtained; −0.35 meV/K for TlInGaAsN/TlGaAs DQW LEDs [23.36]. SIMS measurements indicated that this improvement is caused by the increased incorporation of Tl into the DQW layers by using TlGaAs barrier layers.

TlInGaAsN/TlGaAsN triple QWs (TQWs) with TlGaAsN layers as barrier layers were investigated [23.37]. The TQW samples having higher N concentration in the TQWs have the highest Tl incorporation without deterioration of the crystalline quality. The temperature dependence of the PL peak energy was found to be the least for the highest Tl containing TQW sample.

23.1.4 Tl-III-V LD Application

TlInGaAs/InP double heterostructure (DH) LD structures were grown by GSMBE on (100) InP substrates [23.42]. Temperature variation of the EL peak wavelength as small as 0.06 nm/K was confirmed. This is much smaller than the 0.4 nm/K observed for InGaAsP/InP FP LDs as well as the 0.1 nm/K observed for InGaAsP/InP DFB LDs.

Laser operation was achieved under the pulsed condition from 77 to 310 K [23.42]. The threshold current density at room temperature was approximately 7 kA/cm^2, and the lasing wavelength was about 1660 nm. The characteristic temperature T_0 value for the temperature dependence of the threshold current in the temperature range of 77–300 K was approximately 94 K [23.42], which is similar to that of InGaAsP/InP LDs.

Several longitudinal-mode peaks were observed in the lasing spectra. Each longitudinal mode peak wavelength is determined by the effective refractive index of the TlInGaAs/InP waveguide and the cavity length of the LD. The temperature variation of each longitudinal-mode peak wavelength was as small as 0.06 nm/K [23.42]. However, in the wide temperature range, the main peak of the lasing spectrum moved to another peak of longer wavelength with increasing temperature. The average temperature variation of the main peak wavelength was 0.3 nm/K [23.42]. The temperature variation of the main peak for the FP LDs is mainly determined by the temperature variation of the gain peak. The observed average temperature variation of 0.3 nm/K is due to the temperature variation of the gain peak.

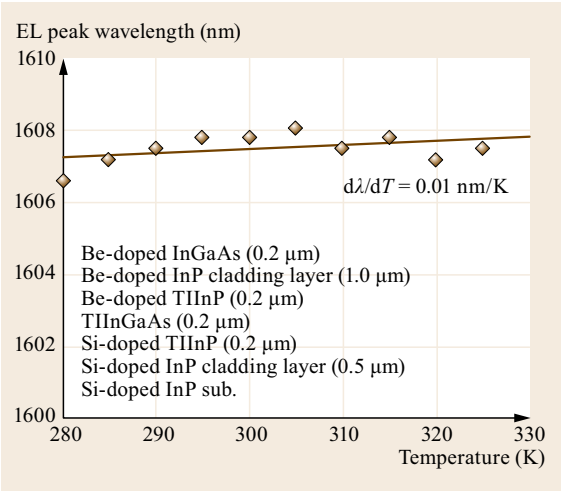

Fig. 23.8 Temperature dependence of EL peak wavelength for the TlInGaAs/TlInP/InP SCH LED. (After [23.43])

Laser light propagates along both TlInGaAs active layer and InP cladding layer; hence the temperature variation of lasing wavelength is influenced by their temperature variations. The addition of Tl into InP cladding layer results in the smaller temperature-dependent refractive index of cladding layer. The refractive index for TlInP was measured with the SE and it was confirmed that the refractive index of TlInP is larger than that of InP [23.43].

The InP/TlInP/TlInGaAs/TlInP/InP separate confinement heterostructure (SCH) LDs were fabricated and the improved temperature dependence of EL peak wavelength was obtained as shown in Fig. 23.8 [23.43]. Temperature dependence of the EL peak wavelength was reduced to 0.01 nm/K. The insertion of TlInP layer also increased the incorporated Tl composition in the TlInGaAs active layer.

The lasing spectra as a function of temperature and the temperature dependence of main peak wavelength for the SCH LDs under pulsed operation are shown in Fig. 23.9 [23.43]. The temperature

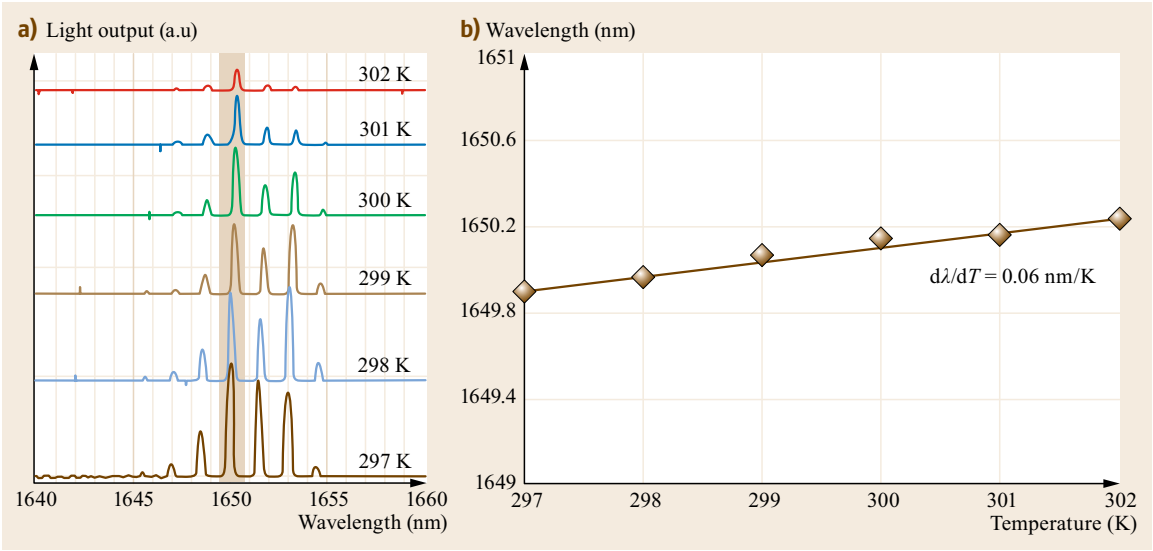

Fig. 23.9 (a) Lasing spectra as a function of temperature and (b) temperature dependence of lasing peak wavelength for the TlInGaAs/ TlInP/InP SCH LD under pulsed operation. (After [23.43])

variation of main peak wavelength is as small as 0.06 nm/K within the experimental temperature range (297–302 K). This value is much smaller than those of InGaAsP/InP FP LDs (0.4 nm/K) and InGaAsP/InP DFB LDs (0.1 nm/K). This reduced temperature variation is considered to be due to the reduced temperature dependence of refractive indices for TlInGaAs and TlInP compared with those for InGaAs and InP [23.43].

The observed temperature variation of the main peak wavelength for the TlInGaAs/TlInP/InP SCH LD is larger than that of the EL peak wavelength, which corresponds to that of gain peak or that of band-gap energy [23.43]. The main peak in the FP LD is one of the longitudinal-mode peaks, which are determined by the effective waveguide refractive index, that is, refractive indices of TlInGaAs active layers, TlInP cladding layers, and InP cladding layers, as well as the cavity (waveguide) length. Therefore, the temperature variation of the main peak cannot be smaller than that of the longitudinal-mode peak [23.43].

23.2 III-V-Bi Alloy Semiconductors

Bismuth-containing III-V (III-V-Bi) semiconductors were first studied for the applications to mid-infrared and far-infrared optical devices [23.44]. InSbBi [23.45–48], InAsBi [23.49, 50], and InAsSbBi [23.49] were grown by various growth methods, such as the Czochralski bulk growth method, RF sputtering, MBE, and MOVPE [23.44]. The solid solubility of Bi in InSb was reported to be as low as 2.6% in the bulk growth [23.45]. Low temperature MBE growth increased the Bi incorporation up to 5% [23.47].

Oe et al. [23.1] suggested the unique possible properties (temperature-independent band-gap energy characteristics) of III-V-Bi semiconductors and proposed the application to the temperature-insensitive wavelength LDs.

23.2.1 Expected Properties of Bi-Based III-V Alloys

Figure 23.10 shows the expected relationships between the band-gap energy and the lattice constant for the III-V-Bi alloy semiconductors [23.44]. As already described, the alloy semiconductors consisting of a semiconductor and a semimetal are expected to exhibit the temperature-insensitive band-gap energy similar to HgCdTe. The temperature-insensitive band gap is caused by the reverse temperature dependence of band gap (overlap) energy between the semiconductor and semimetal [23.1]. InGaAsBi was first suggested as a candidate for the temperature-insensitive band-gap energy semiconductor. GaAs and InAs are

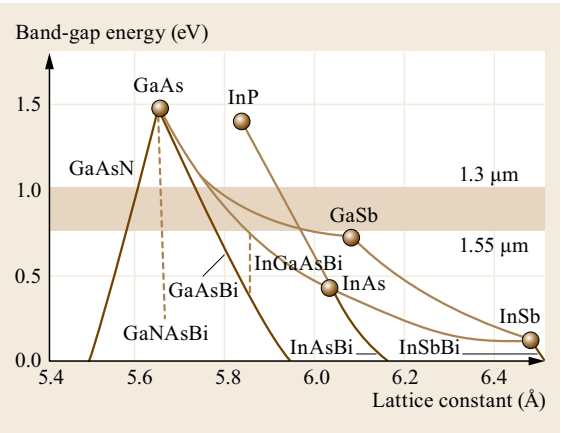

Fig. 23.10 Expected relationships between the band-gap energy and lattice constant for the III-V-Bi alloy semiconductors. (After [23.44])

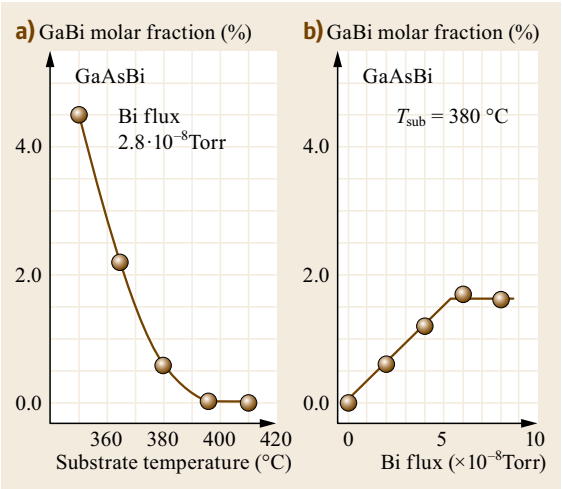

Fig. 23.11 **(a)** GaBi molar fraction in GaAsBi against substrate temperature for the constant Bi flux. **(b)** GaBi molar fraction in GaAsBi against Bi flux for the same substrate temperature. (After [23.52])

semiconductors and GaBi and InBi are semimetals.

To adjust the lasing wavelength of GaAsBi and related alloys to the waveband of optical fiber communication, a quaternary alloy of GaNAsBi was proposed which can be lattice matched to GaAs [23.44]. On the other hand, InGaAsBi is lattice matched to InP, but an additional element such as Al has to be added to InGaAsBi to adjust its band gap to the waveband of optical fiber communication [23.44]. GaAsBi and GaNAsBi have a characteristic of large spin–orbit interaction, which helps in reducing the Auger recombination in LDs [23.51].

23.2.2 Growth of III-V-Bi Alloys

Growth of III-V-Bi Ternary Alloys

In MBE growth of InSbBi, it is imperative to control the V/III ratio (Sb/In flux ratio) in the range of near unity to achieve Bi incorporation into InSb [23.44, 47]. Bi incorporation was suppressed at Sb/In ratio greater than unity despite the existence of Bi atoms on the growing surface. The strength of the In–Sb bond is considered to be stronger than that of In–Bi. Therefore, the Sb atoms are preferentially incorporated and the Bi atoms are difficult to be incorporated when the Sb/In flux ratio is greater than unity. Furthermore, the In–Bi bond is easily replaced by the In–Sb bond. Another important condition is that the growth temperature has to be set lower than 400 °C to avoid re-evaporation of Bi atoms from the growing surface [23.44, 47]. The InBi molar fraction increases by decreasing the substrate temperature (T_{sub}) [23.47].

After the proposal of GaAsBi alloys as a temperature-insensitive band-gap semiconductor [23.1], GaAsBi was grown on GaAs substrates by MOVPE [23.53]. To obtain the GaAsBi alloys, growth at relatively low temperatures was needed because Bi has high vapor pressure. However, in the MOVPE growth, the insufficient decomposition of MOs at low temperatures induced the incorporation of carbon (C) impurity species into GaAsBi films. On the other hand, in the MBE growth, elemental Ga, As, and Bi are used as sources [23.52, 54], and the incorporation of C impurity species is expected to be avoided.

GaAsBi was grown on GaAs (001) substrates at T_{sub} less than 400 °C by MBE [23.52, 54]. During the growth of GaAsBi, the RHEED pattern revealed the surface reconstruction of (2 × 1), suggesting the existence of Bi–Bi or Bi–As dimers [23.44, 55]. The unusual metallic nature of Bi-induced (2 × 1) was proposed as the origin of the surfactant nature of Bi [23.44, 56]. RHEED intensity oscillations observed during growth suggest a layer-by-layer growth [23.57].

For the growth of GaAsBi, the GaBi molar fraction decreased with increasing T_{sub} under constant Ga and As fluxes as shown in Fig. 23.11a [23.52]. At T_{sub} higher than 400 °C, Bi atoms are not incorporated into GaAs. Therefore, the GaAsBi alloys have to be grown at low temperature. However, the GaBi molar fraction increases with Bi flux, followed by the saturation for the constant Ga and As fluxes at the constant T_{sub} as shown in Fig. 23.11b. The unincorporated Bi atoms are desorbed from the surface without the formation of Bi droplets below critical Bi supply, although excess Bi supply forms Bi-containing droplets on the growth surface [23.52]. The droplet

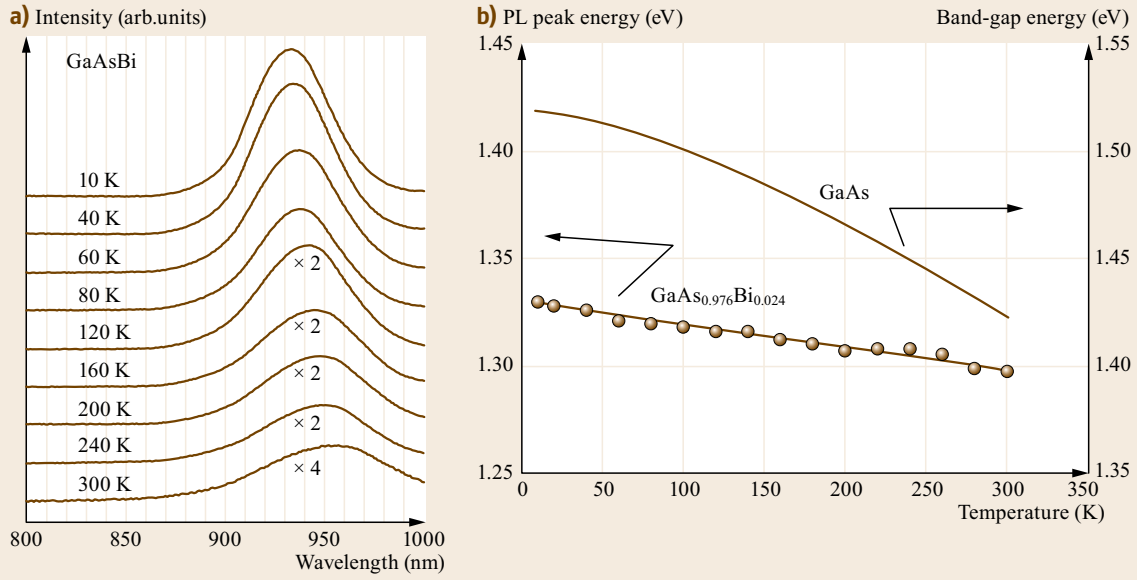

Fig. 23.12 **(a)** PL spectra as a function of temperature and **(b)** temperature variation of PL peak energy for the GaAsBi (GaBi = 0.024). For comparison, the band gap of GaAs is also shown. (After [23.53])

formation causes severe surface roughness and inhomogeneity.

The range of the As flux is also very narrow to obtain GaAsBi films [23.52]. For the growth at T_{sub} = 380 °C with Ga flux = 3×10^{-7} Torr and Bi flux = 2×10^{-8} Torr, only GaAs without Bi incorporation was grown above As flux of 10^{-5} Torr, while below 10^{-6} Torr the surface of the film becomes rough and only heavily degraded film was grown. Therefore, to grow the device quality GaAsBi, careful adjustment of the source supply and T_{sub} is needed.

Growth of III-V-Bi Quaternary Alloys

GaNAsBi quaternary alloys can be lattice matched to GaAs substrate with the band gap of optical fiber communication wavelengths. They were grown on GaAs (100) substrate by MBE using solid sources of Ga, As, and Bi and RF-plasma-enhanced N_2 gas at T_{sub} of 350–400 °C [23.58]. Precise control of As flux within a limited range and low temperature growth was crucial as in the case of GaAsBi. During growth, the (2×1) RHEED pattern was observed also similar to GaAsBi, implying Bi-stabilized reconstruction. The GaBi molar fraction decreased with the increase of T_{sub} for the constant Ga, As, and Bi fluxes, which is similar to the case of GaAsBi growth. Lattice matching between GaNAsBi film and GaAs substrate was achieved by adjusting GaN molar fraction [23.59].

The InGaAsBi quaternary alloy is another extension of GaAsBi and can be lattice matched to InP [23.60]. Considering the band gaps of InAs (0.36 eV) and GaAs (1.42 eV), the band gap of InGaAsBi is expected to cover the whole wavelength range used in the optical fiber communication systems, and InGaAsBi is a promising semiconductor to fabricate the temperature-insensitive wavelength LDs [23.60].

InGaAsBi was grown on InP (100) substrate by MBE using solid sources of In, Ga, As, and Bi [23.60]. T_{sub} was ranging from 270 to 350 °C, which is lower by 50 °C than that for GaAsBi growth, corresponding to the lower desorption temperature of Bi atoms from the InGaAs surface than that from the GaAs surface. During the growth of InGaAsBi, the (1×3) streaky RHEED pattern was observed. The XRD pattern showed a well-defined diffraction peak with distinct Pendellösung fringes, indicating the homogeneous alloy composition and high epitaxial quality with smooth surface. RBS channeling angular scans showed that Bi atoms are located exactly on the substitutional sites in InGaAs.

23.2.3 Optical Properties of III-V-Bi Alloys

Although the GaAsBi films were grown at low temperatures below 400 °C by both MOVPE [23.53] and MBE [23.58, 61, 62], intense PL emission was observed at room temperature. This is considered to be due to the surfactant effect of Bi atoms during growth. Figure 23.12 shows the PL spectra as a function of temperature and the temperature variation of the PL peak energy for the MOVPE-grown GaAsBi

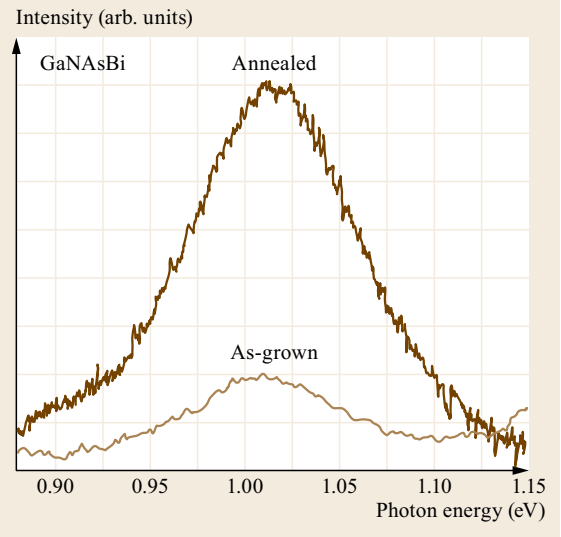

Fig. 23.13 PL spectra of as-grown and annealed GaNAsBi (GaBi = 0.02). (After [23.58])

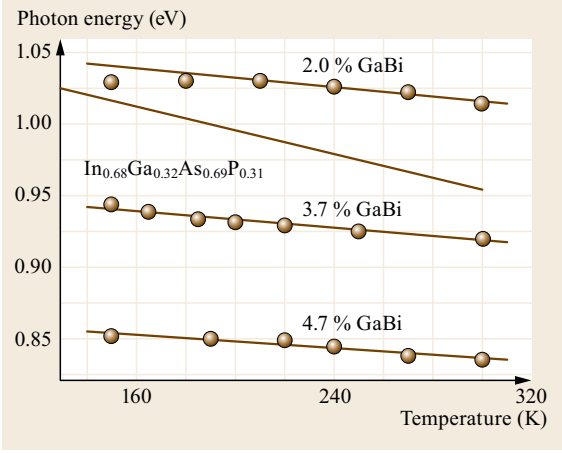

Fig. 23.14 Temperature variation of PL peak energy for GaNAsBi (GaBi = 0.02, 0.037, 0.047) and InGaAsP. (After [23.58])

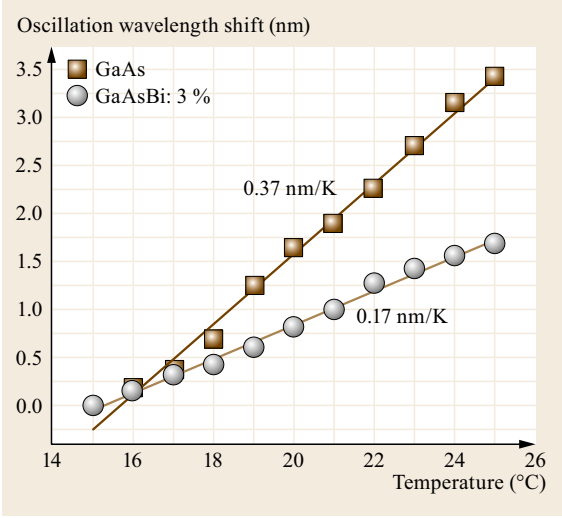

Fig. 23.15 Lasing wavelength shift for the GaAsBi and GaAs FP-LDs from the lasing wavelength at 15 °C in the temperature range of 15–25 °C. (After [23.64])

with GaBi molar fraction of 0.024 [23.53]. The temperature variation of the PL peak energy is as small as 0.1 meV/K, which is much smaller than that of GaAs as can be seen in Fig. 23.12b. The results suggest that the band gap of GaAsBi is less sensitive to temperature than the usual III-V semiconductors [23.53]. The PL peak energy decreased with the increase of GaBi molar fraction [23.58]. Reduction in the temperature variation of PL peak energy was also observed for the MBE-grown GaAsBi samples [23.61, 62]. The temperature coefficient of PL peak energy was 0.23 meV/K [23.61] and 0.15 meV/K [23.62] for the GaBi molar fraction of 0.013 and 0.025, respectively. The temperature coefficients of GaAsBi band gaps obtained by photoreflectance spectroscopy were 0.24, 0.23, and 0.15 meV/K between 150 and 300 K for samples with GaBi = 0.005, 0.013, and 0.026, respectively [23.63]; that is, with the increase of GaBi molar fraction the temperature coefficient of band gap decreased.

To obtain intense PL emission for the grown GaNAsBi, post-growth thermal annealing was needed, similar to GaInNAs. PL intensity of the GaNAsBi (GaBi = 0.02) film was increased by approximately fivefold after thermal annealing as shown in Fig. 23.13 [23.58]. PL peak energy of GaNAsBi showed no notable variation even after thermal annealing. The PL peak energy was decreased with the increase of GaBi molar fraction [23.58]. The temperature coefficient of the PL peak energy for GaNAsBi was very close to that for GaAsBi with the same GaBi molar fraction. Figure 23.14 shows the temperature variation of PL peak energy for three samples [23.58]. The temperature variation of PL peak energy for GaNAsBi is smaller than that of InGaAsP with similar band-gap energy (near 1300 nm). It can be said that the temperature coefficients of GaAsBi and GaNAsBi are governed by GaBi molar fraction and not by GaN molar fraction [23.58].

23.2.4 III-V-Bi LD Application

Photo-pumped lasing oscillation at 983 nm was achieved in the MBE-grown GaAs/GaAsBi/GaAs

(GaBi = 0.025) DH structure sample [23.62]. The temperature coefficient of the lasing wavelength decreased to 40% of that of the band gap of GaAs in the temperature range of 150–240 K. By using the GaAs/GaAsBi/AlGaAs DH structure sample to improve the carrier confinement, the photo-pumped lasing oscillation at the longer wavelength of up to 1200 nm was achieved [23.65]. The temperature coefficient of the lasing wavelength was about 40% to that of the 1300 nm InGaAsP LDs in the temperature range of 20–80 °C.

Electrically pumped lasing oscillation at 947 nm was demonstrated in the GaAsBi (GaBi = 0.022) FP-LD grown by MOVPE [23.66], though the temperature coefficient of the lasing wavelength is unclear. GaAsBi (GaBi = 0.03 or 0.04)/AlGaAs SCH FP-LD was grown by MBE [23.64]. Lasing oscillation was observed in the temperature range of 15–40 °C. The characteristic temperature T_0 for the GaAsBi (GaBi = 0.03)/AlGaAs SCH FP-LD was calculated to be 125 K, which is higher than that of 1300 nm InGaAsP FP-LD (T_0 = 60 K) and is similar to that for the 980 nm InGaAs/GaAs LDs. High T_0 is because of the stronger carrier confinement of the GaAsBi/AlGaAs system than that of the InGaAsP/InP system [23.64]. The temperature coefficient of lasing wavelength was reduced to 0.17 nm/K, which is 45% of that (0.37 nm/K) for the GaAs FP-LD as shown in Fig. 23.15 [23.64].

23.3 Summary

Tl-III-V and III-V-Bi alloy semiconductors are important materials for the fabrication of temperature-insensitive lasing wavelength LDs as well as LWIR optical devices. This chapter described the expected interesting properties of these semiconductors and the present status of their growth, characterization, and device applications. It was shown that these alloy semiconductors have a potential to have temperature-insensitive band gap and to fabricate temperature-insensitive lasing wavelength LDs.

24. Amorphous Semiconductors: Structure, Optical, and Electrical Properties

Kazuo Morigaki, Chisato Ogihara

This chapter is devoted to a survey of the structural, optical and electrical properties of amorphous semiconductors on the basis of their fundamental understanding. These properties are important for various types of applications using amorphous semiconductors.

First, we review general aspects of the electronic states and defects in amorphous semiconductors, i. e., a-Si:H and related materials, and chalcogenide glasses, and their structural, optical and electrical properties.

Further, we survey the two types of phenomena associated with amorphous structure, i. e., light-induced phenomena, and quantum phenomena associated with nanosized amorphous structure. The former are important from the viewpoint of amorphous-silicon solar cells. The latter phenomena promise novel applications of amorphous semiconductors from the viewpoint of nanotechnology.

Amorphous semiconductors are promising electronic materials for a wide range of applications such as solar cells, thin-film transistors, light sensors, optical memory devices, vidicons, electrophotographic applications, x-ray image sensors, europium-doped optical-fibre amplifications etc., particularly, hydrogenated amorphous silicon (a-Si:H) for solar cells, thin-film transistors, x-ray image sensors, and chalcogenide glasses for optical memory devices including digital video/versatile disk (DVD). In this chapter, we emphasize the basic concepts and general aspects of the electronic properties of amorphous semiconductors such as their electrical and optical properties as well as their structural properties [24.1–3]. Furthermore, some basic and important results of these properties are described to understand these applications and to consider their further development. Light-induced phenomena in amorphous semiconductors, which have been considered to be associated with amorphous structure, are also described.

Nanosized amorphous structures exhibit quantum effects associated with two-dimensional (quantum well), one-dimensional (quantum wire) and zero-dimensional (quantum dot) structures, so they have received significant attention on both the fundamental and application sides. These topics are briefly described.

24.1 Electronic States

Long-range disorder in amorphous network breaks down the periodic arrangement of constituent atoms, as shown in Fig. 24.1. In the figure, the structures of amorphous and crystalline silicon are shown. The periodic arrangement of atoms makes it easy to treat the electronic states mathematically, i. e., the so-called Bloch

theory can be applied to crystalline solids. On the other hand, it becomes difficult to treat the electronic states in amorphous solids mathematically. However, electronic states in amorphous semiconductors are simply described in terms of tight-binding approximations and Hartree–Fock calculations. Using these approaches, spatial fluctuations of bond length, bond angle and dihedral angle lead to broadening of the edges of the conduction and valence bands, constructing the band tail. This is due to spatial fluctuations of bond energy between constituent atoms in tetrahedrally coordinated semiconductors such as Si and Ge, in which the bonding state and the antibonding state constitute the valence band and the conduction band, respectively, as shown in Fig. 24.2a. In chalcogenide glasses, the conduction band arises from the antibonding state, while the valence band arises from the nonbonding state, as shown in Fig. 24.2b. The broadening of those bonds also occurs as a result of potential fluctuations associated with the amorphous network of constituent atoms. The static charge fluctuation associated with bond-length and bond-angle variations in the amorphous network has been discussed theoretically [24.4] and experimentally [24.5, 6] in amorphous silicon.

In the band tails, the electronic states have a localized character and their nature changes from localized to delocalized at a critical boundary called the mobility edge, as shown in Fig. 24.3. The energy separation between the two mobility edges of the conduction and valence bands is called the mobility gap. The nature of the conduction and valence bands has been elucidated by means of photoemission spectroscopy [24.7]. The structure of actual samples of amorphous semiconductors deviates from the ideal random network, namely, coordination of constituent atoms deviates from the normal coordination following the $8-N$ rule [24.1], where N designates the number of valence electrons. For instance, the normal coordinations of Si and Se are four and two, respectively. However, in actual samples Si

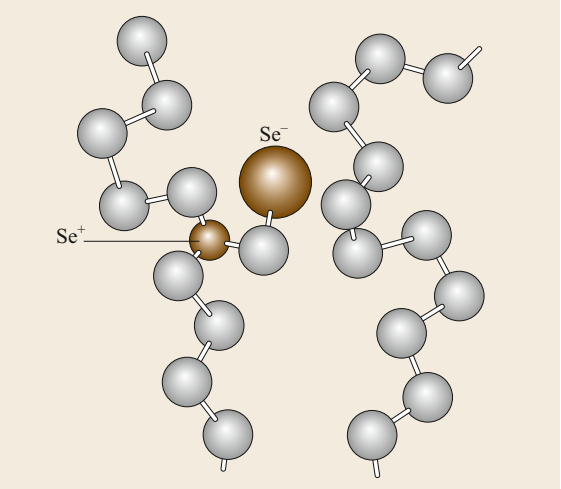

Fig. 24.5 Schematic illustration of two selenium chains with positively charged threefold-coordinated selenium and negatively charged onefold-coordinated selenium

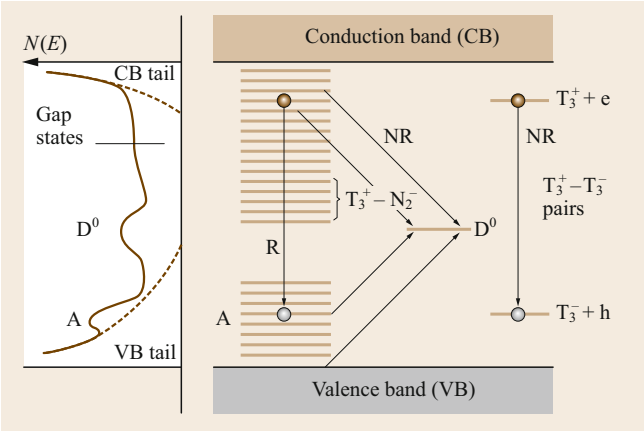

Fig. 24.6 Schematic diagram of the tail and gap states and the recombination processes in a-Si:H. R and NR designate radiative and nonradiative recombination, respectively. A diagram of the density of states spectrum is illustrated on the *left-hand side*. For the definition of other symbols, see the text. (After [24.9])

atoms with a threefold coordination are present in a-Si (Fig. 24.4), and Se atoms with onefold and threefold coordinations are present in a-Se (Fig. 24.5). These atoms are generally called structural defects (gap states) whose electronic energy levels are located within the band-gap region. In the case of chalcogenide glasses, onefold- and threefold-coordinated Se atoms are called valence-alternation pairs (VAP) [24.8]. The detailed properties of structural defects have been elucidated by means of optical spectroscopies such as photoinduced absorption (PA), photothermal deflection spectroscopy (PDS) and the constant-photocurrent method (CPM), capacitance measurements such as deep-level transient spectroscopy (DLTS) and isothermal capacitance transient spectroscopy (ICTS), and resonance methods such as electron spin resonance (ESR) and electron–nuclear double resonance (ENDOR) [24.2].

In the following, we take a-Si:H as an example and describe the nature of its electronic states. Figure 24.6 shows a schematic diagram of the electronic states involved in the band-gap region of a-Si:H proposed by the authors' group [24.9]. The tails of the conduction and valence bands are expressed by an exponential function with widths of 25 meV [24.10] and 48−51 meV [24.11–13], respectively.

In this figure, the processes of radiative recombination and nonradiative recombination are shown, along with the energy levels of the gap states involved in the recombination processes. The radiative recombination occurs between tail electrons and tail holes at higher temperatures and between tail electrons and self-trapped holes (A centres) at lower temperatures, particularly below 60 K. Such recombinations contribute to the principal luminescenceband peaked at 1.3−1.4 eV. These have been elucidated by optically detected magnetic resonance (ODMR) measurements [24.14–16], and are briefly mentioned in Sect. 24.3. The radiative recombination center participating in the low-energy luminescence (defect luminescence) may be attributed to distant T_3^+–N_2^- pair defects [24.17, 18], in which T_3^+ and N_2^- are the positively charged threefold-coordinated silicon center and the negatively charged twofold-coordinated nitrogen center, respectively. The N_2^- centers are created from contaminating nitrogen atoms introduced during sample preparation. On the other hand, close T_3^+–N_2^- pair defects act as nonradiative recombination centers. A typical nonradiative recombination center in a-Si:H is the neutral silicon dangling bond, i. e., T_3^0. The details of the recombination processes in a-Si:H are described in Sect. 24.3.

24.2 Structural Properties

24.2.1 General Aspects

The structural properties of amorphous semiconductors have been investigated by means of x-ray, electron and neutron diffraction, transmission electron microscope (TEM) and scanning electron microscope (SEM), extended x-ray absorption fine structure (EXAFS), small-angle x-ray scattering (SAXS), Raman scattering, infrared absorption (IR) and nuclear magnetic resonance (NMR). The absence of long-range order in amorphous semiconductors is manifested in diffraction techniques, e.g., electron diffraction for a-Si results in a halo pattern as shown in Fig. 24.7a, while Laue spots are seen for c-Si, as shown in Fig. 24.7b. The medium-range order of 0.5–50 nm has been discussed based on SAXS measurements.

24.2.2 a-Si:H and Related Materials

The radial distribution function (RDF) in a-Si has been obtained from an analysis of curves of scattered electron intensity versus scattering angle from electron diffraction measurements, as shown in Fig. 24.8 [24.19]. From a comparison of RDF curves of a-Si and c-Si, it was concluded that the first peak of a-Si coincides with that of c-Si, the second peak of a-Si is broadened compared to that of c-Si, the third peak of c-Si almost disappears and a small peak appears, shifted from the third peak of c-Si, as shown in Fig. 24.8. These results indicate that the bond length of a-Si is elongated by 1% over that of c-Si (= 2.35 Å), and that the bond angle is tetrahedral (= 109.47°) with a variation of 10% from that of c-Si. Using the neutron diffraction technique, the RDF was also deduced from the measured structure factor, $S(Q)$, as a function of Q (the momentum transfer) in a-Si [24.20]. The RDF curve of a-Si exhibiting these features was well simulated by the continuous random network model [24.21]. Since then, computer-generated models have been constructed (see, e.g., *Kugler* et al. [24.20]), using the Monte Carlo (MC) method [24.22], the molecular dynamics (MD) method [24.23] and the reverse MC method [24.24, 25]. Here, the reverse MC method, i. e., a MC simulation repeatedly carried out to reach consistency with the measured RDF curve and curve of structure factor $S(Q)$ versus Q from the neutron diffraction data, is briefly mentioned. First we start with an initial set of Cartesian coordinates (particle configuration) and calculate its RDF and $S(Q)$. Comparing the calculated RDF and $S(Q)$ with the measured ones, the new particle configuration is generated by random motion of a particle, being consistent with the constraint, e.g., the coordination number. From the reverse MC simulation, the bond-angle distribution is derived, i. e., it shows a peak at the tetrahedral angle, 109.5° and small peaks at ≈ 60° and ≈ 90° [24.26].

In a-Si:H, knowledge of the hydrogen configuration is important to understand its electronic properties. This is obtained by NMR [24.27, 28] and IR measurements [24.29]. The bonding modes of Si and H atoms are Si–H, Si–H_2, $(Si–H_2)_n$ and Si–H_3 bonds. The concentrations of these hydrogen configurations depend on the preparation conditions, particularly on the substrate temperature, i. e., the deposition temperature. a-Si:H films prepared at 250 °C mostly contain Si–H bonds in incorporated hydrogen (hydrogen content of ≈ 10 at.%), while those prepared at lower temperatures such as room temperature contain all these bonds in incorporated hydrogen (hydrogen content of ≈ 30 at.%). The hydrogen configuration has also been investigated by neutron scattering measurements using the isotope-substitution method [24.30, 31]. Partial pair-correlation functions of Si–Si, Si–H and H–H are

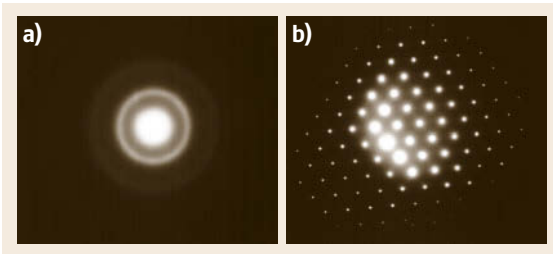

Fig. 24.7a,b Electron diffraction patterns. **(a)** amorphous silicon, **(b)** crystalline silicon

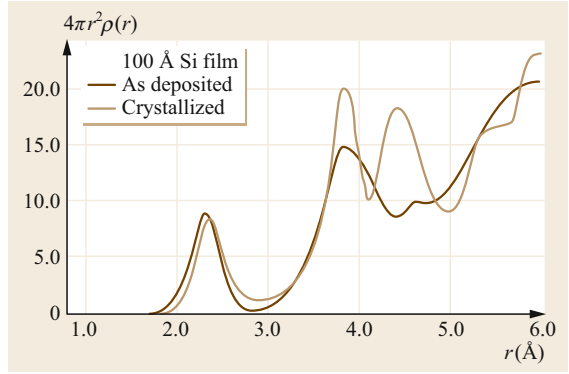

Fig. 24.8 Radial distribution function of amorphous (evaporated) and crystalline silicon obtained from electron diffraction patterns. (After [24.19])

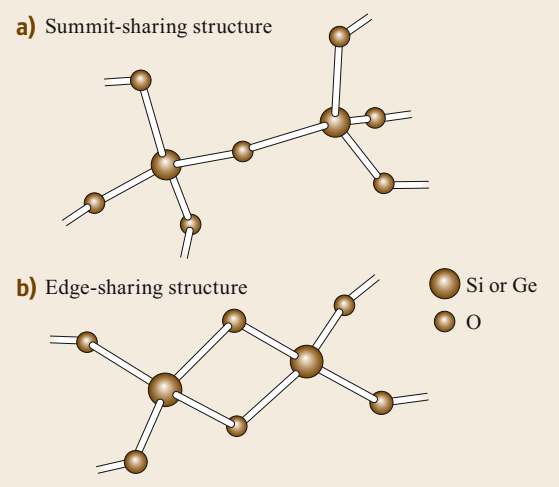

Fig. 24.9a,b Schematic illustration of (a) summit-sharing structure and (b) edge-sharing structure. (After [24.33])

obtained from those measurements. The Si−H bond length is 1.48 Å.

Raman scattering measurements provide useful information about microcrystallinity, i. e., the volume fraction of the amorphous phase in microcrystalline silicon [24.32]. The Raman shift associated with transverse optical (TO) phonons is observed at 520 cm^{-1} for c-Si, while it is observed at 480 cm^{-1} for a-Si.

24.2.3 Chalcogenide Glasses

The chalcogenide glasses are composed of chalcogenide atoms and other constituent atoms such as As, Ge etc. Their crystalline counterpart has a structure consisting of threefold-coordinated As atoms and twofold-coordinated chalcogens, i. e., c-Se and c-As_2S_3 exhibit a chain structure and a layered structure, respectively. The structure of the chalcogenide glasses is fundamentally built from these constituent atoms, keeping their coordination in the crystalline counterpart. However, actual glasses contain wrong bonds, i. e., homopolar bonds such as Se−Se, As−As, Ge−Ge etc. In the following, we take two examples of chalcogenide glasses, As_2X_3 (X = S, Se) and GeX_2 (X = S, Se):

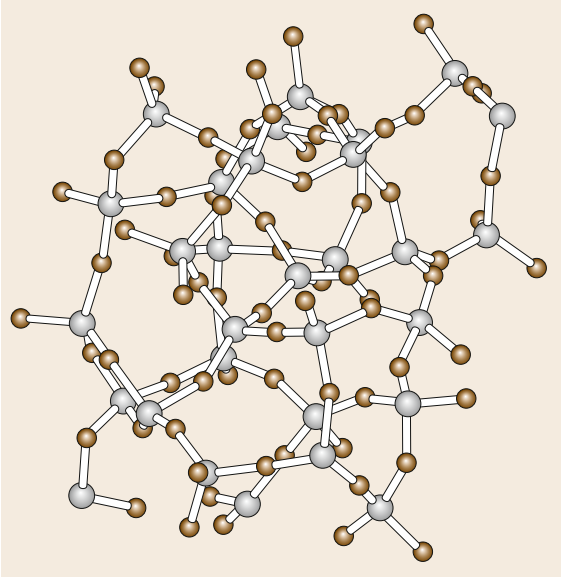

Fig. 24.10 Structural model of germanium disulfide. (After [24.33])

- As_2X_3 (X = S, Se): This type of glass, e.g., As_2S_3, is mainly composed of AsS_3 pyramid units, i. e., a random network of these units sharing the twofold-coordinated S site [24.34]. There is no correlation between As atoms, but interlayer correlation seems to hold even for the amorphous structure.
- GeX_2 (X = S, Se): Silica glass (SiO_2) is a well-known material, which is mainly composed of SiO_4 tetrahedron units sharing the twofold-coordinated O site (the summit-sharing structure. See Fig. 24.9a). On the other hand, SiS_2 and $GeSe_2$ glasses have a different structure from SiO_2 glass: the tetrahedron units are connected through two X sites (the edge-sharing structure) along with one X site (the summit-sharing structure. See Fig. 24.9b). For example, in $GeSe_2$, the edge-sharing structure occurs at a level of more than 30% and the summit-sharing structure with less than 70%. Actually, wrong bonds (homopolar bonds) Ge−Ge, Se−Se exist in $GeSe_2$ glass. A structural model of GeS_2 [24.33] is shown in Fig. 24.10.

24.3 Optical Properties

24.3.1 General Aspects

Optical absorption and luminescence occur by transition of electrons and holes between electronic states such as conduction and valence bands, tail states, and gap states. In some cases, electron–phonon coupling is strong and, as a result, self-trapping occurs. Exciton formation has also been suggested in some amorphous semiconductors.

The absorption of photons due to interband transition, which occurs in crystalline semiconductors, is also observed in amorphous semiconductors. However,

the absorption edge is not clear since interband absorption near the band gap is difficult to distinguish from tail absorption in the absorption spectra. Figure 24.11 schematically illustrates typical absorption spectra of amorphous semiconductors. The absorption coefficient, α, due to interband transition near the band gap is known to be well described by the following equation [24.35]

$$\alpha\hbar\omega = B(\hbar\omega - E_g)^2 \,, \tag{24.1}$$

where $\hbar\omega$ and E_g denote the photon energy and optical gap, respectively. In most amorphous semiconductors, the optical gap E_g is determined by a plot of $(\alpha\hbar\omega)^{1/2}$ versus $\hbar\omega$, which is known as Tauc's plot. The photon energy at which the absorption coefficient is $10^4\,\mathrm{cm}^{-1}$, E_{04}, is also used for the band gap in a-Si:H. The absorption coefficient at the photon energy just below the optical gap (tail absorption) depends exponentially on the photon energy, $E = \hbar\omega$, as expressed by

$$\alpha(E) \propto \exp\left(\frac{E}{E_U}\right) , \tag{24.2}$$

where E_U is called the Urbach energy and also the Urbach tail width. In addition, optical absorption by defects appears at energies lower than the optical gap.

Photoluminescence (PL) occurs as a result of the transition of electrons and holes from excited states to the ground state. After interband excitation, electrons relax to the bottom of the conduction band by emitting phonons much more quickly than the radiative transition. Similarly, the holes also relax to the top of the valence band. In the case of crystalline semiconductors without defects or impurities, there is no localized state in the band gap and PL occurs by transition between the bottom of the conduction band and the top of the valence band. In this case the k-selection rule, $k_{photon} = k_i - k_f$, must be satisfied, where k_{photon}, k_i and k_f denote the wavenumbers of photons, and electrons in the initial and final states, respectively. Since k_{photon} is much smaller than k_i and k_f, we can rewrite the selection rule as $k_i = k_f$. Semiconductors satisfying this condition are called direct-gap semiconductors. Crystalline silicon is one semiconductor in which the direct transition is not allowed by the k-selection rule (indirect-gap semiconductors), but the transition is allowed by either absorption of phonons or their emission. On the other hand, strong PL is observed in a-Si:H. In amorphous semiconductors, the k-selection rule is relaxed and, furthermore, the electrons and holes relax to localized states in the gap before radiative recombination. Thus, PL occurs by transitions between localized states.

E_G is the optical gap determined from **(b)**

The lifetime measurement is important for the identification of the origin of the PL since the PL spectra in most amorphous semiconductors are featureless and do not provide much information. The probability of radiative transition between localized electrons and holes depends exponentially on their separation, R. The lifetime is estimated by $\tau = \tau_0 \exp(2R/R_0)$ where R_0 denotes the radius of the most extended wavefunction [24.36]. When the Coulomb interaction is strong enough, excitons are formed. Exciton formation is also suggested in some amorphous semiconductors. The total spin of excitons S is either 0 or 1. Singlet excitons of $S = 0$ have a lifetime in the nanosecond region, while triplet excitons with $S = 1$ have a lifetime much longer than that of singlet excitons, e.g., $\tau = 1\,\mathrm{ms}$, since the transition is forbidden by the spin selection rule.

PL measurements combined with magnetic resonance are a powerful means to study recombination processes [24.14, 15]. This is called optically detected

magnetic resonance (ODMR) measurements. PL from triplet excitons has been suggested from ODMR measurements, as described in Sects. 24.3.2 and 24.3.3.

The photoconductivity measurements provide us with useful information about the processes of carrier transport and recombination. Their results on a-Si:H and chalcogenide glasses are briefly reviewed in Sects. 24.3.2 and 24.3.3, respectively.

24.3.2 a-Si:H and Related Materials

The band gap of a-Si:H determined from Tauc's plot is 1.7−1.9 eV, depending on the preparation condition, particularly the deposition temperature T_s, i. e., hydrogen content [H] [24.37–40] as shown in Table 24.1. The absorption coefficient of visible light for a-Si:H is of the order 10^5−10^6 cm^{-1}, which is large compared to that of crystalline silicon. A thickness of 1 μm is enough to absorb visible light. Thus a-Si:H is suitable for application to solar cells especially when a thin film is desired.

The optical gap E_g and the Urbach tail width E_U of a-Si:H, a-Ge:H and Si-based alloys are shown in Table 24.2. Some a-Si:H-based alloys such as a-$Si_{1-x}N_x$:H and a-$Si_{1-x}C_x$:H have a band gap wider than that of a-Si:H depending on the composition x. In the preparation of these alloys, x can be varied continuously over a certain range. Thus, the band gap can be varied arbitrarily. It is possible to prepare multilayer films consisting of layers with different band gaps, such as a-Si:H/a-$Si_{1-x}N_x$:H. Quantum size effects in multilayer films will be described in Sect. 24.6.

It is difficult to obtain the absorption spectra below the band gap from transmittance measurements in a-Si:H, which is normally prepared as a thin film. Such low absorption in a-Si:H has been measured by PDS and CPM.

PL from a-Si:H was observed by *Engemann* and *Fischer* [24.49] for the first time. The quantum efficiency has been found to be of the order of unity [24.50], although it decreases with increasing density of dangling bonds [24.51]. PL spectra from a-Si:H films generally consist of two components. The first is observed as a peak at 1.3−1.4 eV with a full-width at half magnitude (FWHM) of 0.3 eV. The other component, which is called low-energy PL (defect PL), is observed at 0.8−0.9 eV.

Table 24.2 Band gap energies, Urbach tail widths and dark conductivities at room temperature for a-Si:H, a-Ge:H and related materials

Material	E_g (eV)	E_U (meV)	σ (300 K) (Ω^{-1} cm^{-1})	References
a-Si:H	1.75	48	10^{-11}	[24.41, 42]
a-Ge:H	1.05	50	10^{-4}	[24.41, 42]
a-$Si_{0.7}C_{0.3}$:H	2.28	183.4		[24.43]
a-$Si_{0.8}C_{0.2}$:H	2.2		10^{-15}	[24.44]
a-$Si_{0.4}N_{0.6}$:H	3.0	≈ 200	≈ 10^{-8}	[24.45–47]
a-$Si_{0.74}N_{0.26}$:H	≈ 2.0	≈ 100	1.4×10^{-8}	[24.45, 46, 48]

The origin of the main peak has not been fully understood. Electrons and holes in the tail states may give rise to this PL. *Dunstan* and *Boulitrop* [24.52] have shown that the PL spectra of a-Si:H can be understood without considering electron–phonon coupling. However, the electron–phonon coupling has still been discussed. *Morigaki* proposed a model on the basis of ODMR measurements [24.14] in which self-trapped holes and tail electrons are the origin of the PL at low temperatures [24.53], while tail holes and tail electrons participate in the PL at high temperatures.

In the case of radiative recombination of localized electron–hole pairs the lifetime depends exponentially on the separation of the electron and the hole, as described in Sect. 24.3.1. When the spatial distribution of electrons and holes is random, a broad lifetime distribution is predicted. This model describes some properties well, e.g., the generation-rate dependence of the lifetime. However, it has been pointed out that we have to consider the PL from specific electronic states such as excitonic PL to understand the lifetime distribution at low generation rate [24.54–56]. PL due to triplet excitons in a-Si:H has been suggested by optically detected magnetic resonance measurements [24.57, 58]. The PL from singlet excitons, which is expected to have lifetime of about 10 ns, has also been reported [24.59–61].

The low-energy PL is emission from deep gap states created by defects. However the origin of low-energy PL is not neutral dangling bonds (T_3^0) of Si since they act as nonradiative centers, as has been suggested from optically detected magnetic resonance [24.62]. *Yamaguchi* et al. [24.17, 18] proposed a model in which the origin of the low-energy PL is $T_3^+ - N_2^-$ pairs.

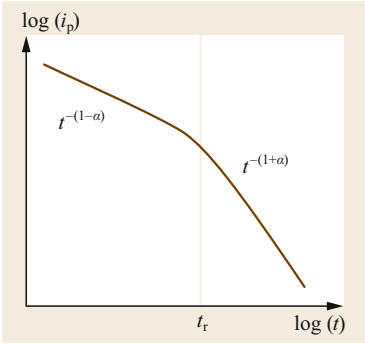

Fig. 24.12 Schematic illustration of the transient photocurrent curve for the dispersive transport

The drift mobility of carriers, i. e., electrons and holes, in a-Si:H has been measured by the method of time of flight (TOF), using blocking electrodes [24.63]. In the measurement, carriers are created by an optical pulse near one of the electrodes and run as a sheet-like shape against another electrode. The transient photocurrent i_p associated with a pulsed optical excitation exhibits a dispersive behavior, as shown in Fig. 24.12 [24.63, 64], which is given by

$$i_p \propto t^{-(1-\alpha)} \quad \text{for} \quad t < t_r \tag{24.3}$$

and

$$i_p \propto t^{-(1+\alpha)} \quad \text{for} \quad t > t_r \,, \tag{24.4}$$

where t_r designates the transit time, as shown in Fig. 24.12, given by

$$t_r = \frac{L}{\mu_d F} \,, \tag{24.5}$$

in which L, μ_d and F are the separation of the two electrodes, the drift mobility and the magnitude of the electric field, respectively. In dispersive conduction, the drift mobility depends on the thickness of the samples. This is due to dispersive carrier processes, which are caused by dispersion of the flight time. Band conduction with multiple trapping of carriers also exhibits dispersive conduction, as was observed in a-Si:H and chalcogenide glasses. For undoped a-Si:H, the drift mobility was on the order of 1 cm^2/V at room temperature. $\alpha = 0.51$ was obtained as 160 K [24.11]. This transient behavior depends on temperature, i. e., it becomes more dispersive at lower temperatures. α is related to the exponential tail width (normally equal to E_U) $E_c \equiv k_B T_c$ as follows

$$\alpha = \frac{T}{T_c} \,. \tag{24.6}$$

From the value of α, the tail width of the conduction band has been obtained to be 25 meV. For hole transport, dispersive behavior has also been obtained and a drift mobility of the order of $10^{-2}\,cm^2/V$ has been obtained at room temperature.

For the steady-state photoconductivity of undoped a-Si:H, it has been generally accepted that photoconduction occurs through electrons in the conduction band at temperatures above ≈ 60 K and through hopping of tail electrons at temperatures below ≈ 60 K. The detailed processes of trapping and recombination of carriers involved in photoconduction have been discussed in many literatures (see, e.g., *Morigaki* [24.2]; *Singh* and *Shimakawa* [24.3]). In relation to this issue, spin-dependent photoconductivity measurements are very useful, and have therefore been extensively performed on a-Si:H [24.68–70].

24.3.3 Chalcogenide Glasses

As mentioned in Sect. 24.3.1, the absorption coefficient for the interband transition in many chalcogenide glasses is well described by Tauc's relationship (24.1). The optical gap E_g is shown in Table 24.3 for various chalcogenide glasses. The effect of light on optical absorption in chalcogenide glasses is known as

Table 24.3 Band gap energies, drift mobilities, and dark conductivities at room temperature for chalcogenide glasses [24.2]

photo-darkening. This effect will be briefly reviewed in Sect. 24.5.

PL has been observed in a-Se, arsenic chalcogenide glasses and germanium chalcogenide glasses. PL in chalcogenide glasses is known to have a large Stokes shift. The peak energy in the PL spectra is approximately half of the band gap. This Stokes shift has been attributed to strong electron–phonon coupling [24.71]. The electronic states responsible for the PL have not been well understood. There has been some experimental evidence for PL from self-trapped excitons. The observation of triplet excitons has been reported in ODMR measurements for chalcogenide glasses such as As_2S_3 and As_2Se_3 [24.72–74].

Dispersive transport was observed in the transient photocurrent for the first time for chalcogenide glasses such as a-As_2Se_3, in which the hole transport dominates over the electron transport [24.63]. The drift mobility of holes ranges between 10^{-3}–$10^{-5}\,\mathrm{cm^2/V}$, depending on the temperature and electric field. The zero-field hole mobility at room temperature is about $5\times10^{-5}\,\mathrm{cm^2/V}$. The steady-state photoconduction in a-As_2Se_3 has been considered to be governed by charged structural defects such as VAPs.

24.4 Electrical Properties

24.4.1 General Aspects

Electrical Conductivity

Electrical conduction in amorphous semiconductors consists of band conduction and hopping conduction. Band conduction in undoped amorphous semiconductors is characterized by

$$\sigma = \sigma_0 \exp\left(-\frac{E_\mathrm{a}}{k_\mathrm{B}T}\right), \tag{24.7}$$

where σ and σ_0 are the electrical conductivity and a prefactor, respectively, and E_a, k_B and T are the activation energy, the Boltzmann constant and the temperature, respectively. E_a is given by either $E_\mathrm{c}-E_\mathrm{F}$ or $E_\mathrm{F}-E_\mathrm{V}$, depending on whether electrons or holes are considered, where E_c, E_V and E_F are the mobility edges of the conduction band and the valence band, and the Fermi energy, respectively. Hopping conduction in amorphous semiconductors consists of nearest-neighbor hopping and variable-range hopping [24.1]. Nearest-neighbor hopping is well known in crystalline semiconductors, in which electrons (holes) hop to nearest-neighbor sites by emitting or absorbing phonons. Variable-range hopping is particularly associated with tail states, in which electrons (holes) in tail states hop to the most probable sites. This type of hopping conductivity σ_p is characterized by the following temperature variation

$$\sigma_\mathrm{p} = \sigma_{\mathrm{p}0} \exp\left(-\frac{B}{T^{1/4}}\right). \tag{24.8}$$

The Hall Effect

The Hall effect is used for the determination of carrier density and its sign in crystalline semiconductors. For amorphous semiconductors, however, the sign of the Hall coefficient does not always coincide with that of the carriers [24.75]. Such a sign anomaly has been observed in a-Si:H, as will be shown in Sect. 24.4.2.

Thermoelectric Power

The thermoelectric power S associated with band conduction of electrons is given by

$$S = -\frac{k_\mathrm{B}}{e}\left(\frac{E_\mathrm{c}-E_\mathrm{F}}{k_\mathrm{B}T}+A\right), \tag{24.9}$$

where A is a quantity depending on the energy dependence of the relaxation times associated with electrical conduction. For hole conduction, S is given by (24.9) except that $E_\mathrm{c}-E_\mathrm{F}$ is replaced by $E_\mathrm{F}-E_\mathrm{V}$ and that the sign of S is positive. The sign of S coincides with that of the carriers. The thermoelectric power S (24.9) is related to the electrical conductivity σ (24.7) as follows [24.76]

$$\ln\sigma + \left|\frac{e}{k_\mathrm{B}}S\right| = \ln\sigma_0 + A \equiv Q\,. \tag{24.10}$$

The temperature-dependent quantity Q is defined as above. The activation energies of σ and S, E_σ and E_S, are equal to each other. Then, Q is defined by Q_0 as follows

$$Q = \ln\sigma_0 + A \equiv Q_0\,. \tag{24.11}$$

However, if E_σ is not equal to E_S, Q is generally expressed by

$$Q = Q_0 - \frac{E_Q}{k_\mathrm{B}T} \tag{24.12}$$

$$E_Q = E_\sigma - E_S\,. \tag{24.13}$$

It has been generally observed that E_σ is greater than E_S, i. e., $E_\sigma > E_S$. This has been accounted for in terms of long-range fluctuation of the band edge. The electrical conduction is due to those carriers that are thermally

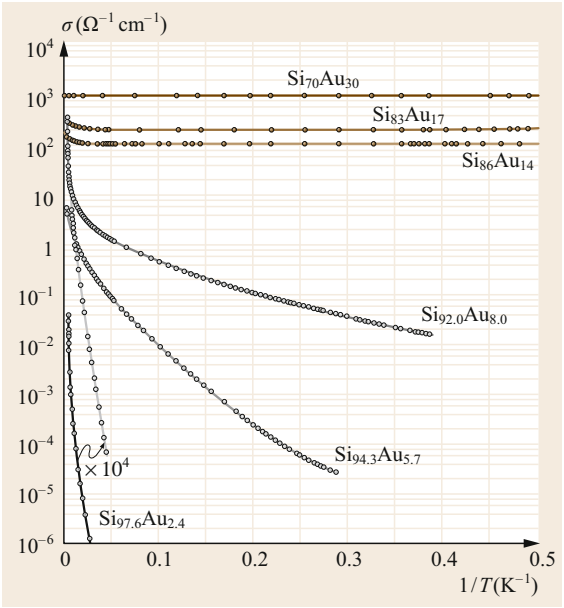

Fig. 24.13 Temperature dependence of the electrical conductivity for an a-Si_xAu_{1-x} film. (After [24.77])

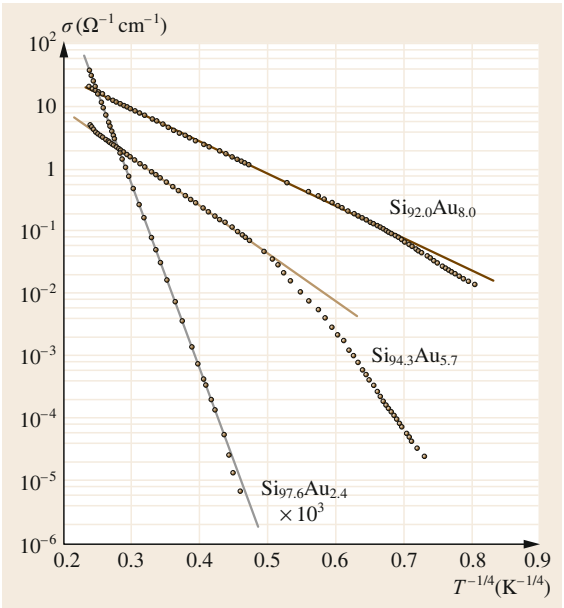

Fig. 24.14 Electrical conductivity versus $T^{-1/4}$ for a-Si_xAu_{1-x} films. (After [24.77])

excited into the valley of the band-edge fluctuation and cross over its barrier, while the thermoelectric power, i. e., transport of phonon energy by carriers, is governed by carriers in the valleys. Thus, a relationship of $E_\sigma > E_S$ can be accounted for in terms of long-range fluctuation of the band edge [24.76].

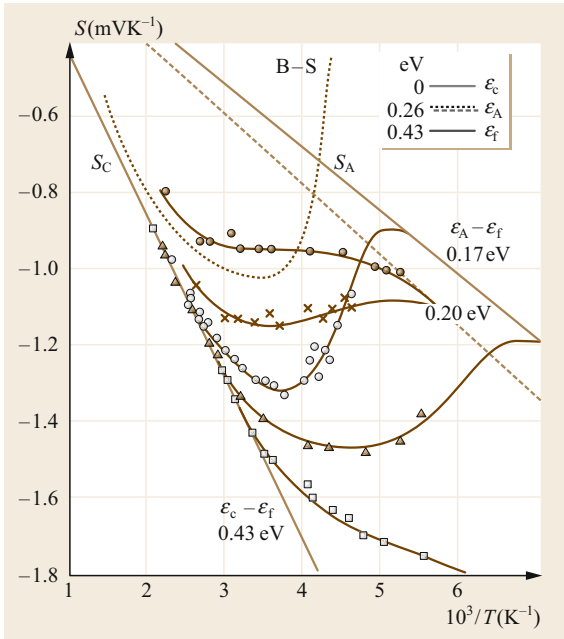

Fig. 24.15 Thermoelectric power versus T^{-1} for various a-Ge:H films. The *solid lines* are the calculated results. The *insert* shows the model on which the calculations are based. Carriers in states just above E_A move in extended states, those at E_A move by hopping. The *dotted curve* marked B–S was obtained by *Beyer* and *Stuke* [24.78] for a slowly evaporated sample annealed at 310 °C [24.79]

Drift Mobility

The drift mobility of carriers is measured by the TOF method, as mentioned in Sect. 24.3.2. The drift mobility μ_d is estimated from (24.5).

In the following, the electrical properties of a-Si:H and related materials and chalcogenide glasses are described.

24.4.2 a-Si:H and Related Materials

A typical example of band conduction and variable-range hopping conduction is shown in Fig. 24.13, which is the temperature dependence of the electrical conductivity for a-Si_xAu_{1-x} films prepared by vapor evaporation [24.77]. Band conduction occurs at high temperatures and variable-range hopping conduction at low temperatures. The $T^{-1/4}$ law of temperature variation of electrical conductivity is clearly seen in Fig. 24.14. The values of the dark conductivities of a-Si:H, a-Ge:H and related materials at room temperature are shown in Table 24.2. Figure 24.15 shows the temperature dependencies of S for a-Ge:H, in which two slopes of the curve of S versus T^{-1} are seen with 0.43 eV in the high-temperature range and 0.17 eV in

the low-temperature range [24.79]. This crossover of two slopes is accounted for in terms of two different mechanisms of electrical conduction, i. e., band conduction at high temperatures and hopping conduction in the band-tail states at low temperatures [24.80]. In amorphous semiconductors, doping control is generally difficult, because the constituent atoms obey the so called $8-N$ rule to satisfy the coordination of covalent bonds with their neighboring atoms. In a-Si:H, however, n-type doping and p-type doping were performed by using phosphorus (group V element) and boron (group III element), respectively [24.81].

The Hall coefficient of a-Si:H has been measured [24.75]. In crystalline semiconductors, when the carriers are electrons, its sign is negative, and when the carriers are holes, its sign is positive. The sign of the Hall coefficient is generally negative irrespective of that of the carriers in amorphous semiconductors. This has been accounted for in terms of the random phase model [24.82]. However, for the Hall coefficient of a-Si:H, this is not the case, i. e., when the carriers are electrons, the sign is positive, and when the carriers are holes, the sign is negative. Such an anomalous Hall coefficient in a-Si:H is called double reversal of the Hall coefficient and has been accounted for, taking into account antibonding orbitals for electrons and bonding orbitals for holes [24.83].

24.4.3 Chalcogenide Glasses

The values of the dark conductivities of chalcogenide glasses at room temperature are shown in Table 24.3 along with those of μ_d at room temperature. In chalcogenide glasses, the Fermi level is pinned near the midgap and this has been considered to be due to VAP defects with negative correlation energy. Thus, doping seems difficult, except for a few cases, e.g., the incorporation of Bi into a-Ge:S and a-Ge:Se increases the direct current (DC) conductivity by 6–7 orders of magnitude [24.84, 85]. This doping effect is due to chemical modification instead of conventional doping. Furthermore, Cd–In–S chalcogenide glasses exhibit $\sigma \approx 1\times10^{-2}\,\Omega^{-1}\,\mathrm{cm}^{-1}$ at room temperature [24.67].

24.5 Light-Induced Phenomena

Light-induced phenomena in amorphous semiconductors were first observed for chalcogenide glasses as photo-darkening, PL fatigue and photostructural changes associated with illumination whose energy equals to or exceeds the band-gap energy (see, e.g., *Shimakawa* et al. [24.86]; *Singh* and *Shimakawa*, [24.3]). Photo-darkening is an effect in which the absorption edge shifts towards lower photon energy under illumination, as shown in Fig. 24.16 [24.87]. PL fatique is the decrease of the PL intensity associated with illumination. Photostructural changes are observed as changes of the volume (generally expansion) of the sample with illumination. PL fatigue may be due to light-induced creation of charged structural defects acting as nonradiative recombination centers. For the photo-darkening and the photostructural change, it has been discussed whether they are independent of each other or not. Thus, the origins of these phenomena are still unclear.

Light-induced phenomena in a-Si:H were observed first in the dark conductivity and photoconductivity, i. e., drops in their values after prolonged illumination of band-gap light (the so-called *Staebler–Wronski* effect [24.88]). Subsequently, such phenomena have been observed in PL, optical absorption and ODMR etc. [24.2]. This effect also gives rise to degradation of the performance of amorphous-silicon solar cells, so that this has received great attention from the viewpoint of application. After prolonged illumination, dangling bonds were found to be created [24.89, 90],

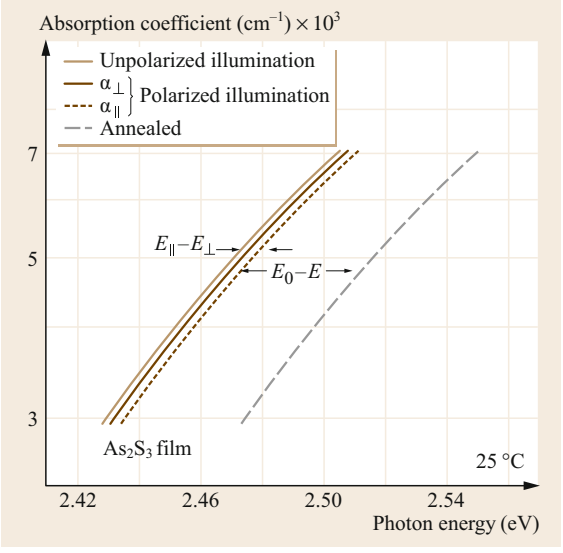

Fig. 24.16 Optical absorption edge of As_2S_3 films annealed or illuminated with unpolarized or linearly polarized light ($\alpha_\perp$: *solid line* and $\alpha_{||}$: *dashed line*). $\alpha_{||}$ and $\alpha_\perp$ refer to polarization along the plane of illumination and perpendicular to it, respectively. (After [24.87])

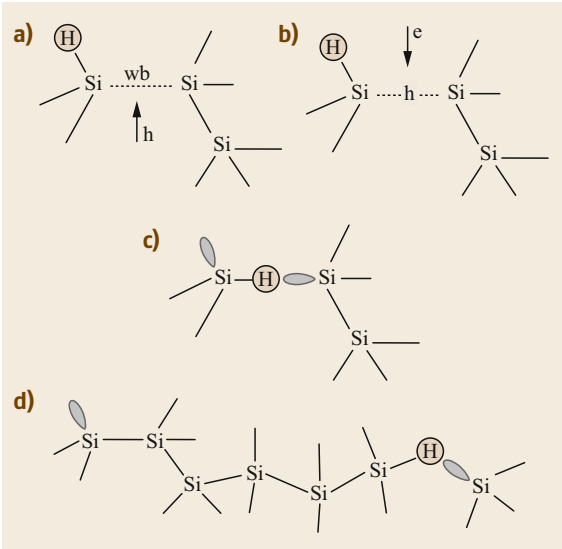

Fig. 24.17 **(a)** Self-trapping of a hole by a weak Si−Si bond adjacent to a Si−H bond. **(b)** Nonradiative recombination of a self-trapped hole with an electron. **(c)** A Si−H bond is switched toward the weak Si−Si bond and a dangling bond is left behind. **(d)** Formation of two separate dangling bonds after hydrogen movements and repeating of processes shown in **(a–c)**

so that light-induced creation of dangling bonds has been considered as the origin of these phenomena. Several models have been proposed for mechanisms for light-induced creation of dangling bonds [24.53, 91–96], but this issue is still controversial (see, e.g., *Morigaki* [24.2]; *Singh* and *Shimakawa* [24.3]). Very recently, the creation of a number of dangling bonds such as 1×10^{19} cm^{-3} after pulsed optical excitation has been observed in high-quality a-Si:H films [24.97, 98]. This result has been accounted for in terms of the authors' model [24.99], based on a combination of the following processes occurring during illumination. Self-trapping of holes in weak Si−Si bonds adjacent to Si−H bonds triggers these weak bonds to break using the phonon energy associated with nonradiative recombination of electrons with those self-trapped holes (Fig. 24.17a,b). After Si−H bond switching and hydrogen movement, two types of dangling bonds are created, i. e., a normal dangling bond and a dangling bond with hydrogen at a nearby site, i. e., so-called hydrogen-related dangling bonds (Fig. 24.17c,d). In the latter, hydrogen is dissociated from the Si−H bond as a result of nonradiative recombination at this dangling bond site. Dissociated hydrogen can terminate two types of dangling bonds (Fig. 24.18c,d) or can be inserted into a nearby weak Si−Si bond (Fig. 24.18a). The dependencies of the density of light-induced dangling bonds on illumination time and generation rate have been calculated using the rate equations governing these processes. The results have been compared with experimental results obtained under continuous illumination and pulsed illumination with good agreement. Light-induced structural changes, i. e., volume change [24.100] and local structural changes around a Si−H bond [24.101] have also been observed in a-Si:H and the origins for these changes have been discussed [24.102–104]. Further references are included in [24.105].

24.6 Nanosized Amorphous Structure

Recent technologies have enabled us to control the properties of semiconductors by introducing artificial structures of nanometer size such as quantum wells, quantum wires and quantum dots. The quantum well is formed by preparing multilayers consisting of two semiconductors. Figure 24.19a illustrates the conduction and valence band edges in such multilayers consisting of two semiconducting materials with different band gaps, plotted as functions of the distance from the substrate z. The curves of the conduction and valence bands in Fig. 24.19a are considered to be the potentials for the electrons and holes, respectively. The motion of the electrons and holes is assumed to be described by effective mass equations which are similar to the Schrödinger equation. When the barriers of the potentials are high enough to prevent the carriers from moving to the adjacent well, the quantum levels (for motion along the z-axis) are as illustrated in Fig. 24.19a. The band gap of the multilayer E_g is equal to the separation of the quantum levels of the lowest energy in the conduction and valence bands, as shown in Fig. 24.19a. E_g increases with decreasing thickness of the well layer L_w; this is well known as the quantum-size effect. When the height of the barrier is infinite, $\Delta E = E_g - E_{gw}$ is proportional to L_w^{-2}, where E_{gw} denotes the band gap of the material of the well layer.

Multilayers of various amorphous semiconductors have been prepared. Observation of the quantum size effect has been reported in some amorphous semiconducting multilayers. For example, the shift of the optical gap of an a-Si:H/a-$Si_{1-x}N_x$:H multilayer from that of a-Si:H, ΔE, is proportional to L_w^{-2}, where L_w is the thickness of the a-Si:H layers (e.g., *Morigaki* [24.2]; see *Yamaguchi* and *Morigaki* [24.106]; and references therein). The result, $\Delta E \propto L_w^{-2}$, is consistent with quantum size effect in a square-well potential.

In the case of amorphous semiconductors, it is easy to introduce a potential well of arbitrary shape, because the optical gap of the amorphous semiconducting alloy, which depends on the composition, can be varied continuously within a certain range. The authors have prepared a new type of a-Si:H-based film called band-edge modulated (BM) a-$Si_{1-x}N_x$:H, in which the potentials for electrons and holes are sinusoidal functions of z [24.107, 108]. The band-edges for the BM films are illustrated in Fig. 24.19b. In this case, the quantum size effect is also expected, similarly to the case of multilayer films. However, the quantum levels and the size dependencies of the band gap are different from those in the case of multilayer films. In the case of BM, the potential is approximately parabolic at the bottom of the well. In this case the quantum levels have the same separation as that illustrated in Fig. 24.19b. We expect that the shift of the optical gap in BM films ΔE will be proportional to L^{-1}, where L denotes the modulation period. The band gap of BM films observed in experiments are in agreement with that expected from the above consideration [24.107]. Parabolic potentials in crystalline semiconductors have also been introduced (see *Gossard* et al. [24.109]). However it is difficult to obtain such structures that are small enough to observe significant quantum effects in crystalline semiconductors.

Recently, preparation of amorphous silicon quantum dots in silicon nitride has been reported [24.110]. Theoretical calculations for silicon nanostructures [24.111] have predicted that the oscillator strength in low symmetry is larger than that in high symmetry. A large quantum efficiency for PL is expected in the case of amorphous quantum dots. Thus, amorphous quantum wires and dots have potential applications in light-emitting devices with high efficiency.

Chalcogenide glasses multilayers have been prepared [24.112–114], whose optical properties such as optical absorption and PL, and electrical properties have been measured.

Acknowledgments. We wish to thank M. Ichihara, K. Suzuki and M. Yamaguchi, Institute for Solid State Physics, University of Tokyo, for providing us with their unpublished materials (Fig. 24.7a,b). Stimulating and helpful discussions were held with Prof. S. Kugler during the stay of one of us (K.M.) at the Budapest University of Technology and Economics, for which K.M. is grateful.

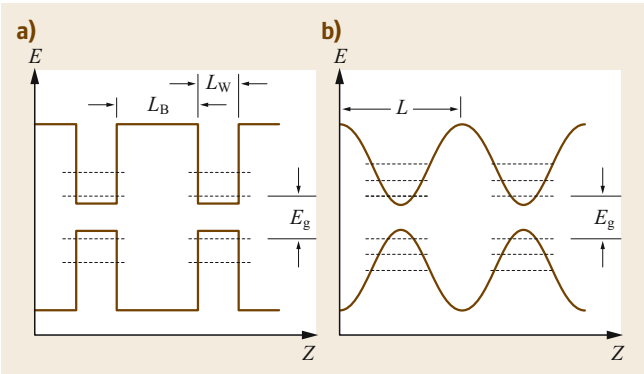

Fig. 24.19 The edges of the conduction and valence bands in **(a)** multilayer films and **(b)** band-edge modulated films, as functions of z, where z denotes distance from the substrates. The *dashed lines* indicate quantum levels. The band gap E_g, which increases due to the quantum size effect, is also shown

25. Amorphous and Microcrystalline Silicon

Akihisa Matsuda

Processes used to grow hydrogenated amorphous silicon (a-Si:H) and microcrystalline silicon (μc-Si:H) from SiH_4 and H_2/SiH_4 glow discharge plasmas are reviewed. Differences and similarities between growth reactions of a-Si:H and μc-Si:H in a plasma and on a film-growing surface are discussed, and the process of nucleus formation followed by epitaxial-like crystal growth is explained as being unique to μc-Si:H. The application of a reaction used to determine the dangling-bond defect density in the resulting a-Si:H and μc-Si:H films is emphasized, since it can provide clues about how to improve the optoelectronic properties of those materials for device applications, especially thin-film silicon-based solar cells. Material issues related to the realization of low-cost and high-efficiency solar cells are described, and finally recent progress in this area is reviewed.

Hydrogenated amorphous silicon (a-Si:H) and microcrystalline silicon (μc-Si:H) are recognized as being useful materials for constructing devices related to optoelectronics, such as solar cells, thin-film transistors, etc. [25.1, 2]. Several methods have been proposed for the preparation of device-grade a-Si:H and μc-Si:H. These include: reactive sputtering of a crystalline silicon target with $Ar+H_2$ plasma [25.3]; mercury-sensitized photochemical vapor deposition (CVD) utilizing a decomposition reaction of silane (SiH_4) molecules with photoexcited Hg (Hg*) [25.4]; a direct photo CVD method where high-energy photons from a Xe-resonance lamp or a low-pressure Hg lamp are used for the direct excitation of SiH_4 molecules to excited electronic states [25.5, 6]; a hot-wire CVD method for decomposing SiH_4 by means of catalytic reactions on a heated metal surface [25.7]; and a plasma-enhanced CVD method (PECVD). The PECVD method is the most widely used of these due to its ability to consistently prepare uniform, high-quality materials on a large-area substrate.

In this chapter, the PECVD method is highlighted, details regarding the processes used to grow a-Si:H and μc-Si:H from reactive plasmas are explained, and the determination reaction (which is used to obtain the dangling-bond defect density in the films: one of the most important structural properties that influences device performance) is interpreted in order to obtain clues about how to control the optoelectronic properties of those materials for device applications.

25.1 Reactions in SiH_4 and SiH_4/H_2 Plasmas

The initial event required for the growth of a-Si:H and μc-Si:H is the decomposition of the source gas material in SiH_4 or SiH_4/H_2 glow discharge plasma. Figure 25.1 shows a schematic of the dissociation pathway of SiH_4 and H_2, during which the molecules are excited to higher electronic states due to inelastic collisions with high-energy electrons in the plasma [25.8]. As the electrons in the plasma usually have a wide variety of energies, from zero to several tens of electron volts (eV), ground-state electrons of source gas molecules are excited into their electronic excited states almost simultaneously due to inelastic collisions with energetic electrons. Excited electronic states of complicated molecules like SiH_4 are usually dissociating states, from which dissociation occurs spontaneously to SiH_3, SiH_2, SiH, Si, H_2 and H, as shown in Fig. 25.1, depending on the stereochemical structure of the excited state. Hydrogen molecules are also decomposed to atomic hydrogen. Excitation of ground-state electron to vacuum-state gives rise to ionization events, generating new electrons and ions, which maintains the plasma.

Reactive species produced in the plasma also experience secondary reactions, mostly with parent SiH_4 and H_2 molecules, as shown in Fig. 25.2, resulting in a steady state. Reaction-rate constants for each reaction are summarized in the literature [25.9]. Steady-state densities of reactive species are basically determined by the balance between their generation and annihilation rate. Therefore, highly reactive species such as SiH_2, SiH and Si (short-lifetime species) have much smaller densities than SiH_3 in the steady-state plasma, although the generation rates of those species are not very different from that of SiH_3 showing low reactivity along with SiH_4 and H_2 (long-lifetime species).

Steady-state densities of reactive species have been measured using various gas-phase diagnostic techniques [25.10–16], such as optical emission spectroscopy (OES) [25.10], laser-induced fluorescence (LIF) [25.12], infrared laser absorption spectroscopy (IRLAS) [25.13], and ultraviolet light absorption spectroscopy (UVLAS) [25.16]. Figure 25.3 shows the steady state number densities of the chemical species, including both emissive and ionic species, in the SiH_4 and SiH_4/H_2 plasmas used to prepare device-grade a-Si:H and μc-Si:H. It is clear from Fig. 25.3 that the SiH_3 radical is the dominant chemical species in the growth of both a-Si:H and μc-Si:H, although the density ratio of short-lifetime species to SiH_3 changes depending on the conditions used to generate the plasma. For instance, when high electric power is supplied to the plasma (high electron density) under low SiH_4 flow rate conditions, SiH_4 is rapidly dissociated and then depleted, giving rise to reduced probabilities of gas-phase reactions of short lifetime species with SiH_4 molecules. This leads to an increased contribution of short-lifetime species to the film growth, which causes a deterioration of the structural properties of the resulting films.

The steady-state density of atomic hydrogen (H) varies widely in the plasma, as shown in Fig. 25.3. This is mainly due to the change in the hydrogen dilution

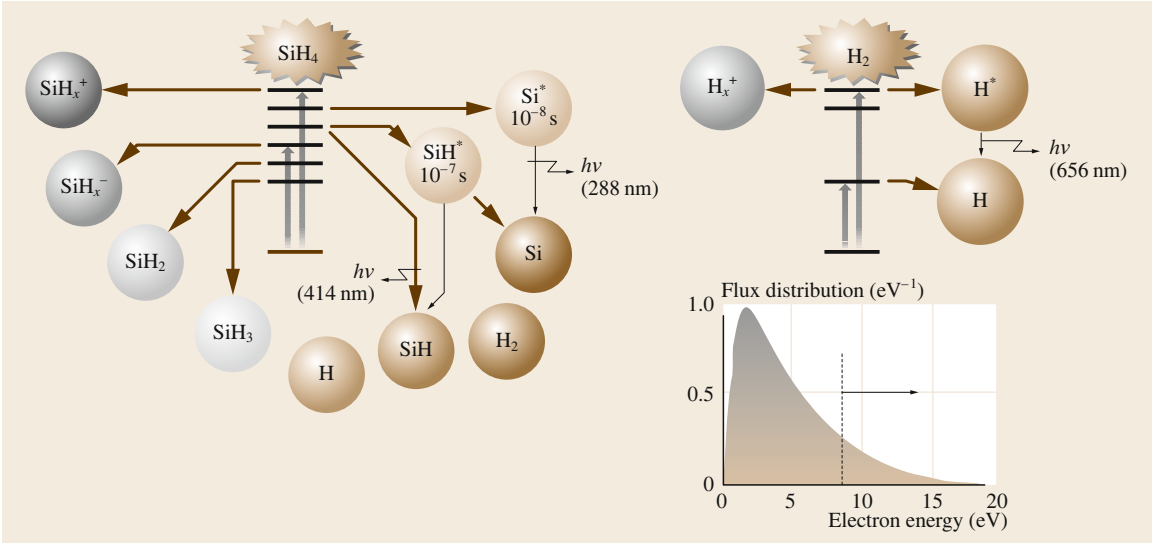

Fig. 25.1 Schematic showing the dissociation of SiH_4 and H_2 molecules to a variety of chemical species in the plasma via excited electronic states. The electron energy distribution function in the plasma is also shown

Ion exchanging	$SiH_x^+ + SiH_4$	$SiH_x + SiH_4^+$
Ion–Molecule	$SiH_x + SiH_4$	$SiH_3 + SiH_3$
Neutral–Molecule	$SiH + SiH_4$	Si_2H_5
Disproportionation	$Si + SiH_4$	$SiH_3 + SiH$
Insertion	$SiH_2 + SiH_4$	Si_2H_6
Recombination	$SiH_2 + H_2$	SiH_4
Abstraction	$SiH_3 + SiH_4$	$SiH_4 + SiH_3$
	$H + SiH_4$	$H_2 + SiH_3$
Ion–Radical, Radical–Radical	less probable	

Fig. 25.2 Representative secondary reactions of the chemical species produced in the plasma with SiH_4 and H_2 molecules. Their reaction rate constants are available in the literature

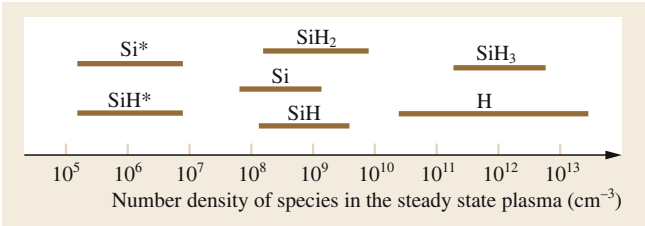

Fig. 25.3 Number densities of chemical species in realistic steady-state plasmas measured or predicted by various diagnostic techniques

ratio R (H_2/SiH_4) in the source gas material, i. e., the density of atomic hydrogen increases with increasing R. Noting the fact that more μc-Si:H is formed with increasing R at constant electron density in the plasma and constant substrate (surface) temperature, it is clear that atomic hydrogen plays an important role in μc-Si:H growth [25.17] although SiH_3 is the dominant film precursor for both a-Si:H and μc-Si:H growth [25.18].

25.2 Film Growth on a Surface

25.2.1 Growth of a-Si:H

Upon reaching a film-growing surface, some of the SiH_3 is reflected at the surface, while the remaining SiH_3 is adsorbed on the surface. Some adsorbed SiH_3 molecules interacts with the surface hydrogen at its landing site, forming SiH_4 and leaving dangling bonds on the surface. This is known as growth-site formation. Other adsorbed SiH_3 radicals begin to diffuse across the surface to find the site containing the dangling bonds, whereupon Si–Si bond formation (film growth) occurs, as shown schematically in Fig. 25.4. This surface reaction scheme for film growth has been proposed on the basis of two experimental results [25.18].

Figure 25.5 shows the general concept of the surface-reaction process. Some the flux of SiH_3 is reflected off the surface (the proportion of molecules reflected is given by the reflection probability). The remaining SiH_3 is adsorbed onto the surface and it changes its form as follows:

1. SiH_3 abstracts bonded H from the surface, forming SiH_4, or two of the SiH_3 radicals interact on the surface, forming Si_2H_6 (with a recombination probability γ);
2. Surface-diffusing SiH_3 sticks to the site containing the dangling bond, forming Si–Si bond (with a sticking probability s).

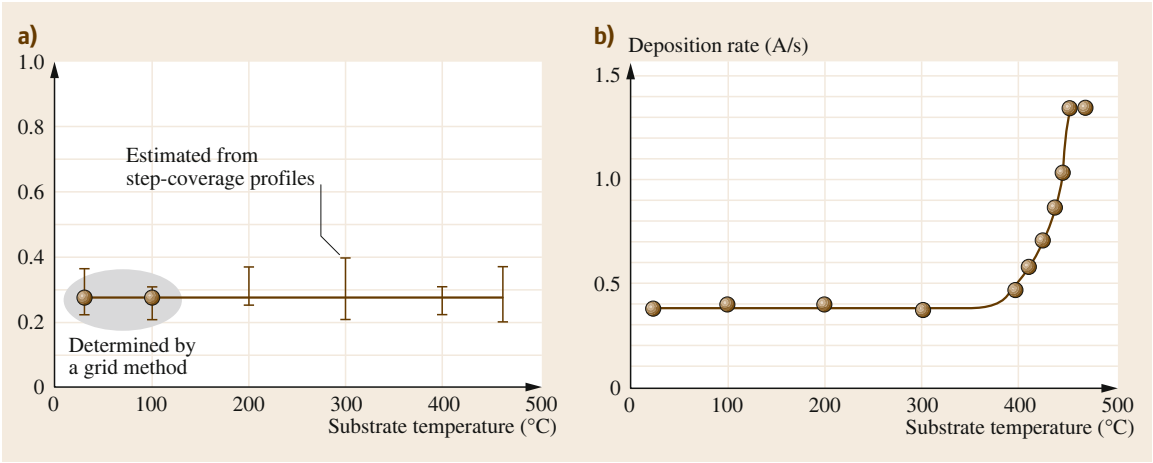

Fig. 25.6 Loss probability β **(a)** of SiH_3 radicals reaching the film-growing surface, as measured using the grid method and the step-coverage method, and the deposition rate (corresponding to the sticking probability s for SiH_3) **(b)** as a function of substrate temperature during the growth of a-Si:H

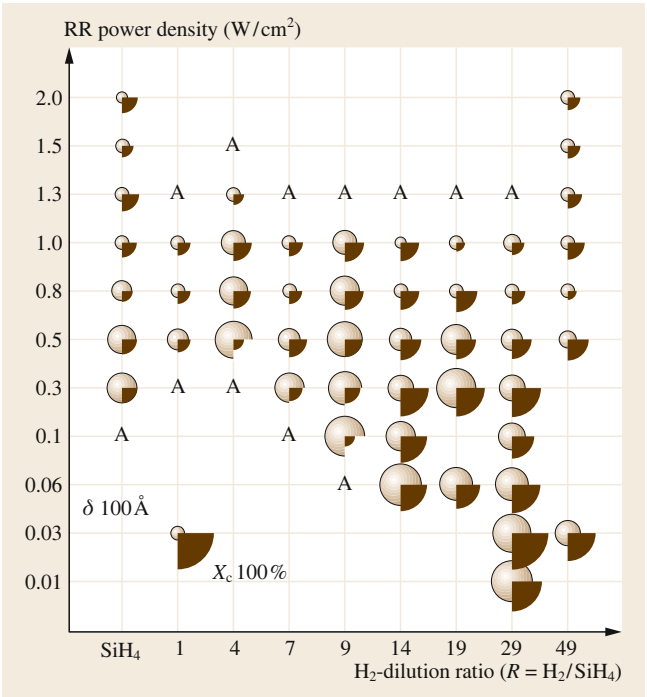

Fig. 25.7 Crystal size (*light*: δ) and volume (*dark*: X_c) of microcrystallites in the resulting films, mapped out on the RF power density/hydrogen dilution ratio plane

The total loss probability (β) is given by the sum of recombination probability and the sticking probability ($\gamma + s$), and the reflection probability is therefore $1-\beta$. Among the reaction probabilities mentioned above, the loss probability has been measured using a grid method (GM) as well as a step-coverage method (SCM). Figures 25.6a and 25.6b show the loss probabilities obtained by GM and SCM, as well as the sticking probability predicted from the film deposition rate as a function of the substrate temperature, respectively.

The loss probability β, related to the reflectivity $(1-\beta)$, is simply dependent on the nature of the site where SiH_3 from the plasma lands. Therefore, the temperature-independent $1-\beta$ seen in Fig. 25.6 suggests that almost all of the surface sites are covered with bonded H over the whole temperature range used in the experiment, although a few dangling bonds are created thermally above 350 °C, as shown by in situ infrared reflection absorption spectroscopy (IRRAS) [25.19]. On the other hand, SiH_3 diffusing across the surface is easily captured by even just a few dangling bonds, because a mobile species on the surface can find a specific site at a distant location from the landing site.

The temperature-independent behavior of $1-\beta$ and the temperature-dependent behavior of s observed in Figs. 25.6a and 25.6b have been perfectly reproduced by theoretical simulations based on the surface-reaction scheme shown in Fig. 25.4, assuming reasonable activation energies for the surface diffusion of SiH_3, the abstraction reaction of H with SiH_3, the saturation of the site containing the dangling bond with SiH_3, and thermal H-removal processes [25.20].

25.2.2 Growth of μc-Si:H

Atomic hydrogen reaching the film-growing surface plays an important role in the growth of μc-Si:H. This has been confirmed in the μc-Si:H-formation map drawing on the radio frequency (RF) power den-

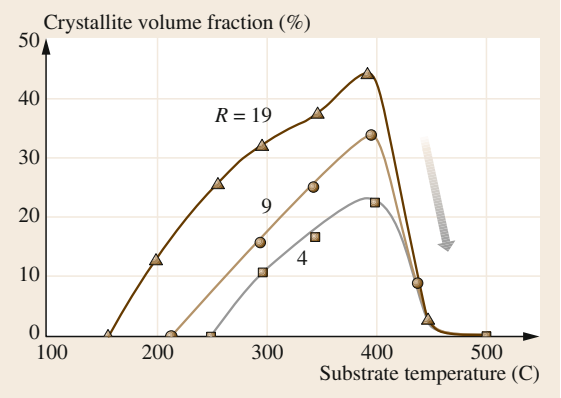

Fig. 25.8 Volume (X_c) of microcrystallites in the resulting films plotted against the substrate temperature during film growth

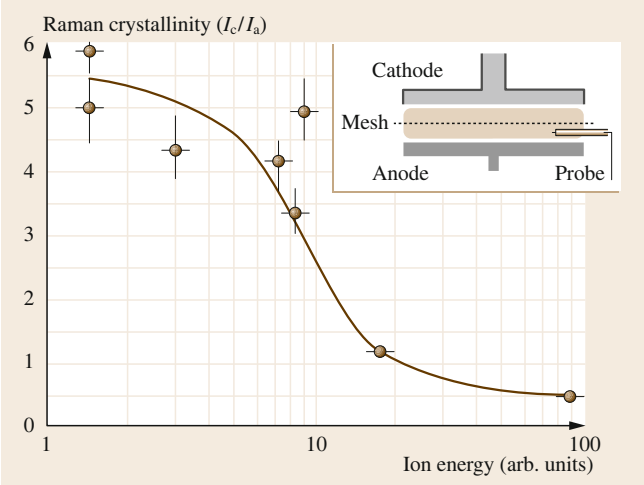

Fig. 25.9 Raman crystallinity in the resulting μc-Si:H as a function of the energy of the ions impinging on the film-growing surface (which is controlled by the application of the positive bias voltage to the mesh electrode during film growth)

sity/hydrogen dilution ratio plane as shown in Fig. 25.7. As seen in the figure, large-crystallite μc-Si:H is prepared under high hydrogen dilution conditions, indicating the importance of atomic H in the growth of μc-Si:H. Figure 25.8 shows the crystalline volume fraction (determined by the x-ray diffraction peak area) in the resulting μc-Si:H as a function of the substrate temperature during film growth for three different hydrogen dilution ratios [25.17]. The crystalline volume fraction increases with increasing substrate temperature, reaching a maximum at around 350 °C, and then suddenly drops to zero above 500 °C. The lack of μc-Si:H formation above 500 °C suggests that surface hydrogen coverage is a requirement for crystallite formation in the resulting film [25.17].

Figure 25.9 shows the negative effect of ionic species impinging on the film-growing surface on the formation of μc-Si:H, studied using a triode reactor, as shown in the inset of the figure [25.21]. The Raman crystallinity I_c/I_a, defined as the ratio of the peak intensity from the crystalline phase at around 520 cm^{-1} to that from the amorphous phase at 480 cm^{-1} in the Raman scattering spectrum, deteriorates as the energy of the ionic species impinging on the film-growing surface (controlled by the bias voltage applied to the mesh electrode) is increased.

The surface reaction behavior of SiH_3 reaching the film-growing surface has also been investigated for μc-Si:H growth using GM and SCM, in contrast to a-Si:H growth [25.18]. Figures 25.10a and 25.10b show the loss probability (β) and the deposition rate (corresponding to the sticking probability s) of SiH_3 reaching the film-growing surface as a function of the substrate temperature for the growth of both μc-Si:H and a-Si:H. Unlike in the case of a-Si:H growth, the loss probability β shows a significant dependence on substrate temperature and the sticking probability s shows no temperature dependence in the case of μc-Si:H growth.

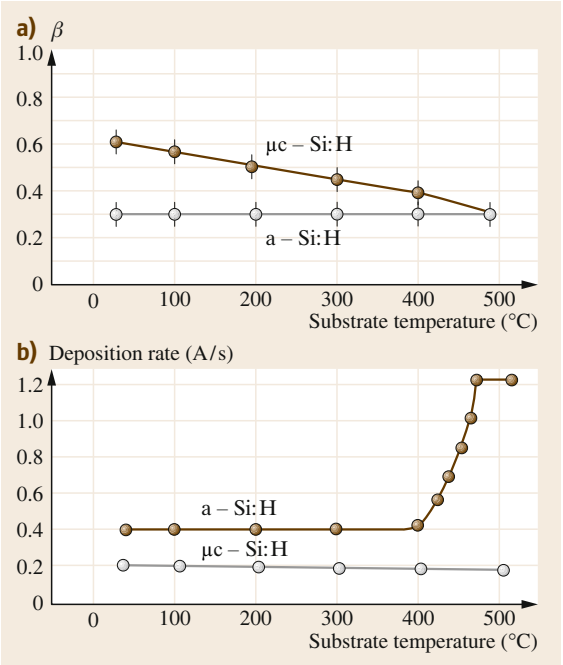

Fig. 25.10 Loss probability β and deposition rate as a function of substrate temperature for μc-Si:H growth in comparison to those for a-Si:H growth

Based on these experimental results, the following properties of the formation process of μc-Si:H can be specified:

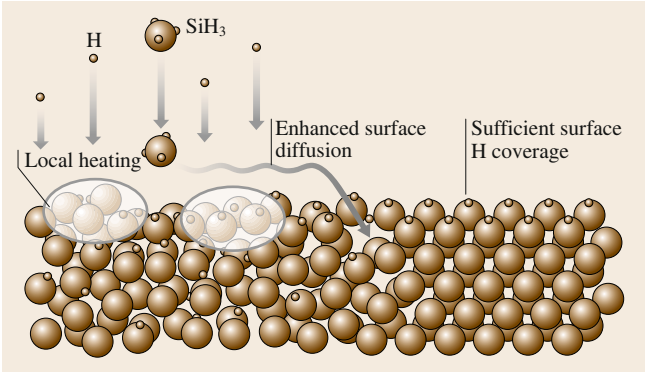

Fig. 25.11 Surface diffusion model for μc-Si:H formation. The *large spheres* and *small spheres* represent Si and H, respectively

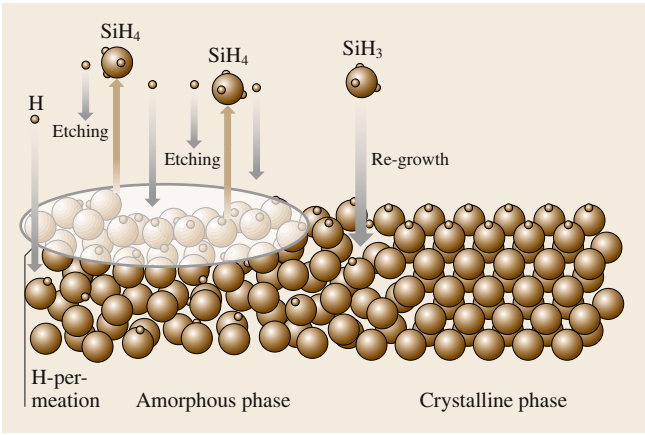

Fig. 25.12 Etching model for μc-Si:H formation

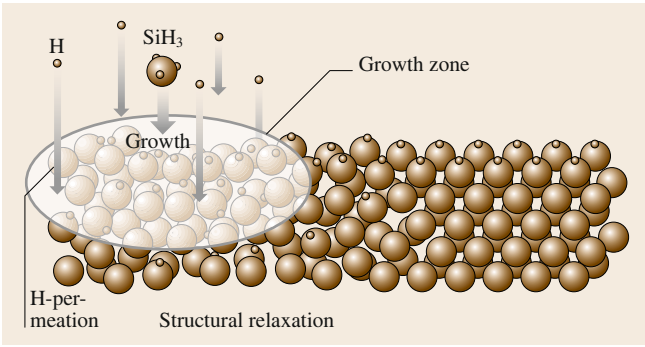

Fig. 25.13 Chemical annealing model for μc-Si:H formation

1. The film precursor is SiH_3, the same as in the case of a-Si:H growth.
2. Atomic hydrogen reaching the film-growing surface plays an important role in the formation of μc-Si:H.
3. The film becomes amorphous when the substrate temperature is higher than 500 °C.
4. High-energy ions impinging on the surface result in crystallinity deterioration.
5. The surface loss probability shows a temperature dependence whereas the sticking probability does not show a temperature dependence in the case of μc-Si:H growth.

Growth Models for μc-Si:H

In an attempt to explain the specific phenomena observed during the formation of μc-Si:H, three models have been proposed:

1. The surface diffusion model [25.17]
2. The etching model [25.22]
3. The chemical annealing model [25.23].

The surface diffusion model is depicted schematically in Fig. 25.11. Here, a high atomic H flux from the plasma results in full bonded hydrogen surface coverage and also local heating through hydrogen exchange reactions on the film-growing surface. These two actions enhance the surface diffusion of film precursors (SiH_3). As a consequence, the SiH_3 adsorbed on the surface can find energetically favorable sites, leading to the formation of an atomically ordered structure (nucleus formation). After the formation of the nucleus, epitaxial-like crystal growth takes place with enhanced surface diffusion of SiH_3 [25.17, 24].

The etching model has been proposed due to the observation that the rate of film growth decreases with increasing hydrogen dilution ratio R. The concept behind the etching model is shown schematically in Fig. 25.12. Atomic H reaching the film-growing surface breaks Si−Si bonds, preferentially weak bonds involved in the amorphous network structure, leading to the removal of Si atoms weakly bonded to other Si atoms. This site is replaced with a new film precursor SiH_3, creating a rigid, strong Si−Si bond, which gives rise to an ordered structure [25.22, 24].

The chemical annealing model has been proposed in order to explain the observation that crystal formation is observed during hydrogen plasma treatment; growth occurs layer-by-layer via an alternating sequence of thin amorphous film growth and hydrogen plasma treatment. Several monolayers of amorphous silicon are deposited, and these layers are exposed to hydrogen atoms produced in the hydrogen plasma. This procedure is repeated several tens of times in order to fabricate the proper thickness to be able to evaluate the film structure. The absence of any significant reduction in film thickness during the hydrogen plasma treatment is difficult to explain using the etching model, and so the chemical annealing model was proposed, as schematically shown in Fig. 25.13. During the hydrogen plasma treatment, many atomic hydrogens permeate through the subsur-

face (the growth zone), giving rise to the crystallization of an amorphous network through the formation of a flexible network without any significant removal of Si atoms [25.23, 24].

These three models have been carefully examined, and the merits and drawbacks of each model have been discussed [25.24, 25].

More microscopic observations have recently been reported, based on the use of in situ diagnostic techniques, and a detailed mechanism for the formation process of μc-Si:H has been proposed.

Formation of the Nucleus

Figure 25.14 shows the evolution in surface roughness during film growth, as obtained by spectroscopic ellipsometry (SE), for three hydrogen dilution ratios R of 0, 10 and 20 [25.26]. As is seen in the figure, after the formation of an island, the enforced coalescence of islands takes place, which results in a smooth surface under μc-Si:H-growth conditions ($R = 20$). After the smooth surface is obtained (formation of the nucleus is confirmed at this point in time), surface roughness is then enhanced due to an orientation-dependent crystal growth rate [25.27]. As soon as the smooth surface appears, a particular surface absorption band is observed in the infrared absorption spectrum, as measured using the in situ attenuated total reflection technique (ATR) during film growth [25.27, 28]. Figure 25.15 shows the surface infrared absorption spectrum, showing the presence of specific bands at 1897 cm^{-1} and 1937 cm^{-1} together with the usual Si−H_x surface and bulk absorption bands (which occur between 2000 cm^{-1} and 2150 cm^{-1}). This new absorption band is assigned to the SiH_2(Sid) complex, which is also sketched in Fig. 25.15. Note that the number density (absorption intensity) of the SiH_2(Sid) complex is found to be proportional to the magnitude of the internal stress in the film just before these complexes appear. A nucleation model has been proposed based on the experimental facts mentioned above. The enforced island coalescence due to the enhanced surface diffusion of SiH_3 gives rise to an internal stress involving many strained Si−Si bonds in the amorphous incubation layer [25.27]. Atomic hydrogen attacks the strained Si−Si bonds, forming SiH_2(Sid) complexes on the film-growing surface. These complexes provide structural flexibility, which enables structural order to be obtained via successive Si−SiH_3 bond formation at this site; in other words it acts as a prenucleation site on the film-growing surface.

Epitaxial-Like Crystal Growth

Figure 25.16 shows a cross-sectional transmission electron microscope (TEM) image of typical μc-Si:H films

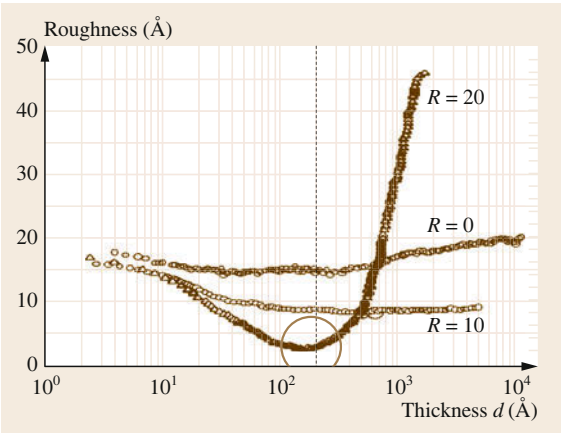

Fig. 25.14 Evolution in surface roughness, as measured using spectroscopic ellipsometry, during film growth for three different R_s

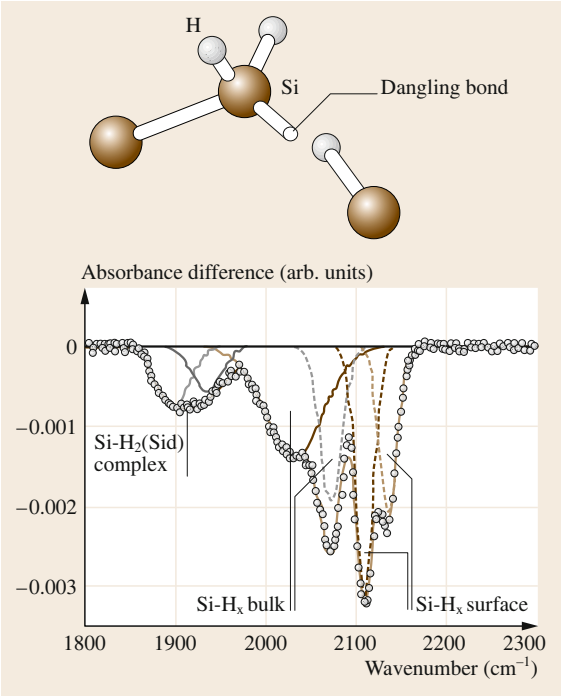

Fig. 25.15 Surface infrared absorption spectrum from the film just before nucleus formation, showing the appearance of the Si−H_2(Sid) complex whose structure is also shown

deposited on a glass substrate [25.29]. In the figure, epitaxial-like crystal growth is clearly observed to occur from the nucleus. It is a well-known fact that epitaxial crystal growth occurs only when the surface diffusion length of the film precursor is sufficiently long. In order to investigate the origin of the enhanced surface diffusion of SiH_3 during the formation of μc-

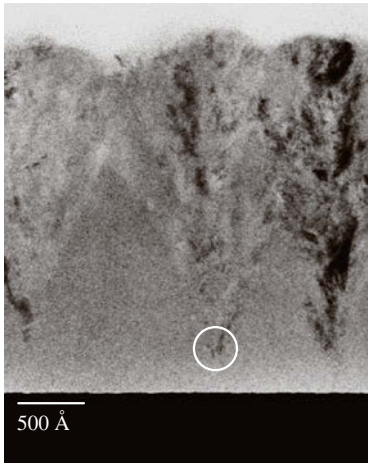

Fig. 25.16 Cross-sectional transmission electron microscope image of typical μc-Si:H deposited on a glass substrate

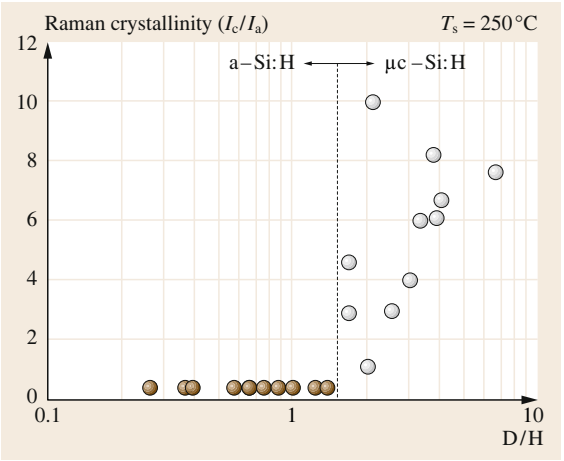

Fig. 25.17 Raman crystallinity plotted against the number density ratio of D/H incorporated into the resulting films prepared from D_2/SiH_4 plasmas

Si:H, an isotope labeling experiment has been carried out [25.30]. D_2 was used as the source gas material (D_2/SiH_4) instead of H_2/SiH_4 during film growth under constant substrate temperature conditions, and the number densities of both D and H incorporated into the resulting film are measured by infrared absorption spectroscopy in order to estimate the degree of H-to-D exchange reactions, which mostly occur on the film-growing surface (and the first layers below).

Figure 25.17 shows the Raman crystallinity I_c/I_a plotted against the number density ratio of the D/H incorporated in the resulting films. As is clearly from the figure, μc-Si:H is obtained only when D/H exceeds a critical value, indicating that the D/H exchange reaction is required to some extent for the formation of μc-Si:H. The D/H exchange reaction involves two steps:

1. Atomic D reaching the film-growing surface abstracts bonded H on the surface (the Eley-Rideal reaction), forming HD and providing a Si dangling bond site;
2. A recombination reaction occurs between the dangling bond and another atomic D adsorbed onto the surface (including the subsurface), forming a Si−D bond.

These abstraction and recombination reactions are known to be strong exothermal reactions, with 1.4 eV and 3.1 eV of energy released, respectively. Considering the highly exothermal nature of the D/H exchange reaction, and the existence of a threshold value for the degree of D/H exchange reactions required for the formation of μc-Si:H, as shown in Fig. 25.17, *local heating* on the film-growing surface is believed to play a major role in the enhanced surface diffusion of the film precursor (SiH_3) during both nucleus formation (strained bond formation and SiH_2(Sid)-complex formation) and the epitaxial-like crystal growth associated with μc-Si:H film growth [25.17, 24, 28, 31].

25.3 Defect Density Determination for a-Si:H and μc-Si:H

One of the most important structural properties of a-Si:H and μc-Si:H for device applications is their dangling bond defect densities, because each dangling bond creates a localized deep state in the band gap of the material, which acts as a recombination center for photoexcited electrons and holes, although the free carrier mobility is another important property in semiconductors.

25.3.1 Dangling Bond Defects

Figure 25.18 shows the dangling bond defect density in the resulting a-Si:H as a function of substrate temperature. This dependency of the dangling bond density on the substrate temperature has been explained by taking into account the steady-state dangling-bond density on the film-growing surface. The structural properties

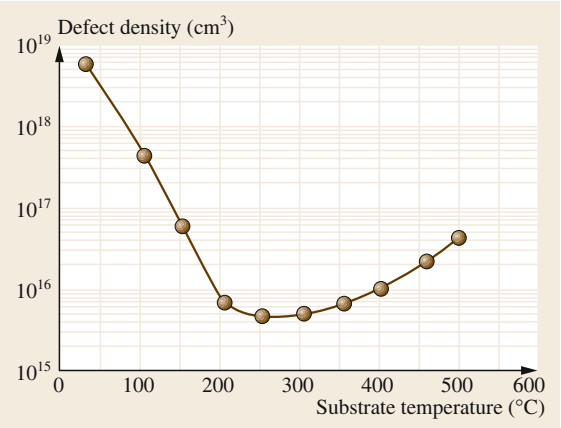

Fig. 25.18 Dangling bond defect density in the resulting a-Si:H films as a function of the substrate temperature during film growth

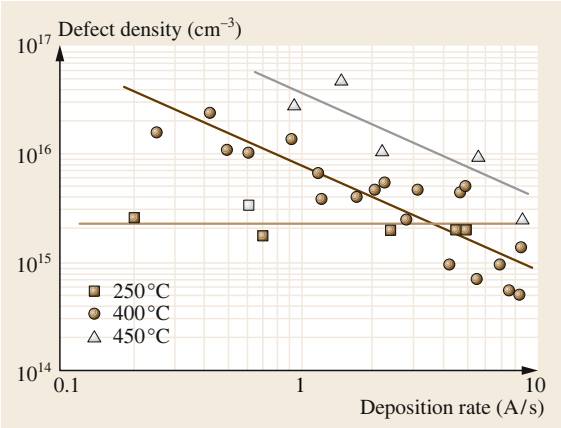

Fig. 25.19 Dangling bond defect density in a-Si:H films plotted against their deposition rates for three different substrate temperatures

of the resulting film are generally largely determined by the steady-state surface properties during the thin film growth process, because the surface formed at any given instant is incorporated into the bulk in the next instant due to the successive layering nature of the film growth [25.32, 33]. The steady state number density of surface dangling bonds is determined by the balance between the rate of generation of dangling bonds and their annihilation rate.

At low substrate temperatures, surface dangling bonds are produced by abstraction reactions of surface bonded H atoms with SiH_3; the reaction rate for this is almost independent of substrate temperature, since the reaction rate involves two rates, i. e., the adsorption rate of SiH_3 on the surface (negative temperature dependence) and dissociation rate of bonded H with SiH_3 (positive temperature dependent). The surface dangling bond is saturated by SiH_3 diffusing across the surface (this is dangling bond annihilation), which exhibits a slower rate at low temperatures due to the slower surface diffusion of SiH_3, which results in high dangling bond density on the steady-state film-growing surface. As a consequence, the dangling-bond density in a-Si:H grown at low substrate temperatures can be as high as $10^{19}\,cm^{-3}$. When the substrate temperature is increased during film growth, the steady state number density of surface dangling bonds is reduced drastically due to the combination of the temperature-independent H-abstraction reaction and the thermally enhanced surface diffusion of SiH_3, which gives rise to a minimum defect density of $10^{15}\,cm^{-3}$ in the resulting a-Si:H at a substrate temperature of $\approx 250\,°C$. The increased dangling bond density of the a-Si:H prepared at substrate temperatures higher than 350 °C is explained by the increased rate of generation of steady-state dangling bonds due to the addition of a new term in the generation rate of these bonds associated with the thermal removal of surface bonded H, although its annihilation rate strictly increases with increasing substrate temperature [25.33, 34].

We note here that a remarkable increase in the contribution from short-lifetime species such as SiH_2, SiH and Si, which show high reactivity and no diffusion on the film-growing surface, is observed upon the depletion of SiH_4-parent molecules, which causes an increase in the number density of dangling bond defects in the resulting films through an enhancement of the dangling bond generation rate and a reduction of the dangling bond annihilation rate on the film-growing surface [25.20, 32].

Based on our understanding of the defect density determination reaction during film growth, several trials have attempted to control the defect density in a-Si:H. The steady state defect density on the film-growing surface could be reduced when the growth rate was much faster than the thermal H removal rate in the substrate temperature range above 350 °C, where the steady state defect density is mainly determined by the thermal H removal process. Figure 25.19 shows the number density of dangling bond defects in a-Si:H films plotted against their growth rate. As expected, the defect density in a-Si:H shows no growth- rate dependence when the film is prepared at substrate temperatures lower than 300 °C, whereas the defect density monotonically decreases with increasing growth rate when the film is deposited at 400 °C and 450 °C, and a defect density of $10^{14}\,cm^{-3}$ has been demonstrated [25.35].

25.3.2 Dangling Bond Defect Density in μc-Si:H

Figure 25.20 shows typical dangling bond defect densities in μc-Si:H as a function of substrate temperature together with those in its a-Si:H counterpart [25.33, 35, 36]. As seen from the figure, the substrate temperature-dependent dangling bond defect density in μc-Si:H in the temperature range above 300 °C shows a similar trend to that for a-Si:H, indicating that the defect determination reaction on the film-growing surface is identical for both μc-Si:H and a-Si:H growth in this temperature range; in other words, the increase in defect density with increasing substrate temperature is controlled by the thermal H removal process on the film-growing surface. On the other hand, the number density of defects in μc-Si:H prepared at low substrate temperatures shows much lower values than those in a-Si:H. Considering that the defect density in the resulting film is largely determined by the defect density on the steady-state film-growing surface, the much lower defect density in μc-Si:H is caused by an increase in the defect annihilation rate (through an enhanced surface diffusion of SiH_3 film precursors) on the film-growing surface due to the local heating from H-exchange reactions that occur during the course of μc-Si:H film growth.

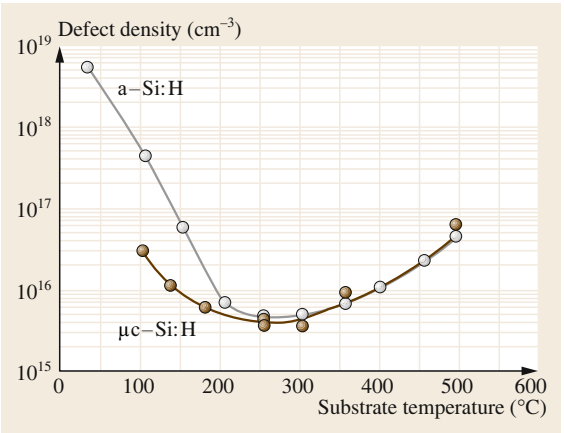

Fig. 25.20 Dangling bond defect density in μc-Si:H films as a function of substrate temperature during film growth in comparison to that in a-Si:H

25.4 Device Applications

a-Si:H and μc-Si:H are highly promising materials applicable to electronic or optoelectronic thin-film devices such as thin-film transistors (TFTs), position sensors, color sensors, solar cells, etc. [25.1, 2].

A thin-film transistor array with a-Si:H active layer has been developed for switching devices in liquid crystal displays (LCD), and large-area LCDs more than 50 in across have already been made commercially available based on this technology. A laser crystallization technique has been developed in order to increase the carrier mobility of a-Si:H-based TFTs and thus reduce the active area of the transistors in the LCD. LCDs with a-Si:H or laser-crystallized thin-film Si-based transistor arrays are widely used as flat panel displays in televisions and monitors, where they are in competition with plasma display panels (PDPs) and other flat panel display systems. If the carrier mobility in as-deposited μc-Si:H is drastically improved through the enhanced control of the film growth process, μc-Si:H will be widely used not only for thin-film transistors but also for signal-scanning devices such as charge-coupled devices monolithically arranged in the periphery of the LCD.

Thin-film Si-based solar cells has also been widely expected to provide low-cost photovoltaics. Actually, a-Si:H-based solar cells have already been widely used in pocket calculators, and now large-area solar cells are being developed for electricity generation. One big advantage of using a-Si:H for solar cell applications is its large optical absorption coefficient compared to single-crystalline or polycrystalline silicon counterparts, showing indirect optical transition properties, and so a thickness of less than 1 μm is enough to absorb sufficient sunlight for electricity generation when using a-Si:H-based solar cells. Low-temperature processes using PECVD are also advantageous in terms of reducing the cost of producing a-Si:H-based solar cells. However, there is a well-known phenomenon that occurs in a-Si:H called photo-induced degradation [25.37], where the conversion efficiency of a-Si:H-based solar cells, usually ≈ 10%, is degraded to less than 8% after prolonged exposure to light. Recombinations photogenerated electrons and holes are believed to trigger this photoinduced degradation in a-Si:H; therefore, increasing the field in the a-Si:H-based solar cell has proved an effective way to reduce the degradation. In fact, 0.1 μm-thick a-Si:H-based solar cells do not show any photoinduced degradation, although the conversion efficiency naturally deteriorates due to the reduced absorption of sunlight. The fabrication of a tandem-type stacked solar cell structure consisting of a top cell with a thin a-Si:H layer and a bottom cell

containing narrow-gap materials such as a-SiGe:H, μc-Si:H and μc-SiGe:H has been proposed as a promising way to overcome photoinduced degradation and so to achieve high conversion efficiency in thin-film silicon-based solar cells. Initially, a-SiGe:H was adopted for the bottom cell material [25.38]; however, this material also shows severe photoinduced degradation. Recently, μc-Si:H or μc-SiGe:H have been proposed as promising candidates for bottom cell materials, because these materials do not exhibit photoinduced degradation [25.39, 40]. In this proposal, high rates of growth of those materials are crucial to the low-cost fabrication of tandem-type solar cells, since μc-Si:H and μc-SiGe:H undergo largely indirect optical transitions. Therefore, urgent material issues for the realization of low-cost/high-efficiency thin-film silicon-based solar cells include the need to improve the photoinduced stability of high-quality a-Si:H and the need to achieve a high rate of growth of device-grade μc-Si:H or μc-SiGe:H.

25.5 Recent Progress in Material Issues Related to Thin-Film Silicon Solar Cells

25.5.1 Controlling Photoinduced Degradation in a-Si:H

A relationship between the degree of photoinduced degradation and the dihydride bonding ($Si{-}H_2$) density has been reported in a-Si:H prepared under a variety of deposition conditions, where the substrate temperature, plasma-excitation frequency, gas-flow rate, hydrogen dilution ratio, working pressure, power density, etc. have all been varied [25.41]. Figure 25.21 shows the degree of photoinduced degradation, defined as the difference in the fill factors of photo-I–V characteristics of Ni-a-Si:H Schottky diode before and after light soaking plotted against the $Si{-}H_2$ density in a-Si:H film, as measured by infrared absorption spectroscopy. Furthermore, it has been suggested from mass spectrometric results that the $Si{-}H_2$ density in the resulting a-Si:H is strongly increased by the contributions from higher silane-related species (HSRS) such as Si_4H_9 when the substrate temperature is kept constant. The contribution of these HSRS to the film precursor (SiH_3) has been theoretically analyzed using a couple of gas-phase reaction-rate equations [25.42]. This analysis predicted that the contribution ratio is a complex function of the electron temperature in the plasma, the electron density in the plasma, the gas temperature, the hydrogen dilution ratio R, and the gas residence time during film growth. Based on our understanding of the network structure ($Si{-}H_2$ bonding configuration) responsible for the photoinduced degradation in a-Si:H and the chemical species (HSRS) responsible during film growth (shown schematically in Fig. 25.22), a guiding principle for obtaining highly stabilized a-Si:H has been proposed [25.42, 43].

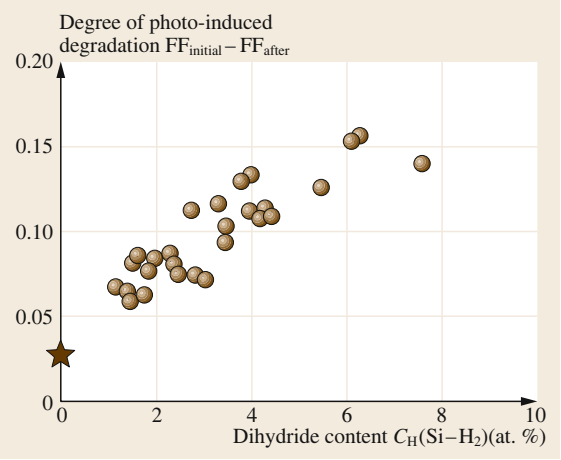

Fig. 25.21 Relationship between the degree of photoinduced degradation and the dihydride ($Si{-}H_2$) content in a-Si:H prepared under various deposition conditions. The *star* symbol represents for a-Si:H prepared under conditions of a reduced ratio of contributions from higher silane-related species versus the SiH_3 contribution at a substrate temperature of 250 °C

By following the guiding principle, a-Si:H with minimized $Si{-}H_2$ density in the network has been prepared by adjusting the plasma parameters during film growth under high growth rate conditions, and an a-Si:H-based solar cell showing a stable conversion ef-

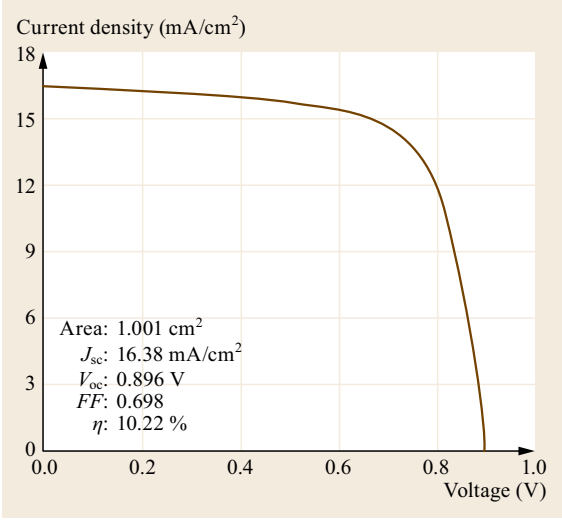

Fig. 25.24 Photo-I-V characteristics of a stable p–i–n a-Si:H-based solar cell fabricated using a triode reactor

ficiency of 8.2% (Fig. 25.23) has been fabricated at a high growth rate of 2 nm/s [25.41].

Moreover, a-Si:H containing a Si−H_2 density of 0% has been successfully prepared using a triode reactor at substrate temperatures as low as 250 °C by making use of the difference in the gas phase diffusion coefficients of SiH_3 (light) and HSRS (heavy) during film growth. High efficiency stable p–i–n a-Si:H based solar cells (efficiency after light soaking of 10.2% as shown in Fig. 25.24) have been fabricated using the triode reactor, although the growth rate is as low as 0.1 nm/s [25.44].

25.5.2 High Growth Rates of Device-Grade μc-Si:H

In the past, conventional high hydrogen dilution methods performed at relatively low working gas pressures (several tens of mTorr) have been used to obtain device-grade μc-Si:H (with low dangling bond defect densities of $\approx 10^{16}/cm^3$) [25.17]. Recently, a simple concept for preparing device-grade μc-Si:H at a high growth rate has been proposed, known as the high-pressure depletion (HPD) method [25.21, 45]. The production rate of the film precursor SiH_3 in the plasma, which is proportional to the growth rate of μc-Si:H, is determined by the product of the electron density and the number density of SiH_4. To increase the production rate of SiH_3 in the plasma, a high power density (radio frequency, RF, or very high frequency, VHF) and high partial pressures are needed, because the electron density is basically a function of the power density applied to the plasma and the number density of SiH_4 is proportional to the partial pressure. However, hydrogen atoms (the chemical species responsible during the formation of μc-Si:H) are strongly scavenged by SiH_4 molecules during their transportation from their production area to the film-growing surface. In order to enhance the survival of the hydrogen atoms, it has been suggested that the SiH_4 molecules should be depleted by applying high power density to the plasma. As conditions of high total pressure are also useful for decreasing the effects of ion bombardment during film growth through the reduction of the electron temperature in the plasma, high working pressures along with SiH_4 depletion conditions (HPD) have recently been popularly adopted for the high-rate growth of device-grade μc-Si:H. It has also been suggested that short lifetime species such as SiH_2, SiH, Si are scavenged by a large number of H_2 molecules present under HPD conditions, although the reaction rate of short lifetime species with H_2 is lower than that with SiH_4 [25.9], by two order of magnitudes.

Figure 25.25 shows the number density of dangling bond defects, as measured by electron spin resonance (ESR), in the resulting μc-Si:H as a function of growth rate [25.46]. When the conventional low pressure regime is used for the growth of μc-Si:H, the defect density increases exponentially with increasing growth rate, as seen in the figure (see A). This is caused by both an increase in the ion bombardment (due to the high power density) and an increase in the contributions from short-lifetime chemical species such as SiH_2, SiH and Si due to the reduced ability of those species to react with SiH_4 and H_2 (due to the low pressure and SiH_4 depletion) during film growth. On the other hand, the slope in Fig. 25.25 becomes shallower when HPD con-

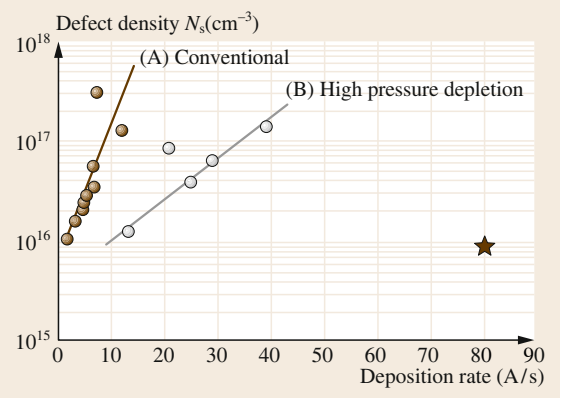

Fig. 25.25 Relationships between the dangling bond defect density in μc-Si:H films and their deposition rates for (A) μc-Si:H prepared using the conventional low-pressure regime and for (B) μc-Si:H prepared using the high-pressure depletion (HPD) method. The *star* symbol represents μc-Si:H prepared under HPD conditions with the novel cathode design

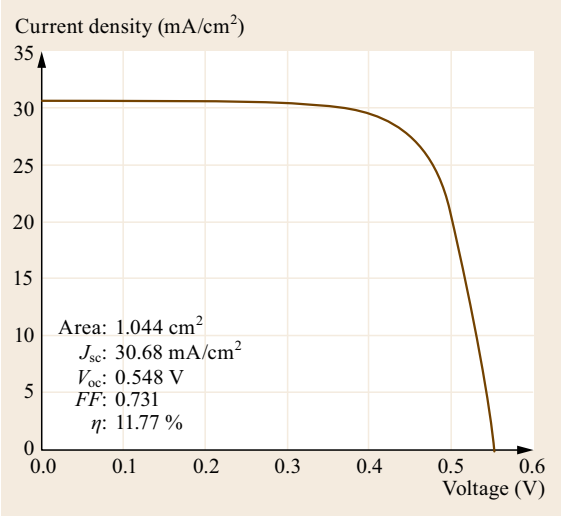

Fig. 25.26 Photo-I–V characteristics of a p–i–n μc-Si:H-based solar cell fabricated at reasonably high growth rate of 2 nm/s under HPD conditions

ditions are used during the growth of μc-Si:H, as shown in the figure (see B), which illustrates the usefulness of the HPD method for obtaining high-quality μc-Si:H at high growth rates.

The validity of the HPD method has also been demonstrated during the fabrication of μc-Si:H-based solar cells. Figure 25.26 shows the photo-I–V characteristics of a μc-Si:H-based p–i–n single-junction solar cell prepared at a high growth rate of 2 nm/s using the HPD method, which exhibits a reasonably high conversion efficiency of 11.8% [25.47].

However, HPD conditions require that the spacing between the cathode and anode is reduced in the conventional capacitively coupled plasma reactor, giving rise to nonuniform plasma production and nonuniform film growth. To overcome this problem encountered when using HPD conditions, the structure of the cathode surface has been designed to produce uniform plasma production even in a large-area parallel plate electrode configuration. Figure 25.27 shows the structure of this novel design of cathode. A multitude of holes (hollows) with interconnecting slots are arranged on the cathode surface, which cause strong coupling between the high-density plasmas produced in each hole where source gas injection is performed. Using this new type of cathode, quite high growth rates (more than 8 nm/s) have been obtained along with reasonably low defect densities in the resulting μc-Si:H, as shown by star symbol in Fig. 25.25 [25.48].

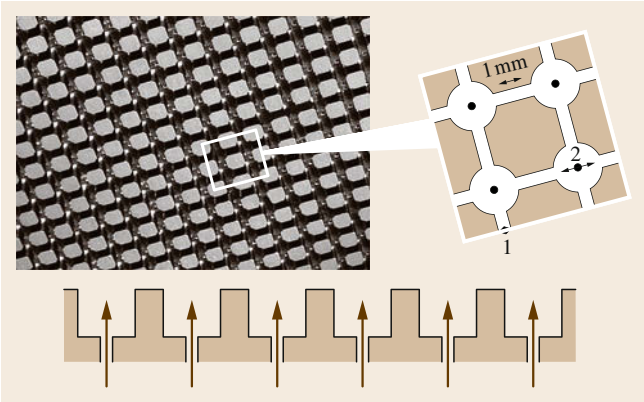

Fig. 25.27 Photograph of the surface structure on the cathode designed for the production of high-density/uniform plasmas

25.6 Summary

In this chapter, the processes involved in the growth of a-Si:H and μc-Si:H from SiH_4 and SiH_4/H_2 plasma have been interpreted in detail. The defect density determination reaction that takes place on the film-growing surface was discussed in order to obtain clues that may lead to enhanced optoelectronic properties in those materials. The recent status of work done in the fields of thin-film transistors and solar cells was reviewed, as these are the main device applications of those materials. Recent progress in resolving material issues related to solar cell applications were also described.

Finally, we note here that the concepts used in and our understanding of the film growth process mentioned here are widely applicable to other processes, especially processes where thin films are grown from reactive plasmas.

26. Ferroelectric Materials

Roger Whatmore

Ferroelectric materials offer a wide range of useful properties. These include ferroelectric hysteresis (used in nonvolatile memories), high permittivities (used in capacitors), high piezoelectric effects (used in sensors, actuators and resonant wave devices such as radio-frequency filters), high pyroelectric coefficients (used in infra-red detectors), strong electro-optic effects (used in optical switches) and anomalous temperature coefficients of resistivity (used in electric-motor overload-protection circuits). In addition, ferroelectrics can be made in a wide variety of forms, including ceramics, single crystals, polymers and thin films – increasing their exploitability. This chapter gives an account of the basic theories behind the ferroelectric effect and the main ferroelectric material classes, discussing how their properties are related to their composition and the different ways they are made. Finally, it reviews the major applications for this class of materials, relating the ways in which their key functional properties affect those of the devices in which they are exploited.

26.1 Definitions and Background

Ferroelectric materials offer a very wide range of useful properties for the electronic engineer to exploit. As we will see, they are also a class of materials that is hard to define accurately in a single sentence. It is useful to start from the class of insulating materials that form dielectrics; in other words materials that will sustain a dielectric polarisation under the application of an electric field. There exists a set of these materials for which the crystal structure lacks a centre of symmetry. (If a crystal structure has a centre of symmetry, it means that for every atom in the structure there is a point in the unit cell through which inversion will bring one to the same type of atom.) A list of the non-centrosymmetric, or *acentric*, point groups is given in Table 26.1. All of the crystalline materials whose structures possess these point groups (with the exception of group 432) exhibit the phenomenon of piezoelectricity, which means that stress will generate a charge separation on the faces of the crystal (the direct piezoelectric effect) and will undergo mechanical strain when subjected to an electric field (the converse piezoelectric effect). Both effects are widely exploited in electronic devices. A well-known example of a non-centrosymmetric material is the mineral α-quartz, which is used for the piezoelectric resonators employed for frequency filtering and electronic clocks.

A sub-set of the non-centrosymmetric crystals also possess a unique axis of symmetry. These crystals are said to be *polar*. The polar point groups are also listed in Table 26.1. Polar crystals are piezoelectric (as they are acentric) and also exhibit pyroelectricity, which means that a charge separation will appear on their surfaces when their temperature is changed. Polar structures effectively have a dielectric polarisation *built in* to the unit

Table 26.1 Polar and acentric (non-centrosymmetric) point groups

Crystal system	Polar (acentric)	Nonpolar (acentric)
Triclinic	1	
Monoclinic	2, *m*	
Orthorhombic	*mm*2	222
Trigonal	3, 3*m*	32
Hexagonal	6, 6*mm*	$\bar{6}$, $\bar{6}m2$
Tetragonal	4, 4*mm*	$\bar{4}$, 422, $\bar{4}2m$
Cubic	None	23, $\bar{4}3m$, 432

cell of the crystal structure. This is sometimes called a *spontaneous polarisation*. The application of stress or a change in temperature causes a change in this dipole moment and it is this change that causes the separation of charge on the surfaces of the crystal. The direction and magnitude of the spontaneous polarisation in a polar dielectric can be changed by the application of an electric field, but on removal of the field it will return to its zero-field value. A well-known example of a polar dielectric is ZnO, which possesses the wurtzite crystal structure in which Zn^{2+} ions sit in the tetrahedrally coordinated sites between hexagonal close-packed layers of oxygen ions. Thin films of ZnO are widely used for piezoelectric applications.

A sub-set of the set of polar dielectrics exists for which the application of a field of sufficient magnitude will cause the spontaneous polarisation to switch to a different, stable direction. Upon removal of the field the polarisation will not spontaneously return to its original direction and magnitude. These crystals are called *ferroelectric*. We can view the relationships between the sets of ferroelectric, polar, acentric and centrosymmetric dielectrics as shown in the Venn diagram in Fig. 26.1.

The history of ferroelectrics is long, as has been described in the excellent review by *Busch* [26.1]. Many very distinguished scientists were involved in its early development, including Brewster (who was one of those who studied pyroelectricity), J. & P. Curie (who discovered piezoelectricity), Boltzmann, Pockels and Debye, to name but a few. Indeed, the term ferroelectricity was first coined by E. Schrodinger. However, credit for the discovery of the effect goes to Joesph Valasek, who found in 1920 that the polarisation of sodium potassium tartrate (Rochelle salt) could be switched by the application of an electric field, thus providing the first demonstration of the process that is the hallmark of ferroelectricity.

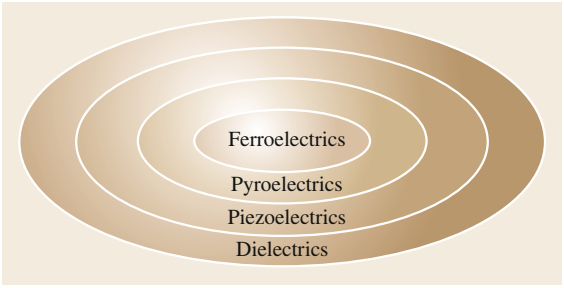

Fig. 26.1 Venn diagram showing how ferroelectrics fit into the different classes of dielectric materials

A reasonable working definition of ferroelectricity is *a polar dielectric in which the polarisation can be switched between two or more stable states by the application of an electric field*. However, as we will see in the discussion which follows, there are exceptions to this definition: some ferroelectrics are semiconducting (and thus are not dielectrics because they cannot sustain an electrical polarisation); the spontaneous polarisation in some ferroelectrics cannot be switched because they cannot sustain an electric field of sufficient magnitude to effect the switching, either because they reach electrical breakdown first, or because they are too conducting.

Since the initial discovery of ferroelectricity in Rochelle salt, the effect has been demonstrated in a wide range of materials, from water-soluble crystals through oxides to polymers, ceramics and even liquid crystals. Many of these will be discussed in this chapter. The range of useful properties exhibited by ferroelectrics covers:

- Ferroelectric hysteresis is used in nonvolatile computer information storage.
- Ferroelectrics can exhibit very high relative permittivities (several thousand) which means that they are widely used in capacitors.
- The direct piezoelectric effect (the generation of charge in response to an applied stress) is widely used in sensors such as accelerometers, microphones, hydrophones etc.
- The converse piezoelectric effect (the generation of strain in response to an applied electric field) is widely used in actuators, ultrasonic generators, resonators, filters etc.
- The pyroelectric effect (the generation of charge in response to a change in material temperature) is widely used in uncooled infra-red detectors.
- The electro-optic effect (a change in birefringence in response to an applied electric field) is used in laser Q-switches, optical shutters and integrated optical (photonic) devices.
- Ferroelectrics exhibit strong nonlinear optical effects that can be used for laser frequency doubling and optical mixing.
- Illumination of transparent ferroelectrics with light of sufficient energy causes excitation of carriers into

the conduction band. Their movement under the internal bias field caused by the spontaneous polarisation causes a refractive-index modulation that can be used for a variety of optical applications, including four-wave mixing and holographic information storage.

- Ferroelectrics exhibit strong coupling between stress and birefringence, which can be used to couple acoustic waves to optical signals with applications in, for example, radar signal processing.
- Doping certain ferroelectric ceramics with electron donors (e.g., $BaTiO_3$ with La^{3+}) can render them semiconducting. Heating these ceramics through their Curie temperature causes a very large, reversible increase in resistivity (by several orders of magnitude in some cases) over a narrow range of temperature (ca. 10 °C). This large positive temperature coefficient of resistance (PTCR) is widely exploited in electric-motor overload-protection devices and self-stabilising ceramic heating elements.

26.1.1 Basic Ferroelectric Characteristics and Models

The switchable spontaneous polarisation in ferroelectrics gives rise to the first characteristic property of the materials: ferroelectric hysteresis. Figure 26.2 shows a schematic plot of polarisation versus electric field as would be observed on a typical ferroelectric. As the field is increased from zero, the overall polarisation in the crystal increases as the polarisations in different dipolar regions are aligned. Eventually, it reaches a saturation point where the only further increase in P is that due to the relative permittivity of the material. (The gradient of the P/E curve for a linear dielectric is equal to its permittivity). Extrapolation of this line back to the abscissa gives the saturation value of the spontaneous polarisation (P_s). Reduction of the field to zero leaves a *remanent polarisation* (P_r), which is usually slightly less than P_s. A negative field will cause the polarisation to reduce, until it reaches zero at the *coercive field* ($-E_c$). A further negative increase in the field will eventually cause a reverse saturation polarisation ($-P_s$) to develop. When the field returns to zero the crystal is left with a negative remanent polarisation ($-P_r$). Increasing the field once more increases the polarisation from $-P_r$ to zero at E_c, and then to $+P_s$, completing the ferroelectric hysteresis loop. The ability to switch the polarisation between two states gives rise to the first application of ferroelectrics – as a nonvolatile memory storage medium. It also permits polycrystalline ferroelectrics (especially ceramics) to be polarised. The fact that the polarisation can possess different directions within different regions of the same crystal gives rise to the existence of *ferroelectric domains*. These are given names according to the angle between the polarisation between adjacent regions. Hence, two adjacent regions in which the polarisations are orientated at 180° to each other are, naturally, called 180° domains. In many ferroelectrics, the polarisation can choose between many different possible directions so that adjacent regions can have polarisations at, for example, 90° to one another.

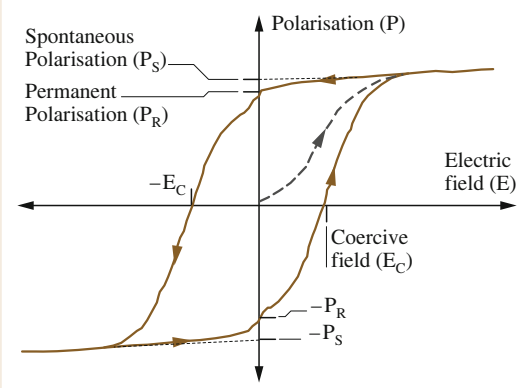

Fig. 26.2 Ferroelectric hysteresis loop

For most ferroelectrics, the polar state only exists over a limited range of temperatures. As the temperature is raised, a point is reached at which there is a transition from the polar, ferroelectric phase to a nonpolar, non-ferroelectric phase (called the *paraelectric* phase). In all cases, the paraelectric phase possesses a higher crystal symmetry than the ferroelectric phase into which it transforms. The temperature at which this occurs is called the *Curie temperature* (T_C). This ferroelectric-to-paraelectric phase transition is a characteristic of most ferroelectrics, but again there are exceptions. Some ferroelectric materials melt or decompose before T_C is reached; the polymeric ferroelectric polyvinylidene fluoride (PVDF) is one such example. For most ferroelectrics (called *proper ferroelectrics*), as the Curie temperature is approached from above, the relative permittivity is observed to increase, reaching a peak at T_C and decreasing below T_C. (There is a class of ferroelectrics, known as *improper* or *extrinsic ferroelectrics*, for which there is no peak in permittivity, just an anomaly. These are described further below.) Very high values of relative permittivity (many thousands) can be reached at T_C, leading to another use of ferroelectric materials – as dielectrics in high-value capacitors. The phase transition at T_C can either be continuous (known as second-order) or discontinuous (known as first-order). In either case, the dependence of permittivity (ε) on temperature above

T_C can be described by $\varepsilon = C/(T - T_0)$. T_0 is called the *Curie Weiss temperature*, and is only equal to T_C for a second-order phase transition. C is called the *Curie Weiss constant*. Figure 26.3 shows typical plots of P_s and ε as functions of temperature for ferroelectrics around T_C. Figs. 26.3a and 26.3b show the behaviour for a first-order phase transition. As can be seen, P_s drops discontinuously to zero at the phase-transition temperature. The permittivity rises as the temperature decreases, peaking at the transition, where there is a discontinuous step down. First-order phase transitions tend to show thermal hysteresis in the transitions, so that the transition occurs at a higher temperature when approached from the low-temperature side than from the high-temperature side. Frequently in practical observations there is actually a region of coexistence where both phases exist together in the same sample at the same temperature. In this case, the Curie temperature is defined as the temperature at which the ferroelectric and paraelectric phases have the same Gibbs free energies. In the case of a second-order phase transition (Figs. 26.3c and 26.3d), P_s drops continuously to zero at T_C and the permittivity rises to a sharp peak. There is no hysteresis in the transition.

There are two types of theoretical model that describe the ferroelectric phenomenon. The first is the phenomenological or thermodynamic theory first proposed by *Devonshire* [26.2]. Here, the Gibbs free energy of the ferroelectric system is described in terms of a power series in the spontaneous polarisation. In this case, P_s is termed the order parameter for the phase transition and the theory is similar in form to the generalised phenomenological theory of phase transitions known as Landau theory. It is not appropriate to go into the details of the theory here, which has been described very well by *Lines* and *Glass* [26.3]. The theory successfully predicts many of the behavioural characteristics of ferroelectric materials in terms of the measurable macroscopic properties, including the ferroelectric hysteresis and the behaviour of the permittivity near T_C. However, it tells us nothing about the microscopic origins of ferroelectricity. This is the province of the two types of microscopic models of ferroelectric behaviour. The first of these is the order–disorder model of ferroelectric behaviour. The second is the displacive model.

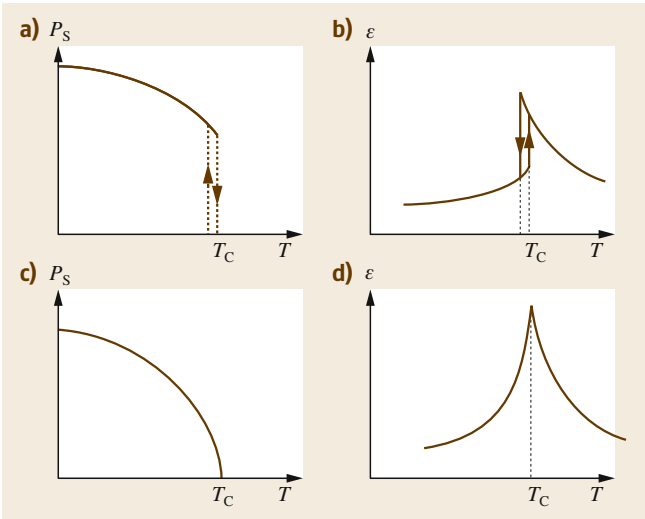

Fig. 26.3a–d The variations of spontaneous polarisation ((**a**) and (**c**)) and permittivity ((**b**) and (**d**)) with temperature for typical ferroelectric materials. (**a**) and (**b**) are for a first-order (discontinuous) phase transition while (**c**) and (**d**) are for a second-order (continuous) phase transition

According to the order–disorder model, the electric dipoles exist within the structure in the paraelectric phase above T_C, but are thermally disordered between two or more states so that the average polarisation is zero. There are several materials for which that is the case, an example being potassium dihydrogen phosphate (KDP), which is paraelectric, tetragonal ($\bar{4}2m$) above 123 K and ferroelectric, orthorhombic ($mm2$) below. The polarisation appears along the tetragonal c-axis. In this crystal structure, the PO_4 groups form tetrahedra that are linked by hydrogen bonds at their corners. The protons in these sit in double potential wells. Above T_C they are delocalised between the the two minima in the wells. Below T_C, they are localised and the PO_4 tetrahedra become distorted. The phosphorous and potassium ions become displaced relative to the oxygen framework, forming the polarisation in the lattice. Replacement of the hydrogen in the structure by deuterium raises T_C to about 220 K because the heavier deuteron delocalises between the two potential minima at a much higher temperature. Another example of an order–disorder ferroelectric is sodium nitrite ($NaNO_2$) in which the polar groups are NO_2^- ions, which become ordered below T_C (163 °C) with their dipoles all pointing along the b-axis of the crystal structure.

In displacive ferroelectrics, there are considered to be no dipoles in the structure above T_C, but the dipoles appear in the structure due to the cooperative motion of ions. Typically this is seen as the *softening* of a zone-centre optical phonon. What this means is that the frequency of an optical phonon mode with zero wavevector goes to zero at T_C. Such a phonon mode involves the displacement in opposite directions of cations and anions in the structure. When the frequency of this mode goes to zero, a dipolar displacement results. Examples of such ferroelectrics include the perovskite-structured oxides such as $BaTiO_3$, which will be discussed further below. One of the successes of soft-mode theory

is that it provides a convincing mechanism for the peak in the dielectric permittivity at T_C. According to the Lyddane–Sachs–Teller relationship (see, for example, [26.3] p. 216), the softening of a zone-centre phonon will make the permittivity diverge at T_C.

In practice, the distinction between order–disorder and displacive ferroelectrics becomes rather blurred, as some ferroelectrics which may be considered to be purely displacive may exhibit significant disordered cation displacement well above T_C, while some order–disorder ferroelectrics show soft-mode behaviour. For a more detailed discussion of these theories, the reader is referred to *Lines* and *Glass* [26.3].

26.2 Ferroelectric Materials

26.2.1 Ferroelectric Oxides

This is by far the most technologically important class of ferroelectric materials. They will be discussed according to the most important crystal classes.

Perovskite Ferroelectrics

These materials possess crystal structures isomorphous with the mineral perovskite ($CaTiO_3$). They all have the general chemical formula ABO_3, where A and B are cations. Typically the A cation will be around 1.2–1.6 Å in radius (similar to the oxygen ions) while the B cations will be around 0.6–0.7 Å in radius. The crystal structure is illustrated in Fig. 26.4. It consists of a network of corner-linked BO_6 octahedra, within which is enclosed the large A cation. Another way to look at the structure is as cubic-close-packed AO_3 layers, with the small B cations sitting in the octahedral sites between these close-packed layers. A pair of layers are shown in Fig. 26.5. The structure is a very tolerant one and will accommodate many different ions. Because of this, it is exhibited by a large number of oxides. The basic criteria for the structure to be stable is that the valencies of the ions should balance and that the ionic radii meet the *Goldschmidt criteria* [26.4]. A tolerance factor t is defined as

$$t = \frac{r_A + r_O}{\sqrt{2}(r_B + r_O)} ,$$

where r_X is the ionic radius of the X cation. The ideal cubic perovskite structure, where the ionstable are just touching each other, will possess $t = 1$. However, the structure will be stable with $0.85 < t < 1.05$. A list of ions that commonly form perovskites, together with their ionic radii, is given in Table 26.2. The closer t is to unity, the more likely the structure will be to be cubic. Conversely, perovskites which have values of $t < 1$ show distorted structures that are frequently ferroelectric. Examples of some perovskites and their tolerance factors are listed in Table 26.3. This table also lists the structures formed by these compounds at

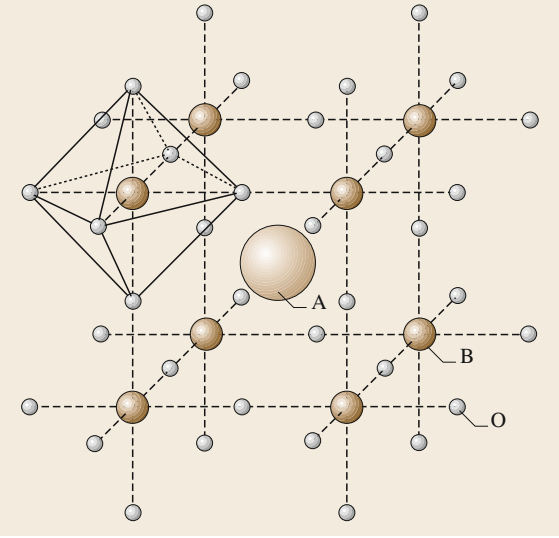

Fig. 26.4 The perovskite crystal structure

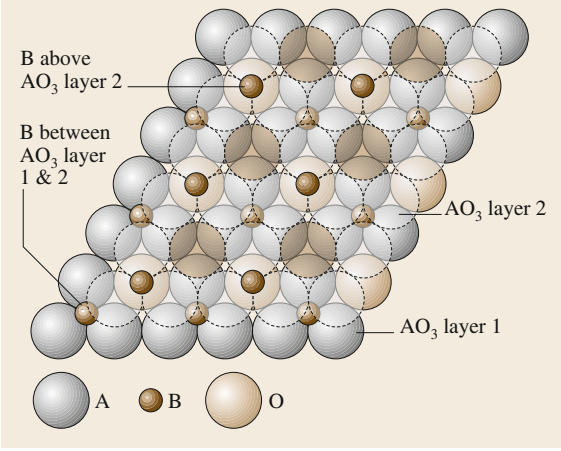

Fig. 26.5 Showing two AO_3 close-packed layers of the perovskite structure, with the B cations sitting in the six-fold coordinated sites between the layers. The second layer has been made semitransparent for clarity

Table 26.2 List of cations frequently found to form perovskite-structured oxides and their ionic radii. (Ionic radii taken from [26.5])

A-site cation	Ionic radius when [12][a] by O^{2-} (Å)	B-site cation	Ionic radius when [6][b] by O^{2-} (Å)
Na^{+}	1.32	Nb^{5+}	0.64
K^{+}	1.6	Ta^{5+}	0.68
Ba^{2+}	1.6	Zr^{4+}	0.72
Sr^{2+}	1.44	Ti^{4+}	0.605

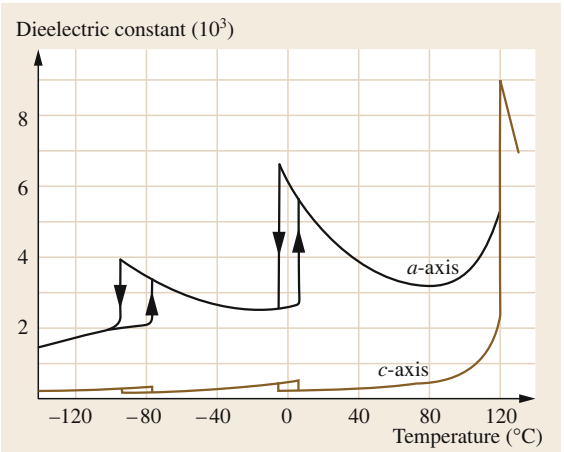

Fig. 26.6 Temperature dependence of the relative permittivity of $BaTiO_3$ measured along [001] and [100] (After [26.7])

room temperature, and whether or not they are ferroelectric. Some of the most interesting perovskites from the point of view of applications are $BaTiO_3$, $PbTiO_3$ and $KNbO_3$. $BaTiO_3$ is cubic above 135 °C, but transforms to a tetragonal ferroelectric structure below this temperature. In this case, the Ba and Ti ions are displaced relative to the anion framework along one of the cubic ⟨001⟩ directions. This means that the polar axis has six choices for direction in the tetragonal phase. At 5 °C there is a second-phase transition from the tetragonal to an orthorhombic phase, where the polarisation now appears due to cation displacements along one of the cubic ⟨110⟩ directions, for which there are 12 choices. Finally, at −90 °C there is a transition to a rhombohedral phase with the cations being displaced along one of the cubic ⟨111⟩ directions, for which there are eight choices. In the case of $PbTiO_3$ there is a single transition to a tetragonal phase at 490 °C, again by cationic displacements along ⟨100⟩. Some perovskites show phase transitions that are not ferroelectric. For example, $SrTiO_3$ shows a transition to a tetragonal phase at 110 K which involves linked rotations, or tilts, of the TiO_6 octahedra about the cubic [100] direction. Tilting of the octahedra is a common feature of the phase transitions that occur in perovskites and can lead to very complex series of phase transitions, as has been observed for $NaNbO_3$. This type of structural modification and a commonly-used notation for it has been described in detail by *Glazer* [26.6].

It is very easy to make solid solutions of the end-member perovskites, such as those listed in Table 26.3, and this has been used to great effect to provide materials with a wide range of properties. For example, Fig. 26.6 shows the temperature dependence of the relative permittivity of a $BaTiO_3$ single crystal [26.7]. There is a peak at each transition where the value perpendicular to the polar axis reaches several thousand, making the material interesting for use in capacitor dielectrics. However, the temperature variation in such a material would make it useless. The formation of ceramic solid solutions of $BaTiO_3$ with $SrTiO_3$, $CaTiO_3$ or $PbTiO_3$ allows the temperature dependence of permittivity to be controlled so that useful specifications can be met with average permittivities of 2000 or more over a wide range of temperatures. *Herbert* [26.8] has discussed the details of these modifications and their

Table 26.3 Some end-member perovskites and their properties

Perovskite oxide	Tolerance factor	Structure at 20 °C	Type	T_C (°C)
$BaTiO_3$	1.06	Tetragonal	Ferroelectric	135
$SrTiO_3$	1.00	Cubic	Paraelectric	
$CaTiO_3$	0.97	Tetragonal	Paraelectric	
$PbTiO_3$	1.02	Tetragonal	Ferroelectric	490
$PbZrO_3$	0.96	Orthorhombic	Antiferroelectric	235
$NaNbO_3$	0.94	Monoclinic	Ferroelectric	−200
$KNbO_3$	1.04	Tetragonal	Ferroelectric	412
$KTaO_3$	1.02	Cubic	Ferroelectric	−260
$BiScO_3$	0.83	Rhombohedral	Ferroelectric	370
$BiFeO_3$	0.87	Tetragonal	Ferroelectric	850

effects on the $BaTiO_3$ transition temperatures. $BaTiO_3$-based ceramics are widely used in ceramic capacitors and form the basis of an industry worth billions of dollars annually. They have also been used for piezoelectric ceramics, but are no longer so important in that field, as they have largely been displaced by ceramics in the $PbZrO_3$–$PbTiO_3$ system. Nevertheless, there is a renewed interest in $BaTiO_3$-based ceramics for lead-free piezoelectrics in response to the legislative drive to reduce lead in the environment.

The perovskite solid solution system between $PbZrO_3$ and $PbTiO_3$ is of great technological importance and is thus worth discussing in some detail. The phase diagram given in Fig. 26.7 shows several phases. Starting at $PbTiO_3$, the ferroelectric tetragonal (F_T) phase persists well across the diagram, until the composition $Pb(Zr_{0.53}Ti_{0.47})O_3$ is reached, where there is a transition to a ferroelectric, rhombohedral phase. The composition where this occurs is called the morphotropic phase boundary (MPB). The rhombohedral phase region splits into two. There is a high-temperature phase ($F_{R(HT)}$) in which the cations are displaced along the cubic [111] direction. There is also a low-temperature ferroelectric rhombohedral ($F_{R(LT)}$) phase in which the $(Zr, Ti)O_6$ octahedra are rotated about the [111] axis. This doubles the unit cell. Close to $PbZrO_3$ (Fig. 26.7b) the room-temperature structure transforms to the antiferroelectric, orthorhombic (A_O) structure. This is a complex structure in which the cations are displaced in double antiparallel rows along the cubic ⟨110⟩ directions, coupled with octahedral tilts. A higher-temperature A_T phase, which is frequently shown when this phase diagram is cited in the literature, has been shown not to exist in pure solid solutions [26.9]. There is another, more modern, modification to this phase diagram. It has been shown by *Noheda* et al. [26.10] that a monoclinic phase exists at the MPB (Fig. 26.7c). The enormous technological and commercial importance of this system derives from the very high piezoelectric, pyroelectric and electro-optic coefficients that can be obtained from ceramic compositions in different parts of the phase diagram, particularly when the base composition is doped with selected ions. These are discussed in more detail below. This solid solution system is frequently referred to generically as *PZT* although, strictly, PZT was the brand name for a set of piezoelectric ceramic compositions manufactured by the Clevite Corporation.

There is another very important class of oxides, termed complex perovskites, where the A or, more commonly B, sites in the structure are occupied by ions of different valency in a fixed molar ratio. These are not solid solutions as they possess a fixed composition. Examples are $PbMg_{1/3}Nb_{2/3}O_3$ (PMN), $PbSc_{1/2}Ta_{1/2}O_3$

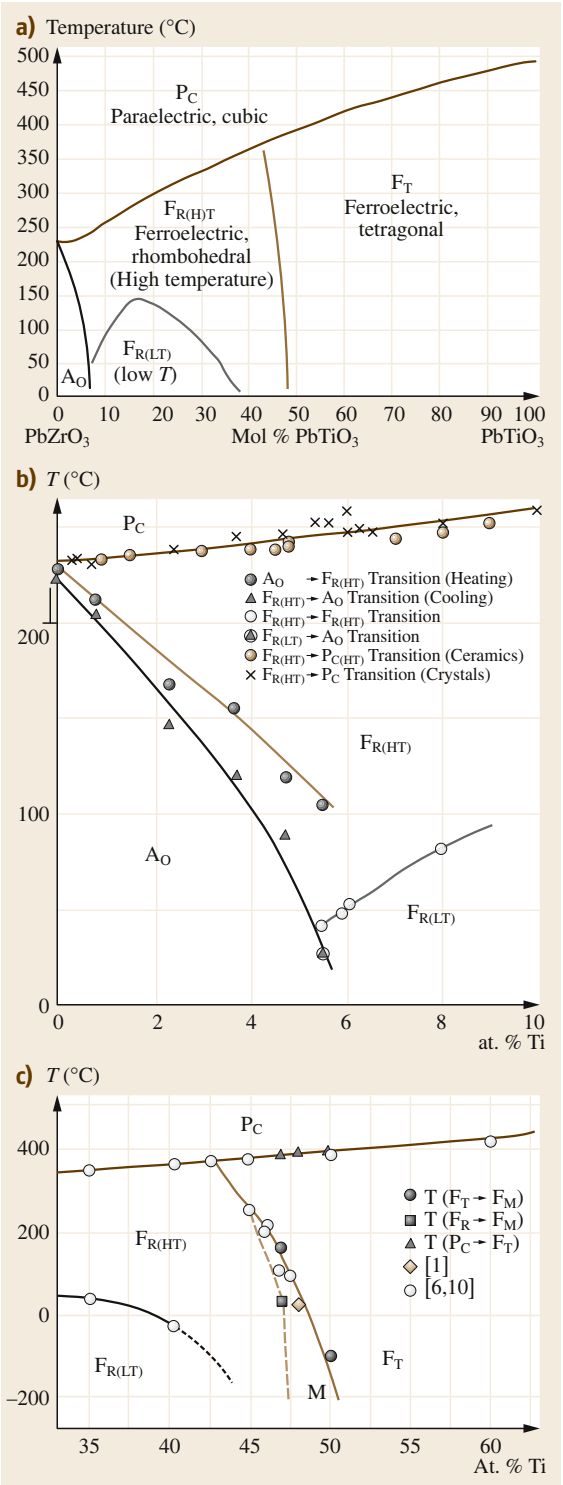

Fig. 26.7 **(a)** $PbZrO_3$–$PbTiO_3$ phase diagram. (After [26.11]) **(b)** Region close to $PbZrO_3$. (After [26.9, 12]) **(c)** Region close to the MPB. (After [26.10])

(PST) and $Bi_{1/2}Na_{1/2}TiO_3$. These are also technologically important and can form end members to solid solutions in their own right, $PbMg_{1/3}Nb_{2/3}O_3$–$PbTiO_3$ (PMN-PT), for example. Many of the complex ferroelectrics (PMN-PT is a classic example) exhibit *ferroelectric relaxor* behaviour. In these materials, the Curie point is no longer a sharp transition but is actually observed over a very wide range of temperatures. A broad permittivity peak is observed and the temperature and height of the peak are strongly dependent on the frequency of measurement. Figure 26.8 shows a typical variation of permittivity with temperature and frequency in PMN [26.13].

The broad tolerance of the perovskite structure to different cations has led to a wide exploration of the inclusion of different iso-valent dopants to obtain different electronic properties. It is also possible to include alio-valent dopants over a wide range, which the structure tolerates through the introduction of cation or anion vacancies, or free charge carriers. For example, it is possible to incorporate Nb^{5+} into the B site of the $BaTiO_3$ system [26.14], and charge balance is maintained through the presence of free electrons. Similarly, Fe^{3+} can be introduced into the B site of the system and this substitution creates O vacancies [26.15].

The vast majority of perovskites are employed in ceramic form, but thin- and thick-film materials are becoming of increasing importance and single-crystal materials are starting to emerge which have exceptionally high piezoelectric coefficients.

Illmenite Ferroelectrics

The illmenite structure is related to the perovskite structure in that it is exhibited by materials with the general formula ABO_3, where the A cation is too small to fill the [12] coordinated site of the perovskite structure. The structure is made up of hexagonal close-packed layers of oxygen ions, with the A and B ions occupying the octahedrally coordinated sites between the layers. Hence, this structure can also be considered to be related to the perovskite structure in that both are based on oxygen octahedra. The two best known illmenite ferroelectrics are $LiNbO_3$ and $LiTaO_3$, whose structure is shown in Fig. 26.9. The materials have high T_C values (ca. 1200 and 620 °C, respectively). In the case of $LiNbO_3$, the T_C is only 50 °C below the melting point. Referring to Fig. 26.9, it can be seen that the cations occupy octahedral sites progressing along the *c*-axis in the order Nb, vacancy, Li, Nb, vacancy, Li etc. The polarisation occurs through displacement of the cations along the three-fold axis, so the structure transforms from $\bar{3}m$ to $3m$ symmetry at T_C. These are *uniaxial* ferroelectrics, in that the polarisation can only be up or down, and only 180° domains exist. The materials are mainly used in

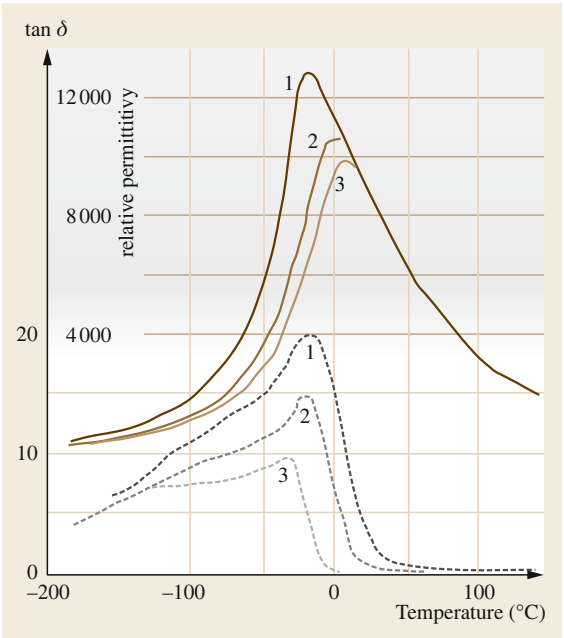

Fig. 26.8 Permittivity (*solid lines*) and dielectric loss (*dashed lines*) versus temperature in PMN. The measurements were made at: (1) 0.4, (2) 45 and (3) 4500 kHz. (Adapted from [26.13])

single-crystal form for piezoelectric and electro-optic devices.

Tungsten Bronze Ferroelectrics

This is another very large family of oxygen octahedral ferroelectrics possessing the general formula $[A1_2A2_4C_4][B1_2B2_8]O_{30}$. The crystal structure is complex, shown schematically in Fig. 26.10. The B1 and B2 sites are octahedrally coordinated by oxygens and have similar sizes and valencies to the B sites in the perovskites. The A1 and A2 sites are surrounded by four and five columns of BO_6 octahedra respectively. The three-fold coordinated C sites in the structure are frequently empty, but can be occupied by small uni- or divalent cations (e.g., Li^+ or Mg^{2+}). There are a wide range of ferroelectric tungsten bronzes, which frequently show nonstoichiometry. All are tetragonal in their paraelectric phase, and can transform to either a tetragonal ferroelectric phase, in which the polar axis appears along the tetrad axis of the paraelectric phase, or (more commonly) into an orthorhombic phase in which the polar axis appears perpendicular to the original tetrad axis. Examples of tungsten bronzes are $PbNb_2O_6$ (lead metaniobate) in which five out of the available six A sites are occupied by Pb^{2+} and the B sites by Nb^{5+}. This crystal and its Ta analogue are metastable below about 1200 °C. They can be stabilised by rapid cooling, or more commonly by doping. Lead metaniobate ceramics are difficult to make, but are commercially available and are occasionally used for piezoelectric devices by virtue of their higher Curie temperatures than members of the PZT system, combined with reduced lateral piezoelectric coupling factors. Substitution of Pb^{2+} by Ba^{2+} can also be used to produce a useful piezoelectric ceramic material $Pb_{1/2}Ba_{1/2}Nb_2O_6$. Other tungsten bronze ferroelectrics such as $Sr_xBa_{1-x}Nb_2O_6$, $Ba_2NaNb_5O_{15}$ and $K_3LiNb_5O_{15}$ have been investigated as single crystals for use in electro-optic devices. However, the growth of highly homogeneous single crystals is difficult because of the formation of optical striations caused by compositional fluctuations.

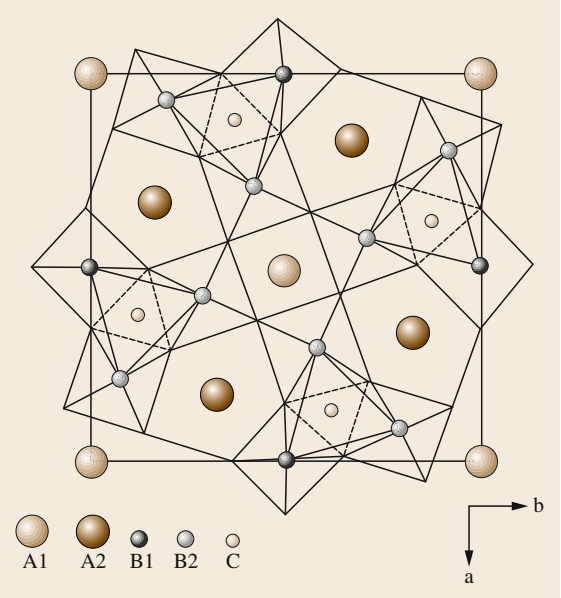

Fig. 26.10 Tungsten bronze crystal structure. (After [26.17])

Aurivillius Compounds

The Aurivillius compounds form another important class of ferroelectrics based on oxygen octahedra. They have a good deal in common with the perovskites in that they consist of layers or slabs of perovskite blocks with the general formula $(A_{m-1}B_mO_{3m+1})^{2-}$ separated by $(M_2O_2)^{2+}$ layers in which the M cation is in pyramidal coordination with four oxygens, the M being at the apex of the pyramid. The structure possesses the general formula $M_2(A_{m-1}B_mO_{3m+3})$. In the ferroelectric phases, M is usually Bi and m is usually between one and five. The A and B cations follow the usual ionic radius and valency criteria of the perovskites, and we see ferroelectric compounds in which A = Bi, La, Sr, Ba, Na, K etc. and B = Fe, Ti, Nb, Ta, etc. Part of the crystal structure is shown schematically in Fig. 26.11, illustrating in this case a structure with $m = 3$. This is just over half of the unit cell, showing one slab of perovskite units and two of the $(Bi_2O_2)^{2-}$ layers. The structures are tetragonal in their paraelectric phases, with the tetrad c-axis being perpendicular to the $(Bi_2O_2)^{2+}$ plane. In the majority of cases they become orthorhombic in their ferroelectric phase, with the spontaneous polarisation appearing in the $a-b$ plane, at 45° to the tetragonal a-axis. Bismuth titanate ($Bi_4Ti_3O_{12}$) is an example of an Aurivillius ferroelectric in which M = A = Bi, B = Ti and $m = 3$, so that there are three blocks in the perovskite slab. In this case, there is a small component of the spontaneous polarisation (ca. 4 $\mu C/cm^2$) out of the a–b plane, with the majority of the polarisation (ca. 50 $\mu C/cm^2$) being in the plane, so that the ferroelectric structure is monoclinic. The T_C is high (675 °C) and ceramics have been explored for use as high-temperature piezoelectrics. The problem with the compounds when used as ceramics is that the piezoelectric coefficients are rather small. Single crystals have been explored for optical light-valve applications but have not received widespread use because of the problems of growth. Thin films of $SrBi_2Ta_2O_9$ (SBT) are receiving considerable attention for applications in ferroelectric nonvolatile memories. Recently, thin films of

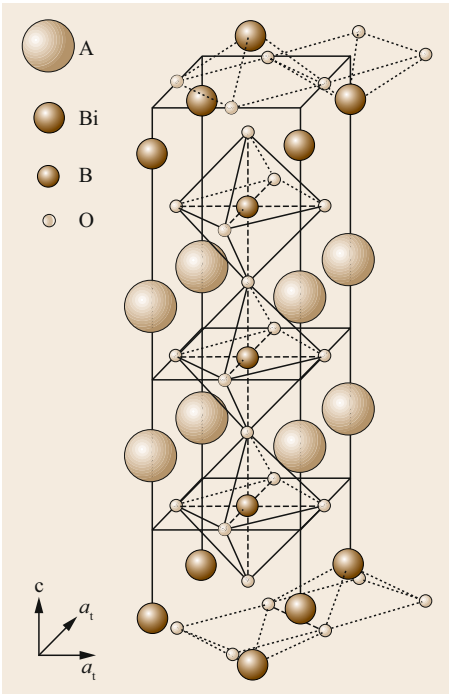

Fig. 26.11 Schematic diagram of half of the unit cell of the crystal structure of an Aurivillius compound with $m = 3$. The cell axes shown are those corresponding to the tetragonal structure

$Bi_6Ti_{2.8}Fe_{1.52}M_{10.68}O_{18}$ with $m = 5$ have been shown to be single phase magnetoelectric multiferroics [26.18].

Other Oxide Ferroelectrics

There is a wide range of other oxide ferroelectric materials, although none have anywhere near the breadth of application of the oxygen octahedral ferroelectrics discussed above. There are two groups of phosphates (in which the phosphorous ions are tetrahedrally coordinated by oxygens) which have found applications in optical systems. The potassium dihydrogen phosphate (KDP) family was referred to above as an example of an order–disorder ferroelectric. KDP, and its deuterated analogue KD*P, can be grown from aqueous solution as large, high-quality single crystals. These can be lapped and polished into plates which are used for longitudinal electro-optic modulators, in which the modulating electric field is applied parallel to the direction of light propagation in the crystal. In this application, the crystals are used at room temperature in the paraelectric phase. One spectacular application for these crystals is as the Q-switches in the large ultra-high-power lasers used for nuclear fusion research, where extremely large (ca. 1 m) crystal slices are needed. Another class of phosphate ferroelectrics is the potassium titanyl phosphate (KTP) system. These crystals can be grown relatively easily from the melt and are used for optical frequency doubling applications, particularly using periodically poled crystals [26.19, 20]. This is a large family in which the potassium can be replaced by caesium or rubidium and the phosphorous by arsenic. Lasers using KTP are finding significant uses in surgical procedures [26.21].

There are other examples of oxygen tetrahedral ferroelectrics. Lead germanate ($Pb_5Ge_3O_{11}$) is an interesting material which has been prepared as a single crystal. It is a hexagonal uniaxial ferroelectric which is also optically active. Ge can be substituted up to 50% by Si, which reduces the Curie temperature from 177 to 60 °C. The sense of the optical rotation switches with the sign of the spontaneous polarisation. This has been considered for optical devices and pyroelectric infra-red detectors, but has not reached any commercial applications. It has been prepared in ceramic and thin-film form and is occasionally used as a sintering aid in lead-containing ferroelectric ceramics. Gadolinium molybdate, $Gd_2(MoO_4)_3$ (GMO), possesses a structure consisting of corner-linked MoO_4 tetrahedra. It is an example of an improper ferroelectric material in which the phase transition from the paraelectric phase is controlled by the softening of a zone boundary mode, which would lead to a nonpolar low-temperature phase, which is in fact *ferroelastic*. The high-temperature phase is acentric, and the ferroelastic lattice distortion couples via the piezoelectric coefficients to give a spontaneous polarisation. The lattice distortion can be reversed by electrically switching the spontaneous polarisation and vice versa. GMO has no commercial applications, although it was at one time considered for optical switches.

26.2.2 Triglycine Sulphate (TGS)

The TGS family is a salt of the simplest amino acid, glycine (NH_2CH_2COOH) with sulphuric acid. In the crystal structure, the glycine groups are almost planar and pairs of them are connected by hydrogen bonds. A ferroelectric transition at 49.4 °C between two monoclinic phases is driven by an ordering of the protons in these hydrogen bonds. The replacement of these protons by deuterons (which can be accomplished by repeated crystallisation of TGS from heavy water) to give DTGS results in a 10 °C increase in T_C. There has been a great deal of academic interest in TGS because it possesses a well-behaved second-order order–disorder ferroelectric phase transition. In addition it has been of considerable technological interest for uncooled pyroelectric infra-red detectors and thermal imaging devices [26.22]. As a consequence, there has been considerable work on the replacement of various components with the objective of either improving performance or increasing T_C, such as can be achieved by deuteration. The replacement of glycine by l-alanine has been demonstrated to result in an internal bias field

in the crystal, which means that the crystals will retain their single-domain structure, even if heated well above T_C.

26.2.3 Polymeric Ferroelectrics

The first polymeric ferroelectric to be discovered was polyvinylidene fluoride (PVDF). The monomer for this possesses the formula CH_2CF_2. It was first shown to be piezoelectric by *Kawai* [26.23] and later *Bergman* et al. [26.24] speculated about the possibility of it being ferroelectric, although no Curie temperature could be shown to exist, as the polymer melts first. The structure of the polymer is complex, as the polymer backbone can adopt a number of configurations depending upon whether the neighbouring carbon-carbon linkages adopt trans or gauche configurations. In a trans (T) configuration, the groups bonded to the carbon atoms sit on opposite sides of the carbon-carbon bond. In a gauche (G) configuration, they sit on the same side. In an all-trans configuration, the carbon backbone of the polymer forms a simple zigzag. In the case of PVDF, there are four different phases with different T and G sequences, and with different ways the polymers stack together in crystal structures. The polymer crystallises from the melt into *form II*, also called the α-phase, in which the bonds arrange themselves into the sequence TG$\overline{\text{T}}\overline{\text{G}}$, see Fig. 26.12. The fluorine atoms are strongly electronegative, which makes the C−F bond polar so that the molecule has a net dipole moment perpendicular to its length. However, the molecules of polymer arrange themselves in the unit cell so that the dipoles cancel each other out. Form II is neither ferroelectric nor piezoelectric, but application of an electric field will convert it into form II_P, also called the δ-phase, in which the polymer molecules are arranged so that the unit cell has a net dipole moment. High-temperature annealing of either of these forms will produce form III (the γ-phase), which has a new TGTTT$\overline{\text{G}}$TT configuration which also has a net dipole moment perpendicular to the long axis of the molecule and these arrange in a crystal structure which is also polar. Subjecting forms II or III to stretching or drawing will produce form I (the β-phase), which is an all-trans configuration (Fig. 26.12). It can be seen from Fig. 26.12 that of the three molecular configurations, the polar bonds all point most-nearly in the same direction and this is retained in the unit cell. Electrical poling makes this the most-strongly piezoelectric phase of PVDF. The stretching

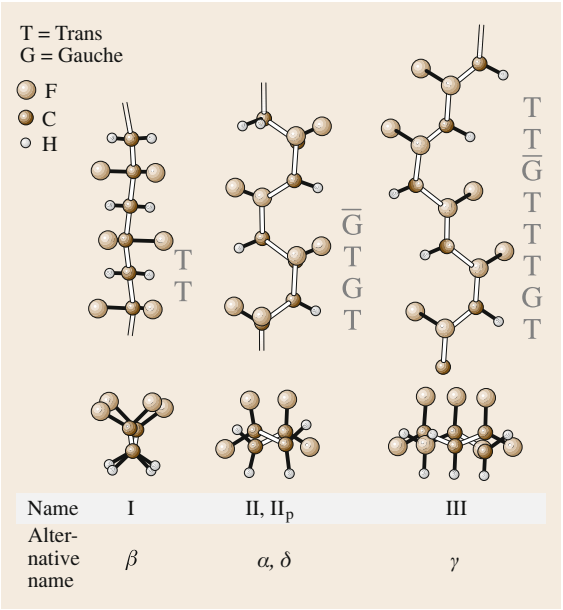

Fig. 26.12 PVDF bond structures

can be in a single direction, called uniaxial and usually achieved by drawing through rollers, or in two perpendicular directions, called biaxial and usually achieved by inflating a tube of polymer. Strong electric fields are needed for poling and these are frequently applied by placing the polymer under a corona discharge. The formation of a copolymer of vinylidene fluoride with between 10 and 46% trifluoroethylene (TrFE) leads to a polymer which will crystallise directly into form I (the β-phase) from either melt or solution. This can be poled to produce a material which is as active as pure PVDF. The copolymers also show clear signs of a ferroelectric-to-paraelectric transition, such as exhibiting peaks in permittivity at T_C, with a T_C that depends on the amount of TrFE in the copolymer. Extrapolation to 0% TrFE implies a T_C in PVDF of 196 °C. PVDF is readily available and has achieved moderately widespread use as a piezoelectric sensor material. It is particularly useful where light weight and flexibility are important, or where very large areas or long lengths are needed. The P(VDF-TrFE) copolymers are not as readily available and are not widely used. Other polymers that have been shown to exhibit ferroelectric behaviour include the odd-numbered nylons, but these are only weakly piezoelectric and have not achieved any technological uses.

26.3 Ferroelectric Materials Fabrication Technology

Ferroelectrics are used commercially in a very wide range of forms, from single crystals through polycrystalline ceramics and thin films to polymers. Hence, only a summary of the fabrication techniques can be presented here.

26.3.1 Single Crystals

As has been shown above, ferroelectrics often have a wide range of complex compositions. This renders the problems of single-crystal growth much more difficult than for single-element crystals such as silicon. In many cases, the most technologically useful compositions are themselves solid solutions of complex ferroelectric end members. Frequently these do not melt congruently and sometimes one or more components of the melt will be volatile. Some of the growth techniques which are used are:

Czochralski Growth

Certain ferroelectric crystals melt congruently and can be pulled from the melt using the Czochralski technique. Examples include $LiNbO_3$ and $LiTaO_3$. Both materials are widely used technologically. $LiNbO_3$ is used in surface acoustic wave (SAW) and electro-optic devices and $LiTaO_3$ in pyroelectric infrared detectors, piezoelectric resonators, SAW and electro-optic devices. $LiNbO_3$ melts congruently at 1240 °C, but the congruently melting composition is not at the stoichiometric composition (Li : Ta = 1), but lies at around 49% Li_2O. Crystals pulled from such melts in platinum crucibles are perfectly adequate for piezoelectric and most optical applications. However, it is known that the stoichiometric composition possesses rather better optical properties than the congruent composition and there is now a premium-grade material available commercially. $LiTaO_3$ melts congruently at 1650 °C. Again, the composition is not at Li : Ta = 1, but is slightly Ta deficient. The growth temperature is above the melting point for platinum. The solution is to use crucibles made from iridium, which is very expensive. Also, IrO_2 is volatile so the growth atmosphere must be N_2, which means that the crystals come out of the melt oxygen-deficient and must be embedded in $LiTaO_3$ powder and annealed under O_2 after growth to make them clear. Pt/Rh crucibles have been used to grow $LiTaO_3$ crystals, but the Rh absorbed into the crystals makes them brown. Such crystals are acceptable for piezoelectric and pyroelectric, but not for optical, applications. Virtually all ferroelectric materials need to be electrically poled before use. In the case of $LiTaO_3$, silver electrodes are applied to faces perpendicular to the polar (c) axis and a pulsed field of about 10 V/cm (1 ms with a 50/50 duty cycle) applied while the crystal is cooled slowly through T_C (620 °C). A similar process can be applied to pole $LiNbO_3$ crystals or, as the T_C is very close to the growth temperature, the field can be applied between the growing crystal and the crucible. This process has also been used to grow periodically poled crystals in which the field is reversed periodically during the growth of the crystal. Such crystals have some advantages in optical frequency-doubling in a process known as quasi-phase matching [26.25].

Solution and Flux Growth

The growth of crystals from aqueous solution is a technology very readily applied to water-soluble materials such as KDP and TGS. There are two processes that have been used. The first consists of rotating crystal seeds in a bath of saturated solution, which is slowly cooled so that material that comes out of solution is deposited on the seeds. The second consists of recirculating the bath solution over feed material, which is held at a slightly higher temperature and then back over the slightly cooler seeds, where the feed material is deposited. In both techniques, very careful control of temperature is essential (better than 0.002 °C) and the growth process can take many days.

The process of growing oxide single crystals from solution or flux is closely related to the above process, in that the crystals are grown from a saturated solution of the required oxide in a molten flux as it is slowly cooled. In the simplest version of this process, the oxides are sealed in a platinum crucible, heated to a *soak* temperature and slowly cooled to room temperature. Small crystals (usually up to a few mm in size) can then be recovered from the solidified melt. This has been applied to growth of a wide variety of small single crystals, such as PZT and PMN-PT solid solutions. PZT, for example, can be grown from $PbO-B_2O_3$ flux mixtures, or even pure PbO [26.26]. $BaTiO_3$ crystals can be grown from KF or TiO_2 fluxes. A major issue with the growth of Pb-containing ferroelectrics from PbO rich fluxes is the evaporation of PbO from the melt at the crystallisation temperature over the long time periods required to grow large crystals. This can be avoided to some degree by the use of sealed crucibles. A variation on the flux growth process is top-seeded solution growth, whereby a seed crystal is immersed from above into a supersaturated solution of the material to be grown. The crystal then grows as the solution is cooled further. The process is difficult to control and it has the major problem, especially when growing from a PbO flux, that the melt is open and therefore very prone to

flux evaporation. It has been successfully applied to the growth of crystals of PMN-PT and PZN-PT solid solutions. The Bridgman process seeks to get over this problem by placing a dense compact of the flux/solute mixture inside a sealed crucible with a conical end, as shown in Fig. 26.13. A seed crystal is placed at the base of the cone which is held cooler than the rest of the crucible by a cooled rod. A molten zone is then allowed to travel up the crucible and the crystal solidifies inside it. Good-quality crystals have been grown this way and it is the preferred technique for the manufacture of PMN-PT and PZN-PT solid solutions. One problem with all flux-growth techniques is that the flux composition is constantly changing during the growth process and therefore the crystals tend to be nonuniform in composition. This is a particular problem for larger crystals, especially for solid solutions.

26.3.2 Ceramics

The vast majority of ferroelectric materials that are used commercially are used in the form of polycrystalline ceramics. These are used in many of the applications listed above, including as dielectrics and in piezoelectric, pyroelectric, PTCR and electro-optic devices. Many different ferroelectric ceramic fabrication technologies have been developed over the years, but they are all based around a similar fabrication sequence. The key points are discussed below. Note that as the vast majority of commercially exploited ferroelectrics are oxides, the discussion will centre around these materials:

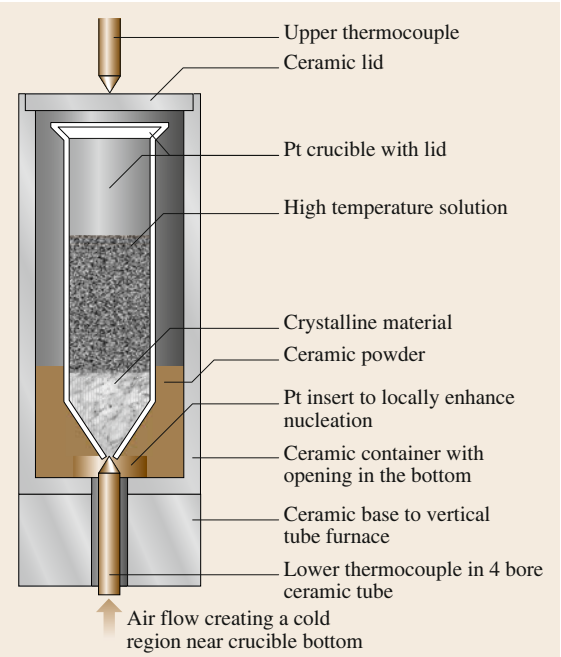

Fig. 26.13 A modified Bridgman apparatus used for growing piezoelectric single crystals. (After [26.27])

- Raw-material selection: The usual starting point for a ceramic fabrication sequence is the selection of the raw materials. For oxide ferroelectrics, the raw materials are usually oxides or carbonates, but occasionally other compounds (e.g nitrates, citrates etc.) are used which will decompose when heated to form the oxides required. High purity (usually $> 99.9\%$ with respect to unwanted cations) is important for good reproducibility. Small quantities of dopants can have a major effect on the final electrical properties, as would be expected for any electronic material, but can also seriously affect the sintering characteristics and grain size of the final ceramic body. Note that high purity does not usually imply the kind of purity that would be needed for a semiconductor material. Indeed, ultra-high purity ($> 99.99\%$) is often obtained by raw-material manufacturers by applying processes which negatively affect the reactivity of the oxide powders. A high degree of solid-state reactivity in the powders is important for the processes which follow. This is usually determined by a combination of raw-material particle size and specific surface area, although selecting the right crystallographic phase can be important. When using TiO_2, for example, it is usually found that the anatase phase is more reactive than rutile. These factors can be analysed for quality control purposes by using laser particle size analysis (taking care to break up loosely bound agglomerates by ultrasonic dispersion in water, with a dispersing agent prior to measurement), BET (Brunauer, Emmett and Teller)-specific gas absorption and x-ray powder diffraction respectively. The majority of ceramics are made by mixing together powdered raw materials, but occasionally solution mixing techniques are used and these will be discussed further below.
- Raw-material mixing: This is usually done in a ball mill consisting of a cylinder containing a mixture of small balls or cylinders made of steel, steatite, zircon or yttria-stabilised zirconia (YSZ). The oxide raw materials are accurately weighed into the ball mill, together with a predetermined amount of a milling fluid (usually deionised water, but occasionally an organic fluid such as acetone). It is usual to add a dispersant to aid the breakup of agglomerates. The ball mill is then sealed and rotated to mix the ingredients. Precise milling conditions are determined by the materials being used, but

the mixing time is usually of the order of a few hours. It is advantageous to use milling balls that are made of a material whose wear products will be reasonably innocuous in the final ceramic. For this reason, YSZ balls are preferred over steel or steatite, as small amounts of iron and silica contaminants can have unwanted or deleterious effects on the properties of many ferroelectric ceramics. For similar reasons, the ball mills are frequently rubber lined. Many variations on this process have been explored. High-energy ball milling is receiving considerable attention. In this process, the milling balls are given very high energy by either aggressively vibrating the ball mill or by stirring them at high speed with a paddle. Raw materials trapped between the balls are both comminuted and, if the energy is sufficiently high, can be forced to react together. Crystalline raw materials can be made amorphous in this process. A significant amount of energy can be stored in the powders after this process so that subsequent sintering can be undertaken at lower temperatures. In an adaptation of this process, it can be done in a continuous flow-through mill, whereby the slurry is pumped through the high-energy mill, making it less of a batch process.

- Drying: The slurry that results from the mixing process is dried after the milling balls are removed. On a small scale, this can be done in an oven or by freeze drying, but on a commercial scale, this is usually achieved by spray drying.
- Calcination: The purpose of this process is to react the raw materials into the required crystallographic phase. The dried powders are placed into a sealed crucible (usually high-purity alumina or zirconia), which is baked in a furnace at a temperature high enough to decompose any non-oxide precursors and cause a solid-state reaction between the raw materials, but not so high as to sinter the particles and form hard agglomerates that will be difficult to break up in subsequent processing. A simple example is the reaction between $BaCO_3$ and TiO_2 to form $BaTiO_3$

$$BaCO_3 + TiO_2 \rightarrow BaTiO_3 + CO_2 \uparrow \ .$$

This reaction will go to completion at about 600 °C. Note that a much higher temperature (> 1000 °C) is required for the decomposition of $BaCO_3$ to BaO in the absence of TiO_2.

- Milling: This is usually done in a similar manner to the mixing process described above, but is done for longer. The objective is to break up hard agglomerates and reduce the powder to its primary particle size. Again, high-energy milling techniques can be used. Dispersants are usually added to aid the process, and pH is controlled so that the powder does not flocculate. Organic binders can be added at this stage. The slurry from the milling process is usually spray-dried or freeze-dried as a free-flowing aggregated powder is required. The objective is to form soft aggregates that will break up on subsequent die pressing. Alternatively, the slurry (or *slip*) can be taken straight to a slip- or tape-casting process.
- Shape forming: After drying, the powders from the above process can be uniaxially pressed into the *green* shape required, typically using a steel punch and die-set. It is important in this process to make sure that the force is applied equally to top and bottom punches. Usually, the die is designed with a slight taper to ease removal of the workpiece after pressing. Faults that can occur at this stage of the process include *capping* or radial cracks in the work piece, which usually result from an uneven distribution of pressure. One way to avoid this is to use cold isostatic pressing. In this process the powder, or more frequently a lightly uniaxially cold-pressed green block, is vacuum-sealed into a rubber mould, which is then immersed in a bath of oil. The oil is taken up to a high pressure, which isostatically compresses the block. The advantage of using this process is that it avoids the nonuniform distribution of pressure that is frequently a problem with uniaxially cold pressing. The high pressure allows the agglomerates to be broken up and the process usually results in a much higher green density, which facilitates the sintering process. Anther process that can be used to form the green item is slip-casting, which involves pouring the ceramic slip into a plaster mould, which is usually gently rotated. The plaster absorbs moisture from the slip and the ceramic particles are deposited as a layer. Surplus slip is poured off and the deposited layer can be separated from the mould after it is dry. This process has been used to make large cylinders of piezoelectric ceramics. A third process that is frequently used to make thin sheets of ceramic is tape-casting, by which the slip is passed under a set of *doctor blades* in the apparatus shown schematically in Fig. 26.14. In this case, the slip is cast onto a continuous roll of plastic tape and a plastic binder is added to the slip which, when dry, holds the powder together and makes a flexible green tape. Sometimes the slip is cast directly onto a glass sheet. The green tapes can be screen-printed with patterns of metallic electrode inks and then laminated by warm-pressing to make multilayer structures with interleaved electrodes. This type of fabrication is widely used for multilayer ceramic (MLC) capacitors and multilayer ceramic piezoelectric actuators.

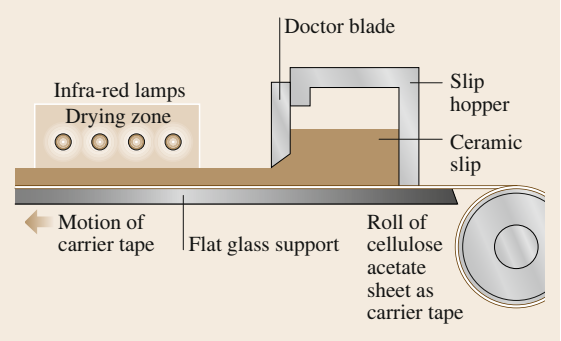

Fig. 26.14 Tape-casting apparatus

- Sintering: The green ceramic bodies are sintered in furnaces at temperatures of 1150–1300 °C, depending on the ceramic being manufactured. There is a good deal of process know-how in the sintering of the ceramic bodies. Key issues are:
  - The heating profile, which must be carefully controlled, especially over the lower range of temperatures up to about 500 °C where the organic matter (dispersants and binder) is burned off. Too rapid heating will cause large pores, or even cracks, to form.
  - For lead-containing ceramics, it is important that air be allowed free access to the vaporising organic material, or it will be carbonised and this can lead to reduction of the PbO in the ceramic to free Pb.
  - Loss of PbO by volatilisation at higher temperatures ($>\approx 800$ °C) means that the ceramic body needs to be sintered in a PbO-rich environment, which is often produced by packing the ceramic body in a *spacer powder* of $PbZrO_3$, or PZT ceramic chips within well-sealed ceramic crucibles or saggers. This tends to restrict the access of air to the sintering ceramic body, which conflicts with the previous requirement.
  - The ceramic body must be free to move during the sintering process, as there is significant linear shrinkage (about 15 to 18%). If the body is unable to slide over the surface on which it sits, this can lead to cracking, especially for large components. One solution to this problem is to sit the body on zirconia sand.

  The sintering process has been very well described elsewhere. It is possible to obtain very high densities ($> 98\%$) by careful control of the sintering conditions. For Pb-containing ferroelectric ceramics, a small excess of PbO is usually added to compensate for PbO loss by evaporation. This also tends to act as a liquid-phase-sintering aid, lubricating the grains of ceramic as they slide over each other in the sintering process, and providing a surface-tension force that pulls the ceramic grains together. The PbO also acts as a solvent, aiding the movement of the ceramic components during sintering and further densifying the ceramic. It is possible to sinter such materials to transparency, which means that there is virtually zero porosity. Very high densities can also be obtained by hot-pressing, in which the green body is placed inside a ceramic punch and die-set and raised to the sintering temperature under a pressure of about 35 MPa. Alternatively, hot isostatic pressing (HIP) can be used. In this process the pressure transmitting medium is a high-pressure gas (usually argon, but if the ceramic is Pb-containing it is important to include a few percent of oxygen to prevent reduction of the ceramic). In this case pressures of 100 MPa or more can be used. If the ceramic is pre-sintered so that there is no open porosity, then this can be achieved without the need for any container, but if there is open porosity, the body must be encapsulated in a suitable metal container, which will usually need to be a noble metal such as Pt.
- Electroding: Good-quality electroding is essential for all ferroelectric devices for a variety of reasons. Any low-permittivity layer between the electrode and the ferroelectric material will manifest itself in a fall-off in capacitance and an increase in loss as the frequency of measurement is increased. Poor-quality electrodes, or even the wrong type of conductive material can lead to problems with device ageing, or even an inability for the device to function as intended. Most piezoelectric materials are supplied with a *fired-on* silver electrode, which is a mixture of silver powder, a finely divided glass frit and a fluxing agent. Obtaining the correct balance between metal and glass contents is important, as too high a proportion of metal will lead to poor electrode adhesion while too high a proportion of glass will lead to poor electrode conductivity. Such electrodes are solderable with the use of appropriate fluxes. Sputtered or evaporated metal electrodes such as Ni or Cr/Au can also be used, as can metal electrodes deposited by electroless processes (e.g., Ni). The ohmic nature of the electrode contact to the ceramic is not usually important for highly insulating materials, such as piezoelectrics, but is important for semiconducting ceramics such as PTCR $BaTiO_3$. In this case it is usual to use Ni electrodes, which need to be annealed after deposition to develop the ohmic contact. In some cases it is necessary to fire on the electrode at the same time as ceramic sintering (cofired electrodes). This is particularly important

where the electrodes are buried in the structure, as with MLC capacitors and actuators. Clearly, there are problems to solve here in terms of the potential oxidation or melting of the electrode material. The conventional materials to use in such electrodes have been noble metals such as palladium (sometimes alloyed with silver) or platinum, which are very expensive. There have been serious efforts to develop ferroelectric compositions that can be fired with base metal electrodes such as Ni. In the case of $BaTiO_3$-based dielectrics, this has entailed the development of heavily acceptor-doped compositions that can stand being fired in a neutral or slightly reducing atmosphere. In the case of MLC actuators, there has recently been some success in developing piezoelectric PZT compositions that can stand being fired in such atmospheres, using Cu as the electrode material.

- Poling: Many devices made from ferroelectric ceramics (all piezoelectric and pyroelectric devices) require poling before they will develop useful properties. This entails applying a field that is significantly in excess of the coercive field (typically 3×), usually at an elevated temperature. It is not usually necessary to exceed the Curie temperature. For example, PZT ceramics with T_C in the range 230–350 °C can be poled by applying 3–5 kV/cm (depending on the type of PZT – see below – soft PZTs need lower poling fields than hard PZTs) at about 150 °C, with the field kept applied while the workpiece is cooled to room temperature. It is usual to immerse the ceramic in a heated bath of oil (mineral or silicone) during the process. One disadvantage of this is that the ceramic then needs to be carefully cleaned after poling. Silicone oil can be very hard to remove completely and its presence as a residue will compromise electrode solderability. For this reason, some workers have developed a process whereby the ceramic is poled under SF_6 gas. There is a rapid decay of properties after poling. This decay stabilises after a few hours, so it usual to wait at least 24 hours before electrical properties are measured.

There are many variations on the above basic process route which have been researched. One of these is the use of solution techniques to prepare the oxide powders. The basic principle here is that if the cations are mixed in solution, then they will be mixed on the interatomic scale without the need for milling processes that can introduce impurities. (This is a matter of discussion, as the act of precipitation and decomposition can lead to separation of the components.) Many routes have been explored, including the use of inorganic precursors such as nitrates and metalorganic precursors such as oxalates, citrates or alkoxides and acetates. Some of these have achieved a degree of commercial success, although the use of solution routes is more complex and the raw materials much more expensive than the mixed oxide routes. The use of mixed barium titanium oxalates has been very successful in producing high-quality fine-grained barium titanate powder for use in the capacitor industry. The use of metal citrates (frequently called the Pechini process) has been successfully used on a research scale to prepare many different types of ferroelectric oxide, but this type of process has not been applied on a commercial scale. Metal alkoxides, such as titanium isopropoxide, are readily soluble in alcohols and will react quickly with water to precipitate a hydroxide gel. Workers have used mixtures of titanium and zirconium alkoxides with lead and lanthanum acetates to coprecipitate a mixed hydroxide gel that could be calcined and sintered to make transparent lead lanthanum zirconate titanate ceramics for electro-optical applications.

26.3.3 Thick Films

There has been considerable interest in the integration of thick (10–50 μm thick) films of ferroelectric materials with alumina and other types of substrates such as silicon, to complement the wide range of other thick-film processes that are available, covering conductors, dielectrics, magnetic materials etc. There are many potential advantages to thick film processing for making certain types of sensor, especially the ability to use screen-printing for depositing the patterns of the materials required. Screen-printing involves using a sheet of wire mesh (the *screen*) that is coated with a photosensitive polymer. Exposure and development of the polymer allows selected areas to be removed, opening regions through which a paste of the required material can be pushed using a rubber blade or squeegee. The principle is simple, but there is a considerable amount of know-how in the formulation of the paste, which consists of the active material (in this case a ferroelectric powder such as PZT), an organic vehicle (a mixture of a solvent and polymer) and a glass frit. The screen is stretched over a former, and held close to, but not in contact with, the surface onto which the print is required. The paste is placed on the screen, and then spread over the screen with the squeegee, which prints the paste onto the substrate. Successive layers of different materials can be printed and cofired, provided there is good compatibility between them. The process has been well developed for piezoelectric films and adequate properties have been obtained from the films, although they are still well below the values that could be expected

from a bulk ceramic material. (See review by *Dorey* and *Whatmore* [26.28] for further details.)

26.3.4 Thin Films

The integration of high-quality thin films ($< 0.1-5\,\mu m$ thick) of ferroelectric materials onto substrates such as silicon has excited considerable interest for potential applications ranging from nonvolatile information storage to their use as active materials in micro-electromechanical systems (MEMS), where they can potentially be used for microsensors and actuators. Almost all the interest has been in the use of oxide ferroelectrics, but there has been some interest in the use of P(VDF-TrFE) copolymer films. These can be spun onto electroded substrates from methyl ethyl ketone solution. They are dried at relatively low temperatures ($< 100\,^{\circ}C$) and crystallised by annealing at $180\,^{\circ}C$ for several hours [26.29]. Such films have been applied to pyroelectric devices. However, the activity coefficients which can be obtained from such films are much lower than those that can be obtained from oxide materials. A range of deposition techniques have been developed for growing ferroelectric oxide films, which are summarised below:

- Chemical solution deposition (CSD): This term is applied to a wide range of processes that involve taking the metal ions into metalorganic solution, which is then deposited on the substrate by spinning, followed by drying and annealing processes to remove the volatile and organic components and convert the layer into a crystalline oxide. There are two broad classes of CSD process: metalorganic deposition (MOD) and sol gel. The MOD processes usually involve dissolving metal complexes with long-chain carboxylic acids in relatively heavy solvents such as toluene. The carbon content of the precursors is quite high, so there is a good deal of thickness shrinkage during firing. MOD solutions tend to be quite stable with time and resistant to hydrolysis. Sol-gel processes use precursors such as metal alkoxides, acetates and β-diketonates in alcohol solution. (For example, a set of precursors to deposit PZT would be Ti isopropoxide, Zr n-propoxide and lead acetate). Alkoxide precursors are very susceptible to hydrolysis, and so careful control of moisture content during the sol synthesis is essential and stabilisers such as ethylene glycol are usually added to the solutions to extend the useable lifetimes of the sols. Whereas MOD solutions are true solutions, the sols are actually stable dispersions of metal oxide/organic ligand particles with a size of about 4–6 nm. Sols possess lower viscosities and tend to produce the oxide layer at a somewhat lower temperature than the MOD processes, but the individual layer thicknesses produced by a single spin tend to be lower. Single crack-free layers tend to be in the range 100–200 nm thick. CSD processes have the advantages that they are low cost, the composition can be easily changed and they produce very smooth layers. The processes are planarising and will not follow underlying surface topology, which can be a disadvantage. Also, the processes are not industry standard in that they are wet and tend to have many variations.
- Metalorganic chemical vapour deposition (MOCVD): This is a variation on the process that has been very successfully applied to the growth of group III–V semiconductor layers. The principle is simple: volatile metalorganic compounds are passed over a heated substrate, where they decompose to form a layer of the desired compound. The problem with the growth of ferroelectric oxides is that most of the available metal organic precursors are relatively nonvolatile at room temperature. There has, therefore, been a great deal of research into the available precursors for the compounds that are required. Metal alkyls (such as lead tetraethyl) are very volatile, but only available for relatively few of the metal ions of interest (Pb being the main one). They are also pyrophoric and highly toxic. Some metal alkoxides, such as Ti isopropoxide, are suitable MOCVD precursors. Metal β-diketonates and related compounds such as tetramethyl heptane dionates (THDs) have received considerable attention as Ba and Sr precursors. All of these precursors need to be heated to give them suitable volatility and this means that the lines connecting the precursor source to the growth chamber need to be heated as well. Some of the precursors (especially THDs) are solids, which means that they are not really suitable for use in conventional bubbler-type sources. There has been considerable success in using solutions of these compounds in tetrahydrofuran (THF). The solutions are sprayed into a vaporiser that consists of a cylinder, containing wire wool or ball bearings, heated to a temperature at which the solution will flash-evaporate. A carrier gas is passed through the cylinder and this carries the precursor vapour into the growth chamber. The growth chamber is usually held at reduced pressure and a certain amount of oxygen is introduced to aid the oxide deposition. Frequently a radio-frequency (RF) or microwave plasma is also introduced to aid the growth of a high density film and reduce the required substrate temperature. The major problem

with the MOCVD process for complex ferroelectric oxides which have many cation components is finding the right combination of precursors that will all decompose at the same substrate temperature (usually ca. 550–650 °C) at a rate that will give the desired composition in the film. The process has been very successful in growing thin films of materials such as $(Ba, Sr)TiO_3$, with potential applications in the dynamic random-access memory (DRAM). The major advantage of MOCVD is that it is a truly conformal growth technique, with major advantages for semiconductor devices with complex topologies, but is a very expensive technique to set up because of the complex growth and control systems needed. Also, precursor availability is still a problem for many systems.

- Sputtering: A range of sputtering processes have been applied to the growth of ferroelectric thin films, including RF magnetron sputtering, direct-current (DC) sputtering and dual ion-beam sputtering. The RF magnetron process is probably the most popular. With all the processes, the major problem is one of obtaining the correct balance of cations in the growing film. Many different solutions have been found to this problem. In reactive sputtering, a composite metal target can be used. This can be made of segments of the metals to be sputtered (for example, Pb, Zr and Ti for PZT) and their relative areas changed to obtain the right composition in the film. Alternatively, multiple targets can be used and the substrate exposed to each one for different lengths of time, or the power applied to each one can be varied. In reactive sputtering, it is necessary to have an amount of oxygen in the sputtering gas (usually Ar). It is possible to sputter ferroelectric thin films from ceramic or mixed powder targets, but it is necessary to adjust the target composition to allow for different yields for each element. In any sputtering process there are many variables to adjust to optimise the process, including the sputtering power, and RF or DC substrate bias, which will affect the ion bombardment of the growing film, the sputtering atmosphere pressure and gas mixture and the substrate temperature. All of these can affect the film growth rate, composition, crystallite size and crystalline phases that are deposited, and the stress in the growing film. For this reason, the development of a sputtering process for a complex ferroelectric oxide can be a time-consuming business, and once a set of conditions has been arrived at for one particular composition, it cannot quickly be changed to accommodate new compositions. Dual ion-beam sputtering differs from the RF and DC processes in that a much lower background pressure is used, the material is sputtered from the target using an ion beam and a second lower-energy ion beam is used to stimulate and densify the growing film. The sputtering processes have the advantage of being well accepted industrially, as they are dry and can readily coat large-area substrates.
- Laser ablation: This process involves bombarding a ceramic target with a pulsed, focussed laser beam, usually from an ArF excimer source. The target is held under vacuum. A plasma plume is produced and the products ablated from the target are allowed to fall on a heated substrate. The advantages of the process are that there is usually good correspondence between the composition of the target and the growing film. Relatively small ceramic targets are acceptable for the process, and it is thus a good method for getting a rapid assessment of the properties of thin films of a given material. The disadvantages of the process are that the plasma plume will only coat a relatively small area of substrate, although there are now systems which use substrate translation to coat large areas, and particles can be ablated from the target, causing defects in the growing film.

In all the techniques used for the growth of ferroelectric oxide thin films, the key issues are control of composition and the formation of the desired crystalline phase (usually perovskite) with the desired crystallinity (crystallite size, morphology and orientation). All of the ferroelectric perovskites have a tendency to crystallise into a non-ferroelectric fluorite-like pyrochlore phase at low temperatures. In the case of the CSD processes, this means that as the film is heated from room temperature, after it loses the organic components, it first forms an amorphous oxide which then crystallises into a nanocrystalline pyrochlore phase, finally forming the desired perovskite phase. The temperatures at which this will occur depend very much on the ferroelectric oxide that is being grown and the precise composition. In the case of PZT, the pyrochlore phase will form above about 300–350 °C. The perovskite phase will start to form above about 420 °C, depending upon the ratio of Zr : Ti in the solid solution. The compositions close to $PbTiO_3$ will crystallise into perovskite much more readily than those close to $PbZrO_3$. In the case of a complex perovskite, such as $Pb(Mg_{1/3}Nb_{2/3})O_3$ or $PbSc_{1/2}Ta_{1/2}O_3$, the pyrochlore phase is much more stable and much higher temperatures (> 550 °C) are needed to convert it to perovskite. Excesses of PbO will tend to favour the formation of perovskite, and deficiencies favour pyrochlore. Higher annealing temperatures will promote PbO loss and it is

possible to get into a position, through PbO loss, where the pyrochlore becomes the most stable phase, even at high annealing temperatures. Residual pyrochlore phase invariably compromises the electrical properties of the films through reduced permittivity and piezoelectric/pyroelectric coefficients. The other growth techniques have the advantage that the films can be deposited onto heated substrates, at temperatures where they will grow directly into the perovskite phase (at least in principle), although there are many examples in the literature of films being deposited (e.g., by sputtering) at low substrate temperatures and converted to the desired perovskite phase by post-deposition annealing, in which case the same problems of pyrochlore formation apply. The control of film crystallinity (crystallite orientation and size) is important as it has a direct effect on the electrical properties. This is usually achieved through control of the crystallite nucleation. Sputtered Pt is frequently used as a substrate onto which ferroelectric thin films are grown. Like many metals, this will naturally grow with a (111) preferred orientation. It is face-centred cubic (fcc), with a lattice parameter of about 3.92 Å, which matches the lattice parameters of many of the ferroelectric perovskites, which are about 4 Å. This means that, with appropriate process control, it is quite possible to get a highly orientated (111) ferroelectric film on Pt, with a crystallite size of about 100 nm. Changing the underlying nucleation layer can allow other orientations to be grown. For example, the use of thin films of TiO_2 or PbO on top of the Pt electrode can induce a (100) orientation. It is important to control the nucleation density of the perovskite phase. If this is allowed to become too low, than large circular grains several microns in diameter (called *rosettes*) can form, which tend to induce defects at their boundaries. (Further details on thin-film ferroelectric growth techniques can be found in the book by *Pas de Araujo* et al. [26.30]).

26.4 Ferroelectric Applications

26.4.1 Dielectrics

As noted above, $BaTiO_3$ possesses a very high permittivity close to T_C. The inclusion of selected dopants can reduce T_C and optimise the properties of the material for capacitor applications. The substitution of Sr^{2+} for Ba^{2+}, for example, will reduce it, so that at about 15% substitution it will occur at about 20 °C. Substitution of Zr^{4+} for Ti^{4+} has a similar effect. The use of off-valent substitutions will have an effect upon resistivity and degradation characteristics, so that substituting La^{3+} on the A site will reduce resistivity at low concentrations. Substituting Nb^{5+} on the B site at the 5% level has been shown to confer resistance to degradation. The addition of Mn to the lattice has been shown to have a positive effect on dielectric loss. Control of grain size has also been shown to have a marked effect on dielectric properties. Reducing the grain size has the effect of increasing the concentration of domain walls per unit volume of ceramic, and thus increasing the domain-wall contribution to the permittivity. A reduction in grain size also brings about an increase in the unrelieved stress on the grains, which further increases the permittivity. Once the grain size falls below about 0.5 μm, the stress on the grains reduces their tetragonality and the permittivity falls. It is also possible to use heterogeneity in the ceramic grains to flatten the curve of dielectric constant versus temperature. A range of Electronic Industries Alliance (EIA) codes have been introduced to define the variation of capacitance with temperature. The X7 temperature range, for example, is −55 to +125 °C, while following this with the letter R would specify a capacitance change of no more than ±15%. Other dielectrics have been developed based on PMN that have higher peak permittivities, but worse temperature characteristics, capable of meeting a Z5U specification (+22 to −56% capacitance variation over the range of 10−85 °C) but not much better. There has been huge progress in MLC technology, with capacitors now available with > 100 layers of submicron thickness and capacitances ranging from a few hundred pF to 100 μF. The majority of these now have base-metal (Ni) electrodes. The fabrication of the ceramic dielectrics for these is a very complex area and a great deal of technology has been developed to service a very large MLC capacitor market (615 Bn units in 2002, worth an estimated $ 8.4 Bn).

26.4.2 Computer Memories

The storage of digital information is of great interest and growing technological importance. The ability of ferroelectrics to store information via the sense of the spontaneous polarisation has made them candidates for this application ever since the advent of the electronic computer. However, it is only with the development of the techniques for the growth of ferroelectric thin films onto silicon at relatively low temperatures (see above) that their use has become a reality. There are two ways in which ferroelectrics can be used in com-

puter memories. The first is the replacement of the dielectric layer in dynamic random-access memories (DRAMs). Here, the motivation is to exploit the high permittivities exhibited by ferroelectric oxides to reduce the area of silicon required to store a single bit of information. The favoured materials here are based on (Ba, Sr)TiO_3, while the favoured technique for thin-film growth is plasma-enhanced MOCVD because of its ability to deposit conformal coatings. No DRAM devices using these thin films have yet reached the market place. The use of the switchable polarisation for the nonvolatile storage of information has received a great deal of research. A good deal of this work has been based upon the use of PZT thin films, grown by a variety of techniques, including CSD, RF sputtering and MOCVD. Initially, there were many problems to solve, including the decay of the switchable polarisation (ca. 35 $\mu C/cm^2$) as the number of switching cycles increased (fatigue), the tendency for the polarisation in a bit to become less easily switched with time and the number of times it is switched in the same sense (imprint) and the tendency for the switchable polarisation in any one bit to decay with time (retention). The fatigue and imprint problems in PZT have been ascribed to the motion of oxygen vacancies addressed by the use of oxide, rather than metallic, electrodes and doping to reduce the vacancy concentration. It has also been demonstrated that Aurivillius compounds such as strontium bismuth tantalate (SBT) and La-doped $Bi_4Ti_3O_{12}$ do not show fatigue behaviour, although they do require rather higher growth temperatures than the PZT family and have a significantly smaller switchable polarisation (ca. 7 $\mu C/cm^2$). A number of companies are now making chips with nonvolatile on-board embedded ferroelectric random-access memory (FRAM). These are going into applications such as smart cards and computer games.

26.4.3 Piezoelectrics

This represents the most diverse range of applications for ferroelectric materials, as noted in the introductory section, covering a wide range of sensors, actuators and acoustic wave components for frequency control and filtering applications. The key properties determining the performance of a piezoelectric material in a particular application are the piezoelectric coefficients, elastic and dielectric constants. These are all tensor properties (see *Nye* [26.31]) and are combined through the constitutive equations

$$D_i = d_{ijk}X_{jk} + \varepsilon_{il}E_l \,,$$
$$x_{ij} = s^E_{ijkl}X_{kl} + d_{mij}E_m \,,$$

where D_i = electric displacement, E_i = electric field, X_{ij} = stress, x_{ij} = strain, d_{ijk} = piezoelectric coefficients, ε^X_{ij} = dielectric permittivity coefficients at constant stress, and s^E_{ijkl} = elastic compliance coefficients at constant electric field.

The above equations use the Einstein repeated-suffix tensor notation. Note that most piezoelectric equations use the reduced-suffix notation for the piezoelectric and elastic constants [26.31].

There are two basic modes of operation for piezoelectric sensors and actuators. The first is well away from any mechanical resonance – usually at low frequency or quasi-DC. Here, the electric signals generated by an applied stress, or the strain generated by an applied electric field can be easily calculated using the constitutive equations of the type quoted above. The commonly used modes for operating piezoelectric ceramic actuators are longitudinal, where the electric field is applied parallel to the direction in which strain is required and the coupling is via the piezoelectric d_{33} coefficient, and transverse, where a field is applied along the polar axis, but the exploited strain is perpendicular to this direction and coupling is via the d_{31} and d_{32} coefficients. Corresponding modes are frequently used for piezoelectric sensors. The two most-commonly used actuator structures are illustrated in Fig. 26.15. Figure 26.15a shows a piezoelectric bimorph, in which two pieces of piezoelectric ceramic are bonded to a central metal shim. Fields are applied parallel to the polar axes of the ceramic elements so that their transverse extensions are equal and opposite. Usually one end of the bimorph is clamped so that the other end bends. In a variation on this structure, a single piece of ceramic is bonded to a piece of metal, making a unimorph. Bimorph and unimorph devices can provide high displacements (several tens to thousands of microns at up to 200-V drive) but relatively low forces (typically up to 1 N), depending on the size of the bimorph. The second widely used actuator structure is the multilayer

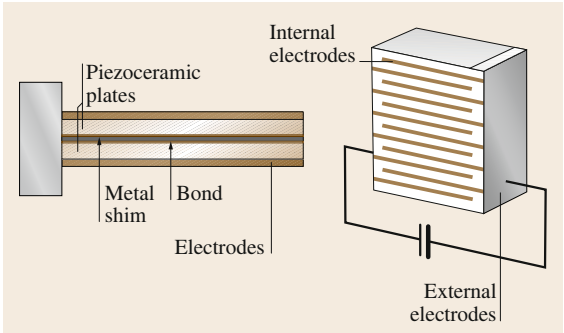

Fig. 26.15 (a) Piezoelectric bimorph and (b) MLC actuator structures

ceramic actuator (Fig. 26.15b). This device operates in longitudinal mode, with applied field and extension parallel to the polar axis. The division of the structure into many thin layers reduces the voltage required to obtain a given extension. Typical devices can produce a few to a few tens of microns extension at a few hundred Volts (depending on dimensions) but high forces (in the kiloNewtons range). It is also possible to use a shear mode of operation for both sensing and actuation. In this actuation mode, the field is applied perpendicular to the polar axis and a shear strain is generated in the plane containing the vectors parallel to the applied field and the polar axis.

Many piezoelectric devices are operated under an alternating electric field whose frequency is tuned to match a mechanical resonance. A piezoelectric element operated well away from resonance will exhibit a capacitative impedance characteristic, As a mechanical resonance is approached, the electrical behaviour of the element can be characterised using an equivalent circuit as shown in Fig. 26.16a. C_0 is the static capacitance. The L_m, R_m, and C_m form the motional arm of the circuit. If the admittance of such a circuit is plotted as a function of frequency, a behaviour is obtained as shown in Fig. 26.16b. The maximum in the admittance is very close to the mechanical resonant frequency (f_r), while the minimum in the admittance is close to antiresonance (f_a); f_r is determined by the elastic properties of the piezoelectric, its density and the dimensions relevant to the particular resonant mode. It is useful to define an effective electromechanical coupling coefficient k_{eff} which is defined by

$$k_{eff}^2 = \frac{\text{mechanical energy converted to electrical energy}}{\text{input mechanical energy}}$$

or

$$k_{eff}^2 = \frac{\text{electrical energy converted to mechanical energy}}{\text{input electrical energy}} ,$$

k_{eff} can be determined from f_r and f_a

$$k_{eff}^2 \approx \frac{f_a^2 - f_r^2}{f_a^2} .$$

It can be shown that, for a simple resonant mode of a piezoelectric element, k_{eff} takes the form

$$k_{eff}^2 = \frac{d^2}{s^E \varepsilon^X}$$

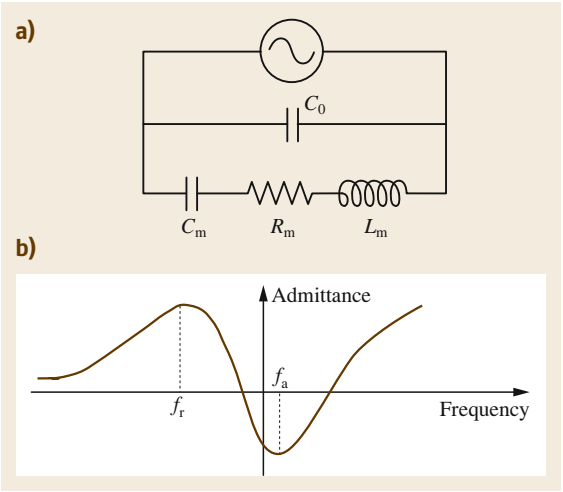

Fig. 26.16 (a) Piezoelectric element equivalent circuit (b) Admittance versus frequency for a typical piezoelectric resonator

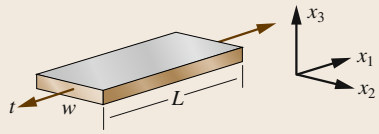
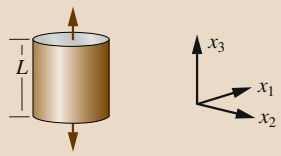
where the d, s and ε coefficients in this equation are combinations of the piezoelectric, elastic and dielectric permittivity coefficients. The precise combination of the coefficients will depend on the shape of the piezoelectric element and the mode being excited into resonance. A list of the more commonly used modes and the dependence of k_{eff} on the relevant materials constants is given in Table 26.4. For more complex structures, such as those which involve a piezoelectric element (or elements) bonded to a metal component, it is still possible to define and measure a k_{eff}, but its value will be a much more complex combination of the materials constants, and will also involve the properties of the metal parts and the relative dimensions of the piezoelectric and metal components. (For more details refer to the IEEE standards on piezoelectricity).

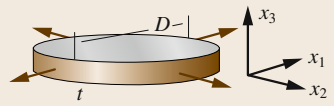
By far the most widely exploited piezoelectric materials system is based on the $PbZr_xTi_{1-x}O_3$ ceramic solid solution series. Most of the compositions of-interest are centred on the morphotropic phase boundary (MPB) region (Fig. 26.7) with $x = 0.52$. In the undoped series, the piezoelectric coefficients and dielectric constants peak at this composition. However, their properties can be greatly enhanced by the inclusion of selected cation dopants. These can be classified as follows:

- Isovalent: These are divalent cations that will substitute for Pb^{2+} on the A site (e.g., Sr^{2+}) or tetravalent ions (e.g., Sn^{4+}) substituting for Ti/Zr^{4+} on the B site.
- Donors: These are cations with a valency greater than the site onto which they substitute (e.g., La^{3+} for Pb^{2+} or Nb^{5+} for Ti/Zr^{4+}).

Table 26.4 A list of the most commonly used piezoelectric resonances and the dependence of the k_{eff} for each on the piezoelectric, elastic and dielectric constants. (After [26.32])







Mode type	Mode shape	Coupling factor
Length extensional mode of a bar using transverse excitation $L > 5w$, $L > 10t$		$k_{31}^l = \frac{d_{31}}{\sqrt{\epsilon_{33}^{\mathrm{T}} s_{11}^{\mathrm{E}}}}$
Length extensional mode of a cylindrical rod using logitudinal excitation $L > 10 \times$ diameter		$k_{33}^l = \frac{d_{33}}{\sqrt{\epsilon_{33}^{\mathrm{T}} s_{33}^{\mathrm{E}}}}$
Radial mode of a round plate using longitudinal excitation $D > 20 \times$ thickness		$k_p = \frac{k_{31}}{\sqrt{2/(1-\sigma^p)}}$
	Grey areas denote the electroded surfaces	

Table 26.5 The effects of substituents in the PZT system. (After [26.11])

Isovalent substituents, e.g., Sr^{2+} for Pb^{2+}, Sn^{4+} for Zr^{4+}	**Donor substituents, e.g., La^{3+} for Pb^{2+}, Nb^{5+} for Zr/Ti^{4+}**
Lower Curie point	No change in Curie point
Increase permittivity	Higher permittivity
Small improvement in linearity at high drive	Higher electromechanical coupling
No change in coupling factor, aging, volume resistivity or low amplitude mechanical or dielectric loss	Poorer high drive linearity
	Lower aging
	Increase resistivity
	Reduced Q_E and Q_M
Acceptor substituents, e.g., K^+ for Pb^{2+}; Fe^{3+} for Zr/Ti^{4+}	**Variable valence substituents, e.g., Mn – can be 2+, 3+, 4+ – for Zr^{4+}**
No change in Curie point	No change in Curie point
Lower permittivity	Range of permittivity
Lower electromechanical coupling	Range of electromechanical coupling – usually lower
Improved drive linearity	High drive/linearity not changed
Little change in aging	Reduced aging
Volume resistivity reduced	
Increased Q_E and Q_M	

- Acceptors: These are cations with a valency lower than the site onto which they substitute (e.g., K^+ for Pb^{2+} or Ni^{3+} for Ti/Zr^{4+}).
- Multivalent: These are ions that take multiple valency (e.g., Mn substituted on the B site).

The broad effects of each class of dopants are listed in Table 26.5.

The resulting PZT ceramics are broadly classified into *hard* or *soft* according to whether they are doped with acceptors or donors, respectively. Each manufacturer has its own nomenclature scheme for its piezoceramic products. However, the US Navy produced a set of specifications under MIL-STD-1376B which are universally recognised. Hard ceramics (e.g., US Navy type III) have relative permittivities in the range of 1000 with high Qs (> 500) and d_{33} of about 215 pC/N. Soft ceramics (e.g., US Navy type VI) have much higher permittivities (3250) and piezoelectric coefficients (d_{33} = 575 pC/N) but lower Q's (65). Hard ceramics have much better drive-voltage stability and higher Curie temperatures than soft ceramics. The soft compositions tend to be used for actuator applications, where the maximum piezoelectric displacement for a given drive

Table 26.6 Typical values for the piezoelectric, dielectric and elastic properties of some selected piezoelectric ceramic materials. (Taken from [26.33])

Material type	I	III	V	VI	Units
Stress-free relative permittivity (ε_{33})	1275	1025	2500	3250	
Dielectric loss tangent ($\tan\delta$)	≤ 0.006	≤ 0.004	≤ 0.025	≤ 0.025	
d_{33}	290	215	495	575	pC/N
k_p	0.58	0.50	0.63	0.64	
Mechanical quality factor Q_m	≥ 500	≥ 800	≥ 70	≥ 65	
Curie temperature (T_C)	325	325	240	180	°C

voltage is sought, while soft ceramics tend to be used for resonant and sound-generation applications. There are, however, exceptions to this. Medical ultrasound transducer arrays tend to use soft, high-permittivity ceramics, because they need to have the maximum charge sensitivity in the reception of the sound waves reflected from tissues within the body, and high permittivities because the small elements usually need to drive transmission lines with significant capacitance.

There are other types of piezoelectric ceramics that are used for specialist applications. Modified $PbTiO_3$ ceramics possess very low values of d_{31} and tend to be used for ultrasound array applications where small cross-coupling between adjacent elements is important. They also possess much higher response to hydrostatic stress than MPB PZT ceramics. Because of this, arrays of small blocks of this type of ceramic are used in flank array sensors in submarines. As noted above, lead metaniobate ceramics are used in high-temperature applications. Table 26.6 lists the piezoelectric and other properties of some selected piezoelectric ceramics.

Single crystals of PZN-PT and PMN-PT have received considerable attention because of the very high piezoelectric d_{33} coefficients and k_{33} coupling factors that can be obtained and single-crystal plates of these are now commercially available. Table 26.7 lists some of the properties that have been measured from these materials, and compares them with a commercial soft PZT ceramic.

Single crystals of $LiNbO_3$ are widely used in surface acoustic wave devices. In these, interdigitated electrodes (IDEs) are applied to one polished face of a crystal. Excitation of these with an RF field will cause the generation of piezoelectrically excited Rayleigh waves, which will propagate with very little attenuation. These can be detected by further sets of IDE placed on the same face of the crystal. Such devices are widely used in signal processing and filtering applications in mobile telecommunication applications.

Thin films of piezoelectric materials, excited into thickness-mode resonance, are being explored for very-high-frequency (> 1 GHz) resonant filter applications. Thin films of PZT are now widely used in inkjet printers.

Table 26.7 Piezoelectric properties of PMN-PT single crystal materials [26.34] compared with those of a commercial soft-piezoelectric ceramic HD3203 [26.35]

Property	Composition	
	PMN-PT X2B	HD3203
$\varepsilon_{33}^T/\varepsilon_o$	5000–7500	3370
T_{RT} (°C)	85–98	NA
T_C (°C)	> 142	195
k_t (%)	55–59	0.536
k_{33} (%)	91–95	0.763
N_{33} (Hz.m)	599	2000
d_{33} (pC/N)	1500–2300	564

26.4.4 Pyroelectrics

The pyroelectric effect is now widely used in uncooled detectors of long-wavelength infrared radiation (IR). The principle behind the operation of these devices is very simple. The radiation to be detected is allowed to fall upon a thin chip of the pyroelectric material. The energy absorbed causes a change in temperature and the generation of a pyroelectric charge, which will cause the flow of current in an external circuit. This can be amplified and used, for example, to switch an alarm. The basic circuit of a pyroelectric detector is shown

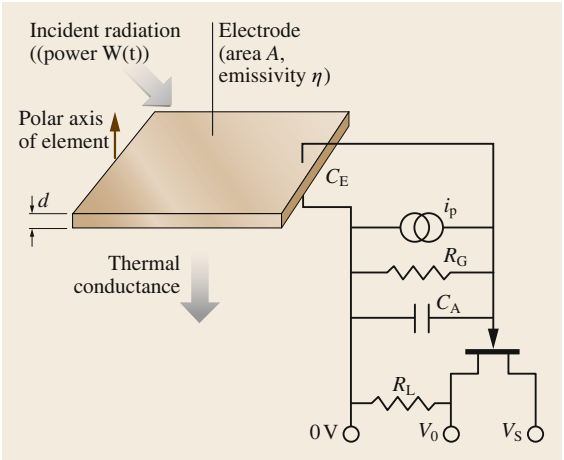


Fig. 26.17 Schematic diagram of a pyroelectric IR sensor

schematically in Fig. 26.17. The field-effect transistor (FET) amplifier needs to be close to the pyroelectric element, ideally in the same package. This is because the latter has a very high output impedance and thus is very noise sensitive. The pyroelectric signal is represented in this circuit as a current source, i_p. i_p is proportional to the rate of change of the element temperature with time. Pyroelectric devices do not have a DC response. They only see changes in the intensity of the radiation with time. This is a major advantage in many applications, where usually there is a requirement to detect changes in the radiation coming from a scene, rather than the average or unchanging background intensity. An example of this is the requirement to detect the radiation from a person coming into the field of view of an IR detector.

Pyroelectric devices have several advantages over other radiation detectors. Their response is independent of the wavelength of the incident radiation, provided there is some means to absorb the radiation. Hence, pyroelectric radiation detectors have been used across the full range of the electromagnetic spectrum, from microwaves to x-rays. Basically a single pyroelectric detector design can be used for different wavelengths of radiation, simply by equipping the package with different windows coated with filters according to the radiation it is desired to sense. Such devices are widely used in spectroscopic sensors for, e.g., automotive exhaust-gas analysis. However, by far the widest application of pyroelectric detectors is in the sensing of IR in the wavelength range $8-14\,\mu m$. The reasons for this are that there is an atmospheric window of low absorption and that objects with temperatures in the range of room temperature (300 K) emit most of their radiative energy in that waveband. However, all of the semiconductor detectors of $-8-14\,\mu m$ IR need to be cooled to about 77 K to work efficiently. On the other hand, pyroelectric detectors work perfectly well uncooled. Cheap detectors are readily available for under $\$1$, and have thus found their way into a host of applications, notably detectors of people in such things as intruder alarms and remote light switches. Pyroelectric arrays have been developed in which a plane of pyroelectric material is interfaced to a silicon chip bearing a two-dimensional array of FET amplifiers and a set of switches which can be used to multiplex the pyroelectric signals onto a single output. These arrays have been used for uncooled thermal imagers with performances comparable to those that can be achieved with cooled semiconductor devices [26.36].

The requirements for the active materials in a pyroelectric device has been described by, for example, *Whatmore* [26.22], *Whatmore* and *Watton* [26.36]. There are two time constants that determine the frequency response of a pyroelectric device: the electrical time constant determined by $R_G(C_E + C_A)$ (see Fig. 26.17) and the thermal time constant determined by H/G where H is the heat capacity of the pyroelectric element and G the thermal conductance from the pyroelectric element to the environment. The capacitance of the element (C_E) is determined by the permittivity (ε) of the pyroelectric material while the heat capacity is determined by its specific heat per unit volume (c'). The pyroelectric current is proportional to the material's pyroelectric coefficient ($p = dP_s/dT$). A full treatment of the physics of device operation shows that detector performance (as determined by specific detectivity) is proportional to one of three basic figures-of-merit (FOMs), which combine the pyroelectric, dielectric and thermal properties of the pyroelectric material together. If the pyroelectric element capacitance is small in comparison with the amplifier capacitance (C_A), then the appropriate FOM is $F_I = p/c'$. If $C_E \gg C_A$ and the noise in the device is dominated by the amplifier noise sources, then the appropriate FOM is $F_V = p/c'\varepsilon$. If the noise is dominated by alternating-current (AC) Johnson noise in the pyroelectric element then the appropriate FOM is $F_D = p/c'\sqrt{\varepsilon \tan\delta}$, where $\tan\delta$ is the dielectric loss tangent of the pyroelectric material. Note that it is very important to measure the dielectric constant and loss at a frequency relevant to the device use. As most pyroelectric devices are used in the frequency range $0.1-100\,Hz$, and dielectric loss is usually much greater at $< 100\,Hz$ than at 1 kHz, a low-frequency measurement is essential. Table 26.8 lists the pyroelectric properties of several ferroelectric materials. Note that many of the literature papers on the subject only quote 1 kHz dielectric measurements. The differences between the FOM for the materials where high- and low-frequency data are available are clear. It can be seen that that the DTGS (deuterated triglycerine sulfate) family gives the largest figures of merit. However, these materials are water soluble and have relatively low Curie temperatures and so they are only still used in the high-performance devices for instruments such as in Fourier-transform infra-red (FTIR) spectrometers. $LiTaO_3$ (LT) is a good pyroelectric material with relatively low permittivity. It is inert and relatively easy to handle. It is used in many single-element detectors. Ceramic materials such as those based on modified $PbZrO_3$ (Mod PZ) or modified $PbTiO_3$ (Mod PT) are widely used in low-cost detectors. Note that, although their FOM are worse than LT, they are low cost and their performance is perfectly adequate for many applications. The PVDF family (represented here by a P(VDF/TrFE70/30 copolymer) have good F_V, but relatively low F_D values compared with the other materials listed. They tend to be used in large-area detectors because of their low permittivi-

Table 26.8 Pyroelectric properties of several ferroelectric materials (taken from *Whatmore* and *Watton* [26.36])

Material	Meas. T (°C)	p (10^{-4} C m^{-2}K^{-1})	Dielectric properties (ε)	(tan δ)	Freq. (Hz)	c' (10^6 J m^{-3}K^{-1})	T_C (°C)	F_V (m^{2}C^{-1})	F_D (10^{-5} Pa$^{-1/2}$)

Mod. PT (Ceramic)	25	3.5	220 220	0.01 0.03	1000 33	2.8	> 250	0.063 0.063	2.9 1.6

ties, low cost and the fact that they are readily made in very thin films with low thermal mass, which is an advantage in some circumstances. They have been demonstrated in linear arrays. It is advantageous for very small-area detectors (say $< 100\,\mu$m square), such as those used in arrays, for the pyroelectric material to have a relatively high permittivity (a few hundred) so that the detector can have a capacitance that matches the input capacitance of the FET amplifier (usually ca. 1 pF). The ceramic materials are well suited to this application for that reason. There has been considerable research into the use in thermal imaging arrays of ferroelectrics with T_C close to room temperature under an applied bias field, which will provide an induced pyroelectric effect well above the normal T_C. This has been called dielectric bolometer mode of operation and the best materials researched for this have been $Pb(Sc_{0.5}Ta_{0.5})O_3$ (PST) and $(Ba_xSr_{1-x})TiO_3$ solid solutions with $x \approx 0.35$. These materials have relative permittivities of > 1000 under the operational conditions and very high pyroelectric coefficients which can give an effective F_D some three times greater than can be achieved using conventional pyroelectric ceramics [26.37].

27. Dielectric Materials for Microelectronics

Robert M. Wallace

Dielectrics are an important class of thin-film electronic materials for microelectronics. Applications include a wide swathe of device applications, including active devices such as transistors and their electrical isolation, as well as passive devices, such as capacitors. In a world dominated by Si-based device technologies, the properties of thin-film dielectric materials span several areas. Most recently, these include high-permittivity applications, such as transistor gate and capacitor dielectrics, as well as low-permittivity materials, such as inter-level metal dielectrics, operating at switching frequencies in the gigahertz regime for the most demanding applications.

This chapter provides a survey of the various dielectric material systems employed to address the very substantial challenge associated with the scaling Si-based integrated circuit technology. A synopsis of the challenge of device scaling is followed by an examination of the dielectric materials employed for transistors, device isolation, memory and interconnect technologies. This is presented in view of the industry roadmap which captures the consensus for device scaling (and the underlying economics) – the International Technology Roadmap for Semiconductors.

27.1 Overview

This chapter considers the role of dielectric materials in microelectronic devices and circuits and provides a survey of the various materials employed in their fabrication. We will examine the impact of scaling on these materials, and the various materials utilized for their dielectric behavior. Extensive reviews are available on the device characteristics for the reader to consult [27.1–4]. We will primarily confine the discussion here to Si-based microelectronic circuits, which continue to dominate the industry.

Dielectric materials are an integral element of all microelectronic circuits. In addition to their primary function of electrical isolation of circuit and device components, these materials also provide useful chemical and interfacial properties. The material (and resulting electrical) properties of dielectrics must also be considered in the context of the thin films used in semiconductor microelectronics, as compared to bulk properties. The dimensions of these dielectric thin films are determined by the device design of the associated integrated circuit technology, and these dimensions decrease due to a calculated design process called *scaling*.

27.1.1 The Scaling of Integrated Circuits

The ability to reduce the size of the components of integrated circuits (ICs), and therefore the circuits

© Springer International Publishing AG 2017
S. Kasap, P. Capper (Eds.), *Springer Handbook of Electronic and Photonic Materials*, DOI 10.1007/978-3-319-48933-9_27

themselves, has resulted in substantial improvements in device and circuit speeds over the last 40 years. Equally important, this calculated size reduction permits the fabrication of a higher density of circuits per unit area on semiconductor substrates. The economic implication of this scaling was captured by *G. Moore* more than 50 years ago [27.5].

Moore's Law

Moore observed that the minimum cost of manufacturing integrated circuits per component actually decreases with increasing number of IC components, and thus with greater circuit functionality and computing power. This is obviously an important economic driving force, as the ability to increase the number of circuits per unit area would lead to a lower minimum cost, and thus higher market demand and more potential profit. Moreover, Moore noted that the rate of increase in the number of components for a given circuit function roughly doubled each year in the early 1960s, and predicted that it would continue to do so through 1975. In 1975, *Moore* revised this estimate of doubling time to 24 months due to the anticipated complexity of circuits [27.6].

The semiconductor industry has generally confirmed (and pursued) these extrapolations, often referred to as Moore's law, over the last 40 years. The extrapolation is often analyzed in the semiconductor industry, and the doubling period, which has varied between 17 and 32 months over the life of the industry, is now roughly 24 months, with projections to lengthen [27.8]. Indeed the cost per transistor has decreased from $\approx 5\,\$/\text{transistor}$ in 1965 to less than $10^{-9}\,\$/\text{transistor}$ today [27.9]. Current advanced Si IC production technology results in the fabrication of well over 1 billion transistors on a microprocessor chip.

Technology Roadmap

The contemporary industry analysis encompassing this observation is presented in the International Technology Roadmap for Semiconductors (ITRS) where the extrapolations of the future technological (and economic) targets for the industry are annually updated [27.7]. The current scaling trends indicate that the compound annual reduction rate (CARR) in device dimensions is currently consistent with the following equation

$$\text{CARR}(T) = \frac{1}{2}^{\left(\frac{1}{2T}\right)} - 1\,, \tag{27.1}$$

where T is the technology node cycle time measured in years. Thus in two years, the rate of reduction is -15.9%. This corresponds to a scaling factor of $\approx 0.7\times$ from a given technology node to the next, or a factor of $\approx 0.5\times$ over the time of two technology nodes. This pace has been enabled through the introduction of new materials technologies such as strained Si, SiGe, and high-k/metal gate technologies. Analysis of the limits of Si-based scaled integrated circuit technology are available, including alternative channel materials, such as Ge and III-V semiconductors integrated on Si, have been discussed [27.10, 11]. According to the most recent ITRS Roadmap, non-Si channel materials may be in transistor production soon [27.7]. Scaling has also driven the transistion from planar complementary metal-oxide-semiconductor (CMOS) technologies in production to three-dimensional (3-D) (vertical) transistor component geometries.

Table 27.1 provides selected scaling targets from the ITRS through 2020 [27.7]. As may be seen, the industry roadmap now has scaling targets which are driven by controlling power consumption. Higher-performance technologies, such as MPU/ASIC applications, require more aggressive scaling, while low power applications require less-aggressive scaling. A key criteria to enable these technologies is the associated power management in the *on* and *off* state, hence leakage current (I_{off}) remains an important distinction amongst the various roadmap applications.

Table 27.1 Selected scaling targets from the ITRS roadmap [27.7]

Year of production	**2013**	**2014**	**2015**	**2016**	**2017**	**2018**	**2019**	**2020**

Performance and Scaling

The concomitant reduction in device dimensions, such as transistor channel length, associated with increasing the number of components per unit area has resulted in a significant increase in processing performance – the speed at which computations can be done. For example, as scaling reduces the distance that carriers must travel in a transistor channel, the response time of the transistor as a digital switch also decreases (as long as sufficient mobility is maintained). Scaling has resulted in the speeds of microprocessors increasing from 25–50 MHz clock frequencies in the early 1990s ($\approx 10^6$ transistors) to 2.2 GHz in 2003 ($\approx 10^8$ transistors) [27.13]. This speed has essentially leveled off since 2003 due to power consumption considerations and the resultant voltage scaling invoked, as well as interconnect limitations [27.9].

The various dielectric materials associated with the components impacts the overall performance of the corresponding IC technology. In the case of transistors, the gate dielectric is integral to the performance of transistor electrical characteristics such as the drive current I_d. The interconnection performance of circuit elements is influenced by the dielectric material that isolates the various metal interconnection lines through the line-to-line capacitance. Memory elements incorporate very-low-leakage dielectric materials for charge-storage purposes. The behavior of these materials with component size reduction is thus an important design consideration in IC technology.

Figure 27.1 shows the dependence of the delay time as a function of technology node (scaling) associated with conventional CMOS transistor gates interconnected with metal lines that are isolated with different dielectrics [27.12]. The total delay time associated with the circuit response for a given technology node is a combination of the temporal response of the transistor gate (influenced by the gate capacitance) as well as the propagation through the interconnecting wire lines associated with the circuit (influenced by the wire resistance and the line-to-line capacitance, i. e., a resistive–capacitive (*RC*) delay) [27.12, 15]. Changing both the interconnect wire material (from Al to Cu) to decrease the line resistivity as well as decreasing the dielectric constant in the material isolating these lines (from SiO_2 to a lower dielectric constant material) to decrease line-to-line parasitic capacitance minimizes the overall *RC* delay time response. Of course, the challenge in adopting this solution was the successful integration of these material changes into a high-volume fabrication line, which took the investment of considerable time and effort.

In order to compare the performance of different CMOS technologies, one can consider a performance metric that captures the dynamic response (i. e., charging and discharging) of the transistors associated with a specific circuit element to the supply voltage provided to the element at a representative (clock) frequency [27.14, 16, 17]. A common element employed to examine such switching-time effects in a new transistor design technology node is a CMOS inverter. This circuit element is shown in Fig. 27.2 where the input signal is attached to the gates and the output signal is connected to both the n-type metal/oxide/semiconductor (MOS) (NMOS) and p-type MOS (PMOS) transistors associated with the CMOS stage. The switching time is limited by both the fall time required to discharge the load capacitance by the n-type field-effect transistor (n-FET) drive current and the rise time required to charge the load capacitance by the p-FET drive current. That is, the switching response times τ are given by

$$\tau = \frac{C_{\mathrm{LOAD}} V_{\mathrm{dd}}}{I_{\mathrm{d}}}\,, \quad \text{where}$$
$$C_{\mathrm{LOAD}} = FC_{\mathrm{GATE}} + C_{\mathrm{j}} + C_{\mathrm{i}}\,, \tag{27.2}$$

and C_j and C_i are the parasitic junction and local interconnection capacitances, respectively. Of course, as one considers the combination of transistors to produce various circuit logic elements to enable computations (viz. a *processor*), it is also clear that the manner in which the transistors are interconnected also plays an impor-

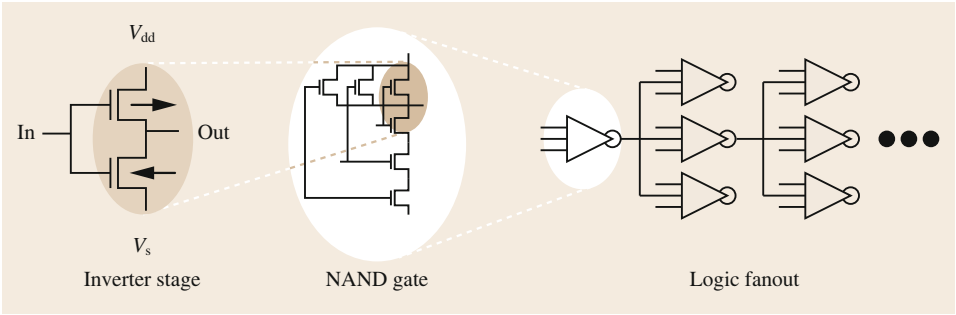

Fig. 27.2 Example circuits employed to evaluate the performance of a transistor technology. For example, elements are combined to simulate processor performance adequately. (After [27.14], AIP, with permission © 2001)

tant role on the overall performance of the circuit. The *fan out* for interconnected devices is given by the factor F. Ignoring delay in the gate electrode response, as $\tau_{GATE} \ll \tau_{n,p}$, the average switching time is therefore

$$\bar{\tau} = \frac{\tau_p + \tau_n}{2} = C_{LOAD} V_{dd} \left(\frac{1}{I_d^n + I_d^p} \right) . \qquad (27.3)$$

The load capacitance in the case of a single CMOS inverter is simply the gate capacitance if one ignores parasitic contributions such as junction and interconnect capacitance. Hence, an increase in I_d is desirable to reduce switching speeds. For more realistic estimates of microprocessor performance, the load capacitance is connected (*fanned out*) to other inverter elements in a predetermined fashion. When coupled with other NMOS/PMOS transistor pairs in the configuration shown in Fig. 27.2, one can create a logic NAND gate, which can be used to investigate the dynamic response of the transistors and thus examine their performance under such configurations. For example, a fan out $F = 3$ can be employed in microprocessor performance estimates, as shown in Fig. 27.2.

One can then characterize the performance of a circuit technology (based on a particular transistor structure) through this switching time. To do this, various *figures of merit* (FOMs) have been proposed that incorporate parasitic capacitance as well as the influence of gate sheet resistance on the switching time [27.16–18]. For example, a common FOM employed is related to (27.3) simply by

$$\text{FOM} \cong \frac{1}{\bar{\tau}} = \frac{2}{\tau_p + \tau_n} . \qquad (27.4)$$

In the case where parasitic capacitance and resistance effects are ignored, it is easily seen then that an increase in the device drive current I_d results in a decrease in the switching time and thus an increase in the FOM value (performance). However, the incorporation of parasitic effects results in the limitation of FOM

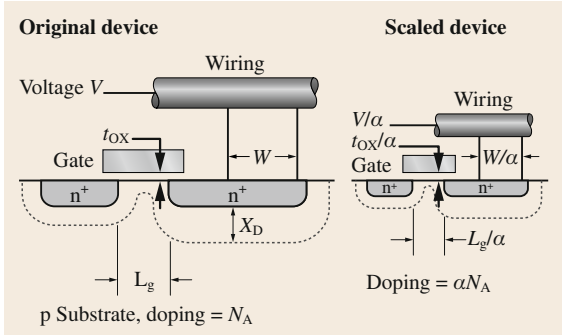

Fig. 27.3 *Classical* scaling methodology for integrated circuit technology. (After [27.21], © 2004 IEEE, with permission)

improvement, despite an increase in the gate dielectric capacitance. All of these issues depend critically upon the materials constituents of the integrated circuit, and dielectrics are an important component [27.14].

Impact of Scaling on Dielectrics

The scaling associated with the device dimensions that constitute an integrated circuit impacts on virtually all film dimensions such as thickness, including the dielectrics employed in the circuit. Various scaling methodologies have been applied since the pioneering work by *Dennard* and coworkers [27.19, 20]. These various methods have been recently summarized [27.2, 21]. For example, following the work by *Dennard* et al., the scaling of the transistor from one node N to the next $N + 1$ under a constant-electric-field condition would result in a relationship between the *new* transistor gate (or channel) length $L_{N+1} = L_N/\alpha$, where $\alpha > 1$ is the constant scaling factor (Fig. 27.3). Other dimensions, such as the gate dielectric thickness and the gate width, scale similarly. The voltage would also scale according to $V_{N+1} = V_N/\alpha$ in this scenario as well. Table 27.1 provides the drive voltage scaling (V_{dd}) anticipated by the ITRS roadmap, depending upon the application.

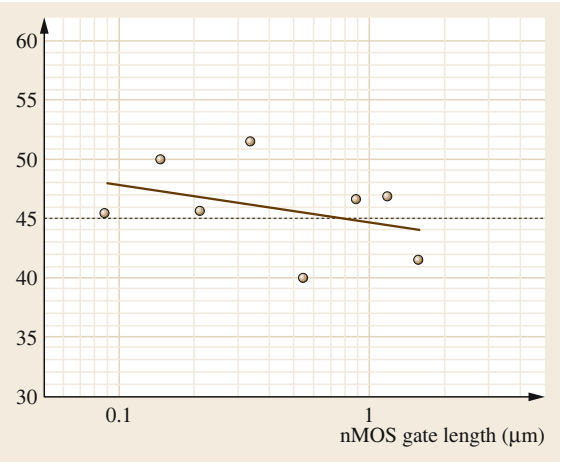

Fig. 27.4 Scaling trends of the planar transistor gate length and the gate insulator thickness for various generations of integrated technologies. The *solid line* is a linear fit to the data. The *dashed line* represents the approximate scaling trend between the gate dielectric thickness and gate length observed over several technology generations: $L_G = 45 \times t_{ox}$. (After [27.22], with permission)

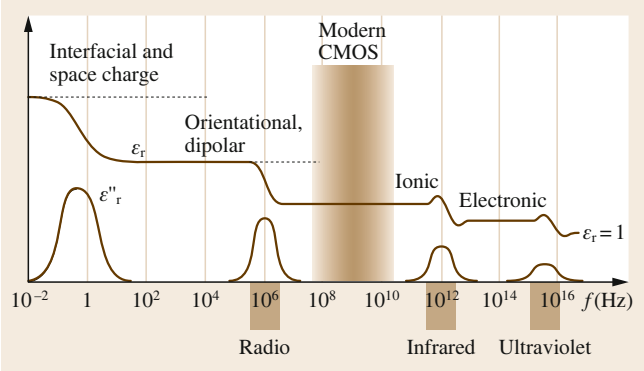

Fig. 27.5 Schematic of the dependence of dielectric permittivity on frequency. (After [27.23], with permission)

This scaling approach has several shortcomings, including the reduction of power-supply voltages with each node, raising problems with circuit power-supply compatibility. So, for earlier technology nodes ($L \geq 0.35\,\mu m$), the power supply was kept constant while the device dimensions were scaled as described above. Eventually, the resultant higher electric fields associated with this scaling approach led to reliability concerns for the gate dielectric, mobility degradation and hot-carrier effects. For further scaling, the power supply was scaled at a different factor (such as $\alpha^{1/2}$) to compensate for such effects. For modern devices with *deep-submicron* gate length, other techniques are used to scale from node to node. Nevertheless, for planar CMOS technology through the 90 nm node, it has been noted that the gate dielectric thickness can be related to the channel length as shown in Fig. 27.4 for a wide variety of device technologies as the depletion depth was scaled with the dielectric [27.22]. As seen in the ITRS Roadmap [27.7], scaling of the gate dielectric has now reached a value just below a $T_{ox} \approx 0.8\,nm$ ($k \approx 12.5$), and projected to decrease to $T_{ox} \approx 0.6\,nm$ by 2020, implying a higher dielectric constant will be needed ($k \approx 16$).

The critical point in the context of dielectric films is that the dimensions and geometry of the devices, and therefore the dimensions (thicknesses) of the dielectric layers, are significantly reduced as scaling proceeds (Table 27.1). At some point, the materials properties associated with the dielectric in a component will be predicted to no longer provide the desirable electrical behavior attained in previous nodes, thus stimulating research on new dielectric materials. In the case of gate dielectrics, scaling results in thinner layers of a given material to a point where quantum-mechanical tunneling becomes an issue. For memory capacitor dielectrics, a specific capacitance density is required, regardless of capacitor dimensions, for a reliable memory element. Indeed, scaling impacts on the selection and integration of numerous constituents of electronic devices including gate electrode materials, source/drain junction regions, contacts, interconnect dielectrics.

27.1.2 Role of Dielectrics for ICs

Dielectrics are pervasive throughout the structure of an integrated circuit. Applications include gate dielectrics, tunneling oxides in memory devices, capacitor dielectrics, interconnect dielectrics and isolation dielectrics, as well as sacrificial or masking applications during the circuit fabrication process.

The basic properties utilized in dielectric materials include their structure and the resultant polarizability behavior. As noted in Fig. 27.5, there are several mechanisms to consider in the polarization of materials in the presence of an electric field. For nonmetallic (insulating) solids in CMOS applications, there are two main contributions of interest to the dielectric constant which give rise to the polarizability: electronic and ionic dipoles. Figure 27.5 illustrates the frequency ranges where each contribution to the real part of the complex relative dielectric permittivity ε_r dominates, as well as the imaginary part of the complex permittivity (dielectric losses), ε''_r [27.23]. The region of interest to CMOS applications includes the shaded area where switching frequencies are in the GHz range at the present time.

In general, atoms with a large ionic radius (i. e., high atomic number, Z) exhibit more electron dipole response to an external electric field, because there are more electrons to respond to the field (electron screening effects also play a role in this response). This electronic contribution tends to increase the permittivity of materials with higher-Z atoms.

The ionic contribution to the permittivity can be much larger than the electronic portion in cases such as perovskite crystals of $(Ba,Sr)TiO_3$ (BST) and $(Pb,Zr)TiO_3$ (PZT), which exhibit ferroelectric behavior below the Curie point. In these cases, Ti ions in unit cells throughout the crystal are uniformly displaced in response to an applied electric field (for the case of ferroelectric materials, the Ti ions reside in one of two stable, non-isosymmetric positions about the center of the Ti−O octahedra). This displacement of Ti ions causes an enormous polarization in the material, and thus can give rise to very large dielectric constants in bulk films of 2000−3000, and has therefore been considered for dynamic random-access memory (DRAM) capacitor applications [27.24, 25]. Since ions respond more slowly than electrons to an applied field, the ionic contribution begins to decrease at very high frequencies, in the infrared range of $\approx 10^{12}$ Hz, as shown in Fig. 27.5.

27.2 Gate Dielectrics

27.2.1 Transistor Structure

A cross-sectional schematic of the structure of a planar metal–oxide–semiconductor (MOS) field-effect transistor (FET) and a modern CMOS transistor, consisting of the n-FET and p-FET pair, is shown in Fig. 27.6. The source- and drain-region dopant profiles reflect modern planar CMOS technologies where an extended, doped region is produced under the gate region in the channel. Additionally, so-called *halo* or *pocket* dopant implantation regions are also shown. These dopant profile approaches have been incorporated in recent years in an effort to permit transistor channel scaling and yet maintain performance [27.27].

As can be seen, there exist several regions of the device which require dielectric materials to enable useful transistor operation. Both n-MOS and p-MOS transistors are isolated with a dielectric, typically deposited SiO_2 in most modern device technologies, which is deposited in trench structures. This isolation technique is called *shallow* trench isolation (STI) as the associated trench depth is $\leq 0.5\,\mu m$. Earlier generations of CMOS (and often devices under research) also utilized the so-called local oxidation of silicon (LOCOS) isolation approach [27.28, 29]. So-called spacer dielectrics (typically SiO_2, SiO_xN_y, or SiN_x) are also used around the transistor *gate stack* for isolation and implantation-profile control. The gate stack is defined here as the films and interfaces comprising the gate electrode, the underlying gate dielectric, and the channel region. The gate dielectric, typically SiO_2 or SiO_xN_y for transistors currently in production, electrically isolates the gate electrode from the underlying Si channel region while allowing the modulation of the carrier flow in the channel. As we shall see, the interface between the gate dielectric and the channel regions is particularly important in regard to device performance.

Transistor structures have further evolved (Fig. 27.7) to a non-planar configuration to enable adequate electrostatics. Drive current and characteristics control with scaling. Examples include the multigate (*FinFET*) and *gate-all-around* transistor

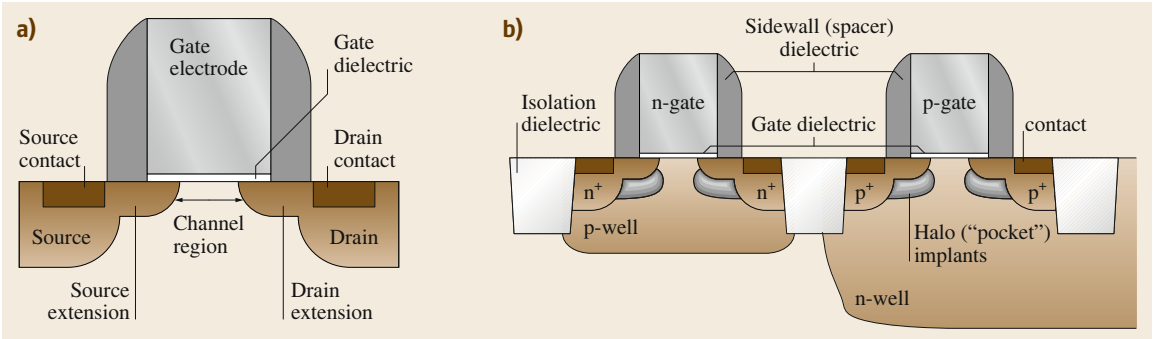

Fig. 27.6a,b Important regions of **(a)** a metal–oxide–semiconductor (MOS) field-effect transistor, and **(b)** a planar CMOS transistor structure. (After [27.26], © 2004 IEEE, with permission)

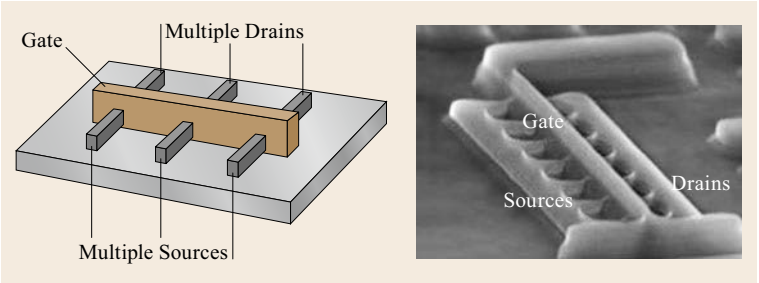

Fig. 27.7 Schematic and image of a *trigate* transistor structure

structures. All of such structures still include a gate dielectric to isolate the gate from the channel, but require conformal deposition processes to enable reproducible and reliable performance.

27.2.2 Transistor Dielectric Requirements in View of Scaling

In addition to the thickness reduction associated with scaling, the gate dielectric must adhere to several requirements that are dependent upon the specific product application, including adequate drive current, suitable capacitance, minimal leakage current, and reliable performance. Table 27.1 provides some selected values describing the ITRS 2013 roadmap.

Drive Current

The improved performance associated with the scaling of logic device dimensions can be seen by considering a simple model for the drive current associated with a FET [27.14, 16, 18, 30]. In the gradual channel approximation, the drive current can be written as

$$I_{\mathrm{d}} = \frac{W}{L}\mu C_{\mathrm{inv}}\left(V_{\mathrm{G}} - V_{\mathrm{T}} - \frac{V_{\mathrm{D}}}{2}\right)V_{\mathrm{D}}\,, \qquad (27.5)$$

where W is the width of the transistor channel, L is the channel length, μ is the channel carrier mobility (assumed to be constant in this analysis), C_{inv} is the capacitance density associated with the gate dielectric when the underlying channel is in the inverted state, V_{G} and V_{D} are the voltages applied to the transistor gate and drain, respectively, and the threshold voltage is given by V_{T}. It can be seen that in this approximation the drain current is proportional to the average charge across the channel (with a potential $V_{\mathrm{D}}/2$) and the average electric field (V_{D}/L) along the channel direction. Initially, I_{D} increases linearly with V_{D} and then eventually saturates to a maximum when $V_{\mathrm{D,sat}} = V_{\mathrm{G}} - V_{\mathrm{T}}$ to yield:

$$I_{\mathrm{D,sat}} = \frac{W}{L}\mu C_{\mathrm{inv}}\frac{(V_{\mathrm{G}} - V_{\mathrm{T}})^2}{2}\,. \qquad (27.6)$$

A goal here is to increase the saturation drive current as much as possible for a given transistor technology design. The term $(V_{\mathrm{G}} - V_{\mathrm{T}})$ is limited in range due to reliability concerns as too large a V_{G} would create an undesirable, high electric field across the gate dielectric. Moreover, practical operation of the device at room temperature (or above) requires that V_{T} cannot easily be reduced below about $8 \times k_{\mathrm{B}}T \cong 200\,\mathrm{meV}$ ($k_{\mathrm{B}}T \approx 25\,\mathrm{meV}$ at room temperature). Elevated operating temperatures could therefore cause statistical fluctuations in thermal energy, which would adversely affect the desired V_{T} value. Thus, even in this simplified approximation, one is left to pursue a reduction in the channel length, increasing the width, increasing the gate dielectric capacitance, or a carefully engineered combination of all of these in order to increase $I_{\mathrm{D,sat}}$. Note that none of these dimensions are, in reality, independent and so substantial resources are utilized to simulate device performance in order to maximize the performance prior to the fabrication of a representative transistor [27.2, 29, 31].

Gate Capacitance

In the case of increasing the inversion capacitance to improve I_{D}, consider the gate stack structure idealized as a parallel-plate capacitor (ignoring quantum-mechanical and depletion effects from a Si substrate and gate [27.32]),

$$C = \frac{k\varepsilon_0 A}{t}\,, \qquad (27.7)$$

where k is the dielectric constant of the material, ε_0 is the electric constant ($= 8.85 \times 10^{-3}\,\mathrm{fF/\mu m}$), A is the area of the capacitor, and t is the thickness of the dielectric between the capacitor electrode plates. (Note that the relative permittivity of a material is often given by ε or ε_{r}, such as with the expression $C = \varepsilon\varepsilon_0 A/t$. Note that the relation between k and ε varies depending on the choice of units (e.g., when $\varepsilon_0 = 1$), but since it is always the case that $k \approx \varepsilon$, we shall assume here that $k = \varepsilon$.) It is clear that transistor designs utilizing planar CMOS scaling approaches discourage increasing the area of the capacitor, and so one is left to considering the reduction of the dielectric thickness in order to increase the capacitance.

In order to compare alternative dielectric materials which exhibit a dielectric constant higher than the standard for the industry, SiO_2, this expression for C can also be rewritten in terms of t_{eq} (i. e., equivalent oxide thickness) and the k_{ox} of the capacitor ($k_{ox} = 3.9$ for the low-frequency dielectric constant of SiO_2). The term t_{eq} then represents the theoretical thickness of SiO_2 that would be required to achieve the same capacitance density as the dielectric (ignoring important issues such as leakage current and reliability). For example, if the capacitor dielectric is SiO_2, $t_{eq} = 3.9\,\varepsilon_0(A/C)$, and so a capacitance density of $C/A = 34.5\,\mathrm{fF}/\mu\mathrm{m}^2$ corresponds to $t_{eq} = 10\,\text{Å}$.

Thus, the physical thickness of an alternative high-k dielectric employed to achieve the equivalent capacitance density of $t_{eq} = 10\,\text{Å}$ can be obtained from the expression

$$\frac{t_{eq}}{k_{ox}} = \frac{t_{high\text{-}k}}{k_{high\text{-}k}} \quad \text{or simply,}$$

$$t_{high\text{-}k} = \frac{k_{high\text{-}k}}{k_{ox}} t_{eq} = \frac{k_{high\text{-}k}}{3.9} t_{eq}\,. \tag{27.8}$$

From this expression, a dielectric with a relative permittivity of 16 therefore results in a physical thickness of $\approx 40\,\text{Å}$, to obtain $t_{eq} = 10\,\text{Å}$. The increase in the physical thickness of the dielectric impacts on properties such as the tunneling (leakage) current through the dielectric, and is discussed further below.

The industry scaling process clearly presents a major challenge for the core transistor gate dielectric as predictions call for a much thinner effective thickness for future alternative gate dielectrics: $t_{eq} \leq 1\,\text{nm}$ [27.7]. The interfacial regions between the gate electrode, dielectric and channel (in totality termed the metal–insulator–semiconductor (MIS) *gate stack* as shown schematically in Fig. 27.8) require careful attention, as they are particularly important in regard to transistor performance. These regions, less than approximately 0.5 nm thick, serve as a transition between the atoms associated with the materials in the gate electrode, gate dielectric and Si channel, and can alter the overall capacitance of the gate stack, particularly if they have a thickness that is substantial relative to the gate dielectric. Additionally, these interfacial regions can be exploited to obtain desirable properties. The upper interface, for example, can be engineered in order to block boron outdiffusion from the poly-Si gate. The lower interface, which is in direct contact with the CMOS channel region, must be engineered to provide low interface trap densities (e.g., dangling bonds) and minimize carrier scattering (maximize channel carrier mobility) in order to obtain reliable, high-performance device. Mobility degradation, relative to that obtained using SiO_2 (or SiON) gate dielectrics, associated with the incorporation of high-k gate dielectrics is an important issue currently under investigation and discussed further below.

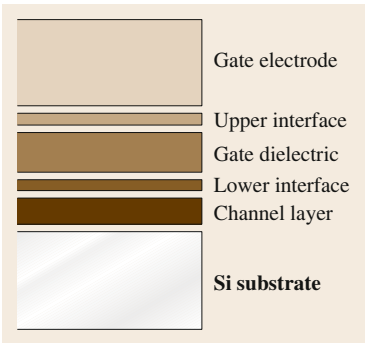

Fig. 27.8 Schematic of the important regions of the transistor gate stack. (After [27.14], AIP, with permission © 2001)

Reactions at either of these interfaces during the device fabrication process can result in the formation of a significant interfacial layer that will likely reduce the desired gate stack capacitance. Additionally, any suitable interfacial layer near the channel must result in a low density of electrically active defects ($\lessapprox 10^{11}/\mathrm{cm}^2\,\mathrm{eV}$ is often obtained for SiO_2) and avoid degradation of carrier mobility in the region near the surface channel.

The reduced capacitance can be seen by noting that the dielectric film that has undergone interfacial reactions results in a structure that essentially consists of several dielectric layers in series. If we suppose that the dielectric consists of two layers, then from electrostatics the total capacitance of two dielectrics in series is given by $1/C_{tot} = 1/C_1 + 1/C_2$, where C_1 and C_2 are the capacitances of the two layers. Thus, the lowest-capacitance layer will dominate the overall capacitance and also set a limit on the minimum achievable t_{eq} value. If we consider a dielectric stack structure such that the bottom layer (layer 1) of the stack is SiO_2, and the top layer (layer 2) is the high-k alternative gate dielectric, (27.8) is expanded (assuming equal areas) to

$$t_{eq} = t_{SiO_2} + \frac{k_{SiO_2}}{k_{high\text{-}k}} t_{high\text{-}k}\,. \tag{27.9}$$

From (27.9), it is clear that the layer with the lower dielectric constant (SiO_2 in this case) limits the ultimate capacitance of the MIS gate stack.

Of course, the actual capacitance of a CMOS gate stack for ultra-large-scale integration (ULSI) devices does not scale simply with $1/t$ due to parasitics, quantum-mechanical confinement of carriers, and depletion effects. Indeed, consideration of these important effects can result in much confusion on the definition of dielectric thickness as extracted from electrical measurements.

Parasitic resistances and capacitances associated with various portions of the transistor structure can result in an overall degradation of performance as defined by a delay time figure of merit [27.14, 17]. There exist several materials issues associated with the control of such parasitics including source/drain dopant-profile control, gate/contact sheet resistance minimization, etc. which are beyond the scope of this chapter.

Quantum-mechanical confinement effects on carriers in the channel region occur as a result of the large electrical fields in the vicinity of the Si substrate surface. These fields quantize the available energy levels resulting in the displacement of the charge centroid from the interface into the Si and at energies above the Si conduction-band edge. The extent of the penetration of the charge centroid is dependent upon the biasing conditions employed for the metal–insulator–semiconductor (MIS) structure and, for accurate estimates of transistor drain-current performance, the inversion capacitance measurement provides accurate determination of the equivalent oxide thickness [27.32–34].

Earlier MIS gate-stack structures employ heavily doped polycrystalline Si (poly-Si) as the *metal* gate electrode for CMOS transistors. Poly-Si gates were introduced as a replacement for Al metal gates in the 1970s for CMOS integrated circuits and have the very desirable property of a tunable work function for both n-MOS and p-MOS transistors through the implantation of the appropriate dopant into the poly-Si gate electrode.

However, in deep-submicron scaled devices, the *poly-Si depletion effect* impacts the overall gate-stack capacitance significantly, as the scaling results in an increased sensitivity to the effective *electrical* thickness resulting from all of the gate-stack component films, including the gate electrode. The depletion effect (which occurs in any doped semiconductor) is a result of the decrease in the density of majority carriers near the poly-Si/dielectric interface upon biasing, resulting in an increased depletion width in the poly-Si [27.27, 35]. This results in a voltage drop across the depletion region, rendering a smaller voltage drop across the remaining portions of the gate stack (i. e., the dielectric and the substrate). As a result, the (low-frequency) capacitance under strong inversion biasing conditions is significantly lower than that obtained under accumulation (Fig. 27.9). Moreover, the inversion-layer charge in the substrate is reduced from that possible in the ideal case where no depletion layer exists in the gate (i. e., an ideal metal conductor for the gate electrode). This reduction in the inversion-layer charge in turn reduces the ideal transistor drive current. As the dielectric thickness is reduced in the scaling process, this effect becomes a serious limitation for transistor drive current.

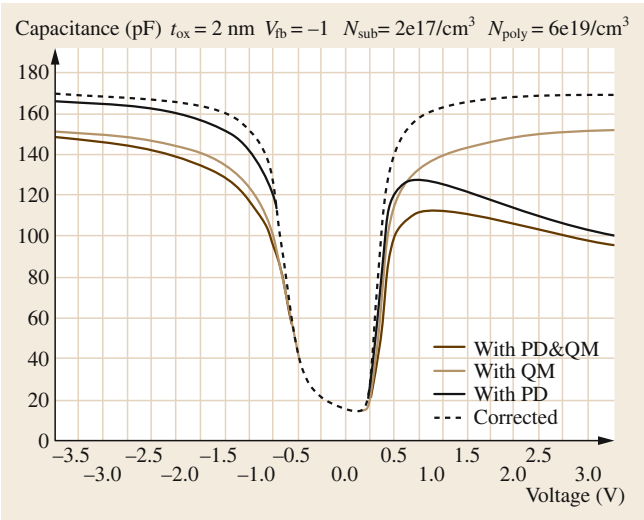

Fig. 27.9 Capacitance–voltage curves demonstrating the effects of poly-Si depletion and quantum-mechanical behavior for scaled transistors. N_{sub} and N_{poly} denote the dopant density for the substrate and poly-Si gate, respectively. (After [27.36])

To solve this problem, a return to metal gate electrode materials has been invoked to eliminate any depletion region in the gate, and thus the interaction of any dielectric with various metal gate candidates is of interest. Compatibility of dielectric materials with metal gate materials is discussed later in this chapter.

When a capacitance–voltage curve is properly corrected for these quantum-mechanical and dopant depletion effects, as seen in Fig. 27.9, one can accurately extract the equivalent oxide thickness (EOT), t_{eq} [27.36]. This thickness definition is in contrast to that derived directly from the raw data in a capacitance–voltage (C–V) measurement, which is termed the *capacitance equivalent thickness* (CET > EOT), or the *physical thickness*, which can be determined by non-electrical characterization methods such as ellipsometry or high-resolution transmission electron microscopy, as seen in Fig. 27.10 [27.36, 37]. Please note that thicknesses derived from quantum-mechanical-corrected accumulation capacitance data are also often abbreviated as t_{qm}.

Leakage Current

Of course, physically thinning the dielectric layer to the nanometer regime raises the prospect of quantum-mechanical tunneling through the dielectric – often referred to as *leakage*. To minimize gate leakage (tunneling) currents, quantum mechanics indicates that the gate dielectric must be sufficiently thick and have a sufficient energy barrier (band offset) to minimize the

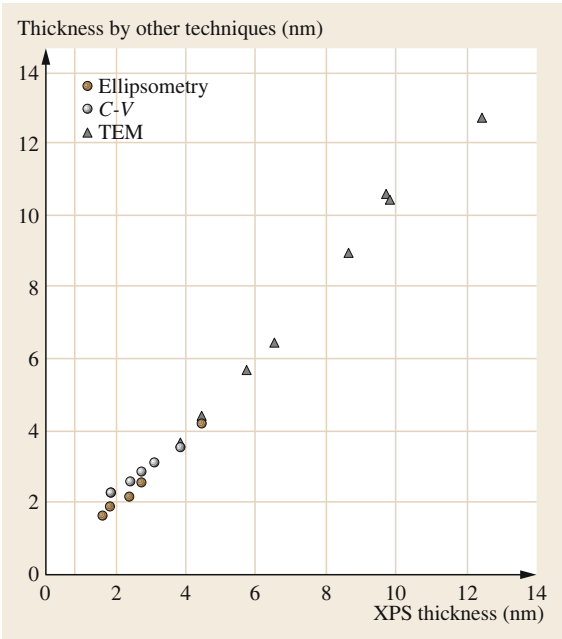

Fig. 27.10 Metrology results for various measurement techniques of the thickness of thin SiO_2 films. X-ray photoelectron spectroscopy (XPS) measured thicknesses are compared to thicknesses derived from high-resolution transmission electron microscopy (HRTEM), *C–V* and ellipsometry. (After [27.37], AIP, with permission © 1997)

resultant tunneling current. Consider the band diagram shown in Fig. 27.11, where the electron affinity (χ) and gate electrode work function (Φ_M) are defined (q is the charge). For electrons traveling from the Si substrate to the gate, this barrier is the conduction-band offset, $\Delta E_C \cong q\,[\chi - (\Phi_M - \Phi_B)]$; for electrons traveling from the gate to the Si substrate, this barrier is Φ_B. The effect of the height of the energy barrier and the film thickness on tunneling current can be seen by considering the expression for the direct tunneling current where electron transport occurs through a trapezoidal energy barrier [27.16]

$$J_{dt} = \frac{A}{t_{diel}^2}\exp\left(-Bt_{diel}\right) \times \left\{\left(\Phi_B - \frac{V_{diel}}{2}\right)\exp\left[\sqrt{\left(\Phi_B - \frac{V_{diel}}{2}\right)}\right] - \left(\Phi_B + \frac{V_{diel}}{2}\right)\exp\sqrt{\left(\Phi_B + \frac{V_{diel}}{2}\right)}\right\} . \quad (27.10)$$

Here A is a constant, $B = 4\pi/h(2m^*q)^{1/2}$, Φ_B is the potential-energy barrier associated with the tunneling

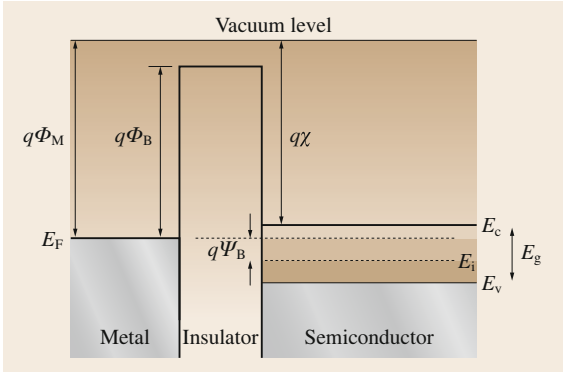

Fig. 27.11 Energy-band diagram for an MIS stack structure

process, t_{diel} is the physical thickness of the dielectric, V_{diel} is the voltage drop across the dielectric, and m^* is the electron effective mass in the dielectric. From (27.10), one observes that the tunneling (leakage) current increases exponentially with decreasing barrier height and thickness for electron direct-tunneling transport. In the context of charge transport through the dielectric, electrically active defects (electron or hole *traps*) can result in charging of the dielectric, which in turn deleteriously affects the electric field in the channel region and therefore mobility. Conduction mechanisms through such fixed charge traps can also be evaluated through electrical characterization techniques [27.16]. In the case of dielectrics layers, tunneling transport has also been previously examined [27.38].

The introduction of a dielectric material that exhibits a suitable energy barrier and thickness, while performing electrically as a thin SiO_2 layer, is now a key research and development goal for the industry to continue the scaling trend. It is also clear that the gate dielectric must exhibit adequate thickness uniformity and integrity over the surface of the wafer. The reduction of this leakage current impacts important circuit properties such as stand-by power consumption, as shown in Fig. 27.12. With the minimization of leakage current as a key driving force, alternate gate dielectric materials appear to be required for low-power CMOS device technologies in the near future and are therefore the subject of intense research.

Reliability

Any gate dielectric material must possess the ability to enable a specified, stable operational lifetime for the transistor. Key areas of concern in this regard includes defect generation/mitigation resulting in dielectric breakdown phenomenon, charge formation within the dielectric and at the associated interfaces, and resistance to energetic (*hot*) carrier interactions. This is often

27.2.3 Silicon Dioxide

As articulated by *Hummel*, silicon has an amazing number of desirable materials (and therefore electronic) properties that no other electronic material can rival [27.42]. Silicon constitutes 28% of the Earth's crust, it is nontoxic, exhibits a useful band gap ($E_G = 1.12$ eV) for applications at room temperature, and can be grown in crystalline form (from abundant sand, i. e., SiO_2). However, it can be argued that the ability of Si to form the stable, high-quality insulator, SiO_2, may be the primary reason that Si-based transistor technology has dominated the industry since the 1960s [27.5, 43]. This compound has a number of material properties that result in outstanding electrical performance. Some of these properties are summarized in Table 27.2. Over the last 25 years, abundant compendia of the properties of SiO_2 with particular emphasis on materials and electrical properties have been published, as well as

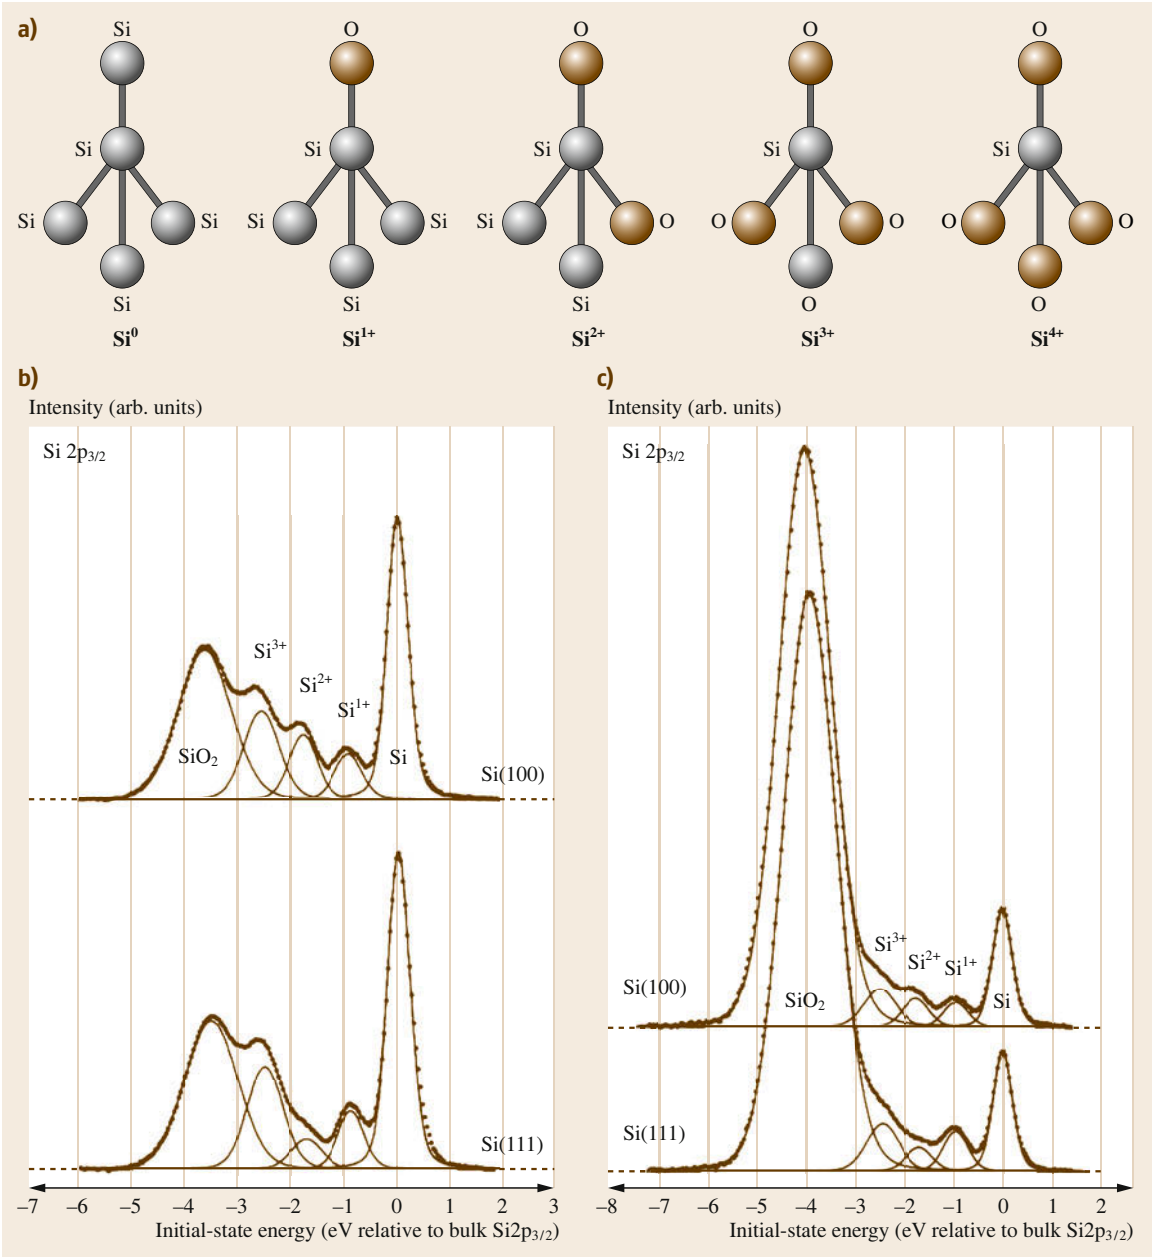

Fig. 27.14 **(a)** Oxidation states and local chemical bonding variations associated with the Si−SiO_2 interface. After [27.41]. conferences which have focused almost exclusively on SiO_2 [27.45–54].

It is noteworthy that the early development of transistor technology utilized the semiconductor Ge, which has a rather unstable oxide, GeO_2, that is water soluble. The utilization of crystalline Si and its stable oxide presented a superior solution for the practical manufacturing of the planar transistor and the associated integrated circuit of the era [27.43]. It was the utilization of the properties of SiO_2 that resulted in the dominance of Si-based device technology over Ge-based technology in the 1960s.

Bonding Arrangements for Thin SiO_2

As can be seen in Fig. 27.13, the phase diagram for SiO_2 has a number of crystalline phases and associated polymorphisms [27.41, 53]. In the context of accessible phase space appropriate for typical CMOS processes (pressure ≈ 1 bar and $T \leq 1100\,^{\circ}\mathrm{C}$), the quartz and tridymite phases are stable [27.57]. High-pressure phases are also well studied [27.58].

The bulk SiO_2 tetrahedral bonding coordination (inset, Fig. 27.13) results in an average Si−O−Si bond angle of $\theta \approx 145^{\circ}$ [27.59] comparable to that observed for vitreous silica [27.41, 60]. As noted originally in the classic work by *Zachariasen*, the bonding interconnections among the various SiO_4 tetrahedra can result in an amorphous SiO_2 film consisting of locally ordered ring structures commonly observed in silica glasses [27.51, 53, 61]. The numerous available variations of the ring structure provide substantial flexibility and minimize bond strain and the density of defects at interfaces [27.62].

For the purposes of microelectronic applications, we first consider so-called *thermally grown* SiO_2. As the name implies, a SiO_2 layer is formed on Si from a thermally activated oxidation process (often referred to as a *thermal oxide*) rather than simply a (low-temperature) deposition process. Thermal oxide films are stable enough to endure high-temperature ($\approx 1000\,^{\circ}\mathrm{C}$) post-implantation/dopant activation anneals. These films have useful electrical properties including a stable (thermal and electrical) interface with minimal electrically-active-defect densities ($\approx 10^{10}\,/\mathrm{cm}^2$) as well as high breakdown strength ($\approx 10\,\mathrm{MV/cm}$) over a large area ($\approx 1\,\mathrm{cm}^2$) [27.16]. The breakdown strength is important for high reliability of devices fabricated with a dielectric, as the scaling of devices typically results in somewhat higher electric fields across the oxide.

Recent experimental results on thin thermal SiO_2 [27.36, 39, 63] combined with modern computational modeling [27.55, 59] of the defects associated with the SiO_2/Si(001) interface, which is the dominant microelectronic materials system, and *bulk* SiO_2 [27.64] has provided a reasonably consistent picture of the known defects and interface structure.

High resolution x-ray photoelectron spectroscopy (XPS) evidence, coupled with other experimental and theoretical modeling results, appears to support the presence of SiO_x ($x = 4$) species (often called *suboxides*) detected as a chemical shift in the associated Si oxidation states (Fig. 27.14) [27.44, 65–67].

More recent high-resolution angle-resolved XPS analysis of ultrathin (6 Å) SiO_2 has resulted in a further understanding of the average oxidation state observed with depth along the interfacial transition region [27.56, 68]. From these experimental results, models of the interface have been constructed from first-principles methods that reproduce the experimental results, as shown in Fig. 27.15 [27.55, 59]. As seen in Fig. 27.15, the transition region between the Si substrate and the SiO_2 consists of interfacial suboxide species of varying abundance (and therefore density). These results appear

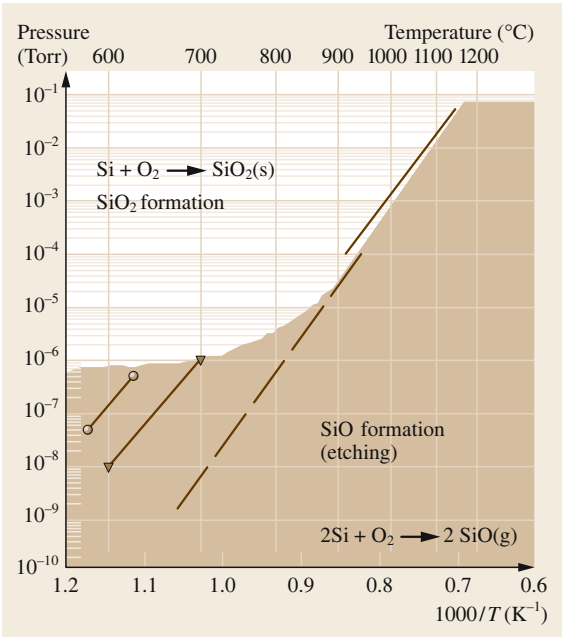

Fig. 27.16 Pressure–temperature phase diagram for thin SiO_2/Si. (After [27.76], © 1997 AIP, with permission)

to be in general agreement with recent high-resolution transmission electron microscopy as well [27.69].

Oxidation Kinetics of Si

The oxidation kinetics of Si have also been exhaustively studied and reviewed [27.27, 39, 70]. Two regimes for oxidation are generally characterized as *passive* and *active* in nature. The passive oxidation regime refers to the low-temperature/high-pressure region of the pressure–temperature (p–T) phase space shown in Fig. 27.16 [27.39, 71–76]. In this portion of the p–T phase space, the reaction between Si and O_2 proceeds as a surface reaction resulting in a thin (≤ 2 nm) SiO_x layer, where $0.5 \leq x \leq 2$. Decreasing pressure and increasing temperature during the reaction results in both Si etching and oxidation – the so-called *active* regime – and the formation of thicker SiO_2 films.

The clever utilization of isotopic labeling techniques coupled with depth profiling from ion scattering [27.77] and nuclear reaction analysis [27.70] has generally confirmed that molecular oxygen (O_2) is the mobile species that interstitially diffuses through a growing oxide and only reacts at the Si interface to form the SiO_2 on the Si surface, as first empirically proposed by *Deal* and *Grove* in 1965 for SiO_2 thicker than about 4 nm [27.78, 79]. The details of the oxidation process for thin films deviates from the Deal–Grove model, and is discussed thoroughly in the review by *Green* et al., for example [27.39].

Defects for Thin SiO_2

In addition to the electrical breakdown strength associated with SiO_2, the physicochemical properties of the interface between the substrate Si and SiO_2 plays a major role in establishing the observed electrical properties [27.63, 67]. Like all interfaces of solids, the interface between bulk Si and bulk SiO_2 naturally results in the presence of point defects (Fig. 27.17). Examples include strained bonds, atoms that are not fully bonded to neighboring atoms (so-called *dangling*), bonds and hydrogenic species bonded among the Si—O bonding network. These defects can result in energy levels in the band structure associated with an MIS device, and serve as *traps* for carriers (electrons and holes).

The dominant orientation for contemporary Si-based integrated circuit technology substrates is Si(100). This is, of course, no accident and the choice of the substrate orientation has much to do with the resultant SiO_2/Si interface. Early in the development of Si-based transistors, it was observed that the density of interface states for SiO_2 grown on Si(100) was significantly lower than that observed on Si(111) [27.80–84]. This difference in interface state behavior is attributed to the density of unsatisfied (*dangling*) bonds at the SiO_2/Si interface.

Techniques sensitive to the presence of such point defects, such as electron (paramagnetic) spin resonance (EPR or ESR) [27.85] have provided valuable insight on the atomic nature of the various defects in the bulk and interfacial regions of SiO_2 [27.86–91]. For such defects, although the electrical manifestation of significant densities ($\geq 10^{10}$ /cm^2 eV) of such *trap states* is easily detected by conventional electrical characterization methods, the unambiguous identification of the moiety responsible for the observed electrical behavior is very difficult using only electrical characterization. From techniques like ESR employed over the last 30 years, point-defect structural models have been established in the bulk regions of SiO_2 and Si, as well as at the interface (including various substrate orientations). A schematic illustration of various known point defects for the Si/SiO_2 system is shown in Fig. 27.17. The major classes of defects that have been examined over the last 35 years by ESR have included interfacial dangling bonds (P_b centers) and bulk defects in SiO_2 (E′ centers) [27.88, 91].

The early discovery and study of P_b centers [27.92–94] eventually led to the interpretation of their ESR signals as due to dangling bonds and the realization of their importance to MOS device physics [27.87, 88, 95, 96]. It has also been noted that P_b-center defects are generated for unannealed, thermally stressed and radiation-damaged MOS structures, and moreover can account for roughly 50% of the density of interface de-

fect states (D_{it}) for Si/SiO_2 interfaces [27.41, 97, 98]. It has been demonstrated that the interface state density can be directly proportional to the density of P_b centers (dangling bonds) for the SiO_2/Si(111) and SiO_2/Si(100) interfaces, as seen in Fig. 27.18. Recently, further ESR work has been performed to establish the detailed structure of the defect on Si(100) and Si(111) [27.99–106].

Mitigation of Defects for Thin SiO_2

Synopses of the early MOS transistor work [27.108–110] examining the importance of the dielectric–semiconductor interface are available [27.3, 43, 111]. Indeed, the close connection between interfacial chemical behavior and electrical device performance was investigated and realized in pioneering surface science work by *Law* and coworkers on the reaction of gaseous species with atomically clean Ge [27.112] and Si surfaces [27.113–115]. In particular, the relative interface state (dangling-bond) density, as measured by the areal density of surface reactions with technologically important species such as H_2O, H_2, O_2, CO, CO_2, provided important clues on the control of the Si/SiO_2 interface and the resultant electrical properties reported 5–10 years later.

The control of the density of interface defects through the chemical reaction of species, introduced mainly through gaseous exposure at elevated temperatures, has proven to be fruitful. As noted above, early surface science work [27.113] indicated the rapid reaction of H_2 with the atomically clean Si surface. By definition, the atomically clean Si surface is saturated

with dangling bonds. The reaction of these bonds with H_2 results in the chemical passivation of the surface – that is, the reaction of the surface to eliminate the dangling bonds and produce a H-terminated Si surface. In the context of the MOS structure [27.48, 116], it was realized early that annealing the structure in

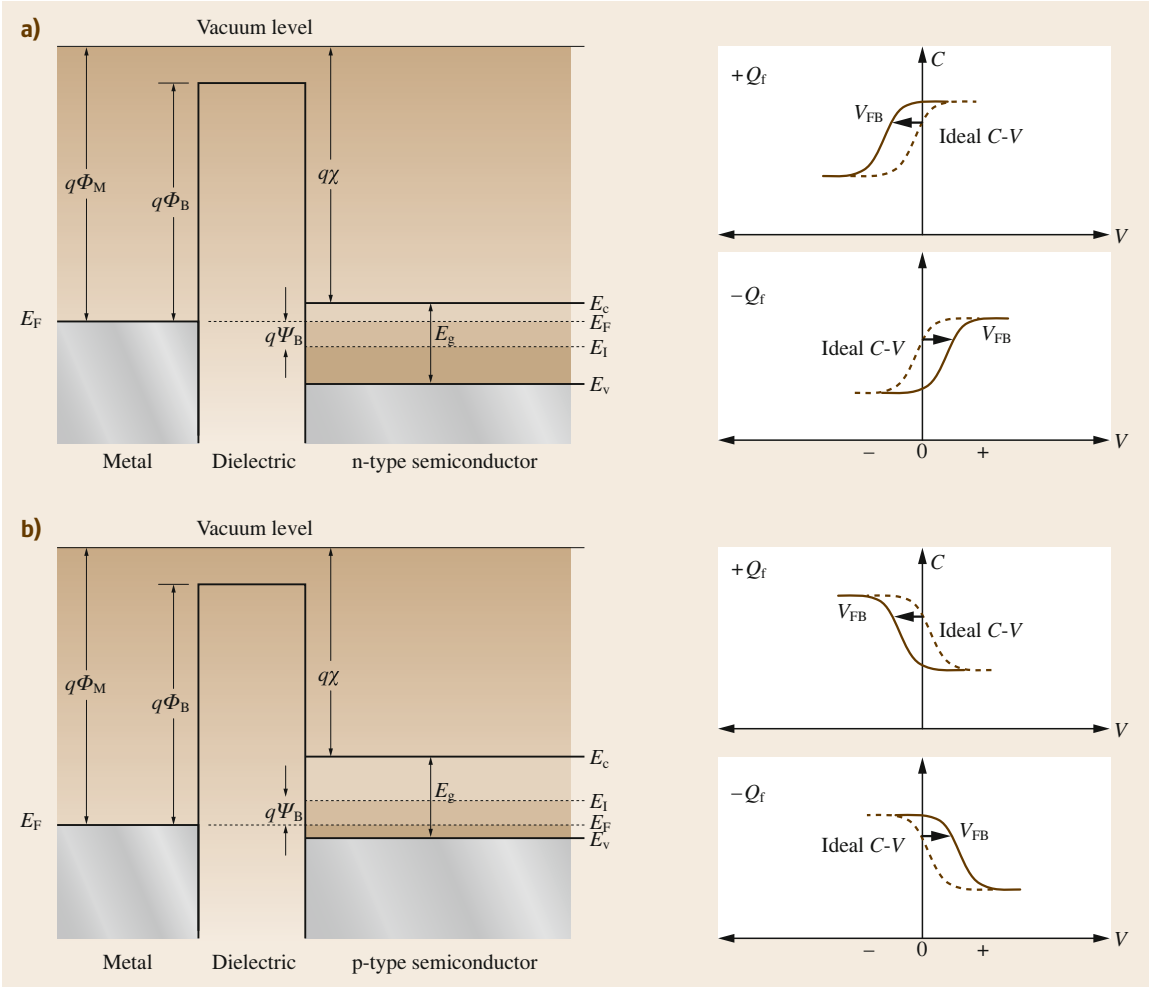

Fig. 27.19a,b The effect of fixed charging of the capacitor dielectric, demonstrating the shift of the associated flat-band voltage for MIS structures with **(a)** n-type and **(b)** p-type substrates. (After [27.14], © 2001 AIP, with permission)

ambient H_2 resulted in beneficial transconductance performance [27.117–120]. The use of anneals in forming gas ($N_2 : H_2$ of various mixtures, typically 90–95% N_2 : 10–5% H_2) were originally developed to improve electrical contacts for the gate and source/drain regions of the metal/oxide/semiconductor field effect transistor MOSFET. *Balk* and *Kooi* established the effect of hydrogen ambients on the reduction of fixed charge in the Al/SiO_2/Si MOS structure [27.119, 121].

Subsequent studies demonstrated that anneals of the MOS structure in hydrogenic environments, typically at 400–500 °C for 30–60 min, results in the passivation of dangling bonds at the interface [27.96, 99–104, 122–125].

Hydrogen incorporation into the bulk of SiO_2 can, however, also be detrimental to dielectric performance in MOS capacitors and FETs [27.41, 126]. For example, silicon bonded to hydroxyl (silanol) species have been identified with fixed charge in the oxide, resulting in undesirable, irreversible voltage shifts. This charge induced shift is shown in Fig. 27.19 for n-type and p-type MIS diode structures from their associated capacitance–voltage response [27.3, 4, 14]. (An analogous threshold-voltage shift would be observed in a transistor turn-on characteristic.) More complicated effects such as negative-bias temperature instability (NBTI), where an increase of the density of fixed charge (Q_f) and interface trap (Q_{it}) density is noted with time upon thermal stress and/or under negative bias, has been attributed to H_2O-induced depassivation of Si dangling bonds (i. e., generation of P_b centers) at the Si/SiO_2 interface [27.41, 127]. Defects generated by radiation damage have also been extensively investigated [27.41, 128] as well as interactions

with annealing ambients such as vacuum [27.129] or SiO [27.123].

Dielectric Breakdown and Reliability of SiO_2

As noted in Sect. 27.2.2, the reliability of dielectrics is obviously an important phenomenon to control. The scaling of microelectronic devices necessarily results in increased stress on the dielectric due to the higher electric fields placed across the dielectric film. As a result, power-supply voltages are also scaled to minimize the likelihood of catastrophic (*hard*) breakdown, which would generally result in complete failure in the associated integrated circuit. As noted by *Hori*, such a catastrophic breakdown phenomenon is dependent upon the presence of defects in the dielectric, and thus requires a statistical analysis of many devices (and therefore films) to enable a reliability prediction for the dielectric layer [27.16]. Evaluation of the breakdown is often performed under the conditions of constant-field stress until a time at which breakdown is observed (called time-dependent dielectric breakdown (TDDB)). Breakdown fields for thermally grown SiO_2 with thicknesses larger than $\approx 10\,\text{nm}$ often exceed $10\,\text{MV/cm}$, providing outstanding insulator prosperities for microelectronic applications. Various models have also been developed to accelerate such testing to perform reliability predictions. A concise review of these is offered in the literature as well [27.16, 27]. Defects such as film nonuniformity, bond stress, surface asperities, contamination, and particulates embedded in the film or the Si substrate are a few examples of potential causes of catastrophic breakdown phenomenon.

With the scaling of the SiO_2 gate dielectric layer to thicknesses well below 10 nm, extensive evaluations have been made of the various models that attempt to predict the reliability of SiO_2 in regard to breakdown. Often, a *soft* breakdown can be observed, where the film exhibits a sudden increase in conductivity, but not to the same degree as that observed in hard breakdown phenomenon. In spite of the many years of research on SiO_2 thin films, the nuances of the dependence of voltage acceleration extrapolation on dielectric thickness and the improvement of reliability projection arising from improved oxide thickness uniformity, have only recently become understood, despite decades of research on SiO_2 [27.130].

27.2.4 Silicon Oxynitride: SiO_xN_y

The introduction of nitrogen in SiO_2, often described as *silicon-oxynitride* (or more simply SiON) has provided the opportunity to maintain the scaling expectations for integrated circuits while minimizing the process variations associated with the modification of the gate

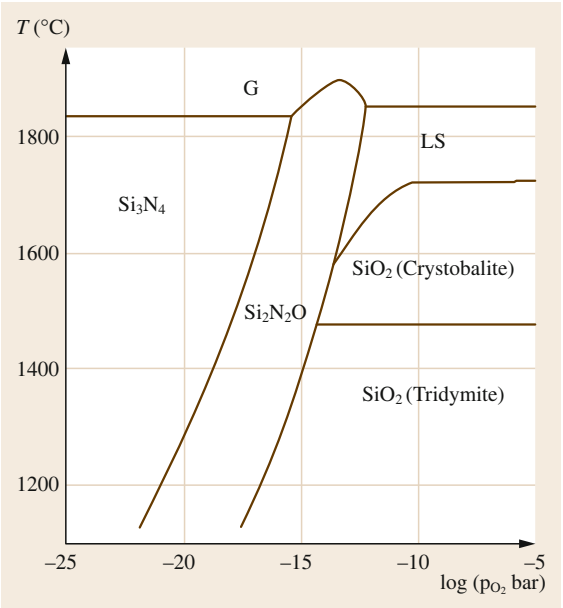

Fig. 27.20 Calculated phase diagram for the growth of Si–O–N for various oxygen partial pressures. (After [27.133], with permission)

dielectric material [27.16, 39, 70, 131]. (It should be noted that engineers and technologists often loosely refer to SiON films simply as oxide or nitride – frequently leading to confusion on the detailed chemical composition of the film.) Introduction of N into SiO_2 has been accomplished by thermal treatments (in N_2, N_2O, NO and NH_3) as well as plasma treatments [27.16, 132]. The bulk phase diagram for the SiON system is presented in Fig. 27.20, which indicates that, under equilibrium conditions, Si_2N_2O is the only stable SiON species and SiO_2 and Si_3N_4 would not coexist [27.133]. As noted by *Green* et al., N would not be expected to incorporate into SiO_2 whenever an even very small partial pressure of oxygen $P_{O_2} > 10^{-20}\,\text{atm}$ is present. However, the nonequilibrium surface reaction kinetics and/or a reduction in interfacial bond strain likely plays a key role in the tendency for interfacial N incorporation for SiON films [27.39].

The dielectric constant and band gap as a function of the SiO_2 content are presented in Fig. 27.21 [27.134]. As noted in Sect. 27.2.2, it is the increase in the dielectric constant that increases the capacitance of an associated MOS structure. Thus, for a SiON film with $k = 7$, a 2 nm SiON film would ideally exhibit electrical behavior (such as capacitance and leakage-current behavior) equivalent to a 1.1 nm SiO_2 film, according to (27.8). The data in Fig. 27.21 implies that the index of refraction (at 635 nm) varies between $n(SiO_2) = 1.46$ and $n(Si_3N_4) = 2$, indicating that optical techniques

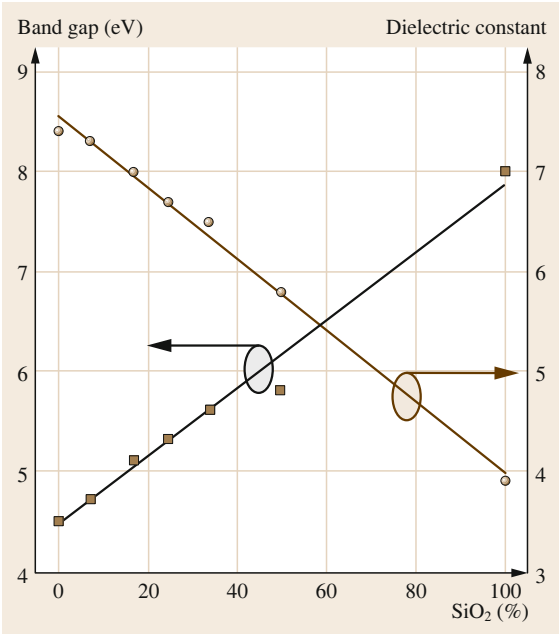

Fig. 27.21 Dependence of permittivity and insulator band gap of SiO_xN_y with SiO_2 content. (After [27.134], with permission)

such as ellipsometry can provide very useful information for such films.

Like the SiO_2/Si system, point defects have also been studied for SiON films on silicon [27.135]. *Lenahan* and coworkers examined the role of strain at the interface and the impact on the associated dangling bonds [27.136]. More recently, work on the effects of hydrogen annealing has also examined the SiON system [27.137].

It is also noted that the SiON material system also exhibits useful diffusion-barrier properties. This property is utilized to inhibit uncontrolled dopant diffusion from the polysilicon gate electrode through the dielectric layer and into the channel region of transistors, for example. The formation of SiON films from the reaction of NO or N_2O with Si, as well as nitridation of Si and SiO_2 from N_2 and NH_3 exposure, has been examined in detail and has been summarized in recent reviews [27.39, 70].

For transistor gate dielectric applications, a controlled variation in the depth concentration profile for N is often required throughout the dielectric to maintain the improved device reliability and mobility associated with SiON thin films [27.27]. An example of such N profiles is shown in Fig. 27.22, where a somewhat reduced N content is noted in the vicinity of the Si channel/dielectric interface relative to that near the

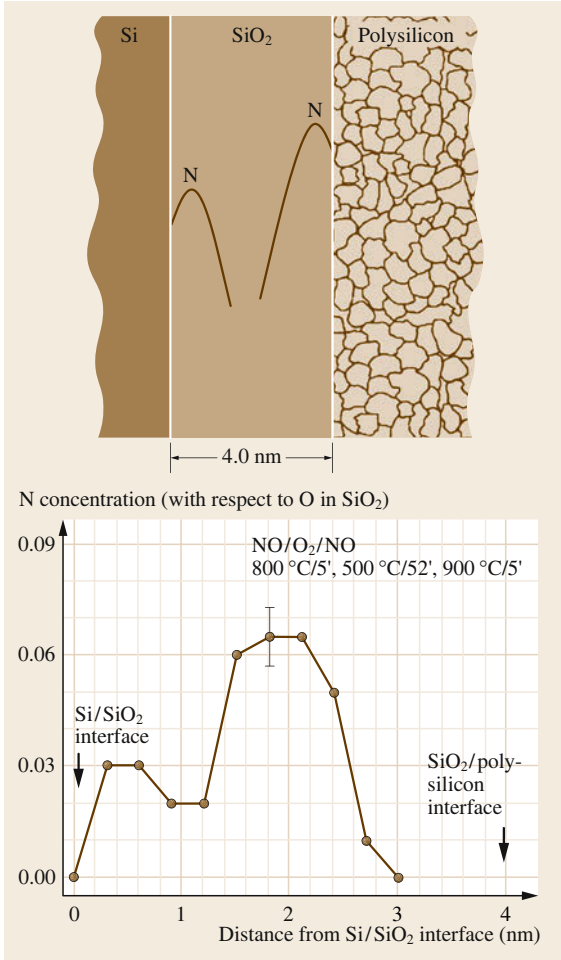

Fig. 27.22 N concentration depth profiles for tailoring the overall dielectric constant and materials properties of a SiON layer. (After [27.36], © 1999 Elsevier, with permission)

dielectric/poly-Si gate interface [27.36]. Such profiles are thought to control effects such as interfacial strain and roughness (which can degrade mobility) and inhibit dopant out-diffusion from the gate electrode. Incorporation of N in thin dielectric films using plasma processes has been studied extensively [27.132, 138–142].

Given the various leakage-current constraints afforded by power limitations and reliability, the scaling of SiON appears to be limited to $t_{eq} \approx 1$ nm, corresponding to the 65 nm node for high-performance microprocessor products [27.7]. As a result, the incorporation of alternative high-k dielectric materials has been achieved for scaled transistors over the last several years.

Table 27.3 Desirable properties for high-k gate dielectrics (65 nm node)

Physical property	Value/criteria	Electrical property	Value/criteria
Permittivity	15–25	Equivalent oxide thickness	< 1 nm
Band gap	> 5 eV	Gate leakage current (low power)	$< 0.03\ A/cm^2$
Band offset	> 1.5 eV	Gate leakage current (high performance)	$< 10^3\ A/cm^2$
Thermodynamic stability to 1000 °C	When in direct contact with Si channel	CV frequency dispersion	Minimal (meV)
Compatibility with metal electrodes	Mimimized extrinsic (pinning) defects	CV hysteresis	Minimal (meV)
Morphology control	Resistance to interdiffusion of constituents, dopants, and capping metals	V_T (V_{FB}) shift (fixed charge, defects, trapping, etc.)	Minimal
Deposition process	Suitable for high-volume production	Channel mobility	Near SiO_2 *universal* curve
Etching	Suitable control for patterning after processing/annealing	Interface quality	Near SiO_2 $D_{it} \approx 5 \times 10^{10}\ /cm^2\ eV$

27.2.5 High-k Dielectrics

High-k dielectrics have now been incoprorated to further enable scaling of transistor (and memory capacitor) technology. In the context of the industry roadmap, the term high-k dielectric more generally refers to materials which exhibit dielectric constants higher than the SiON films ($k \approx 7$) described above.

Desirable Properties for High-k Dielectrics

Many materials systems were originally under consideration as potential replacements for SiO_2 and SiO_xN_y as the gate dielectric material for sub-100 nm (CMOS) technology. A systematic consideration of the required properties of gate dielectrics indicates that the key desirable properties for selecting an alternative gate dielectric include: permittivity and the associated band gap/alignment to silicon as well as mobility, thermodynamic stability, film morphology, interface quality, compatibility with the current or expected materials to be used in processing for CMOS devices, process compatibility, and reliability. The desirable properties are summarized in Table 27.3. Reviews of the developing field and recent research on high-k dielectric materials candidates are available [27.14, 156, 157].

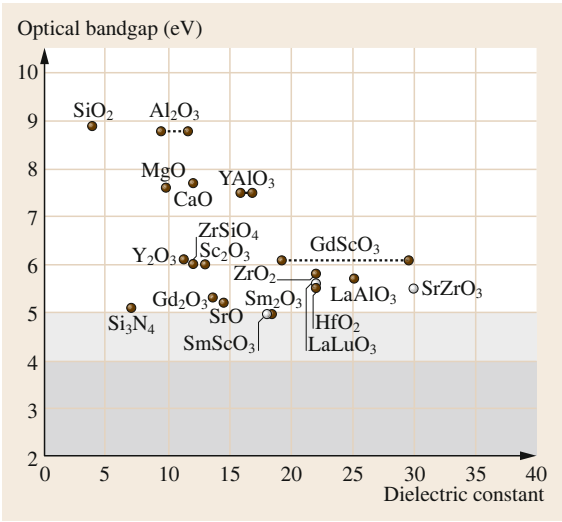

Fig. 27.23 Band gap versus dielectric constant for a number of dielectric materials. (After [27.149], MRS Bulletin, with permission)

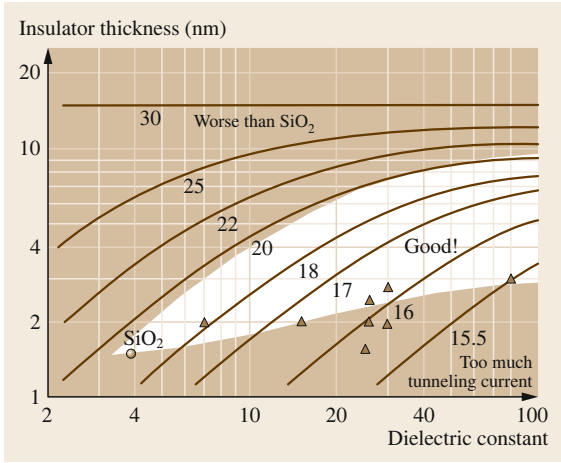

Fig. 27.24 Contours of constant scale length, which is proportional to the transistor gate length, versus dielectric constant and insulator thickness, showing the useful design space for high-k gate dielectrics. Data points are rough estimates of the tunneling constraints for various high-k insulators. The depletion depth is assumed to be 15 nm. The useful design space will shrink with decreasing depletion depth. (After [27.21], © 2004 IEEE, with permission)

Many gate dielectric materials appear favorable in some of these areas, but very few materials are promising with respect to all of these properties. Indeed, many of these desirable properties are interrelated. Many of these materials have been examined over the last 20 years for capacitor applications, for example. With the introduction of Hf-based (and Zr-based) gate dielectrics in research in the mid to late 1990s [27.158–163] and then announced by the industry for 45 nm node production in 2007 [27.164, 165], it is well known that the industry has widely adopted Hf-based oxides, largely based upon the desirable properties mentioned above. Table 27.4 summarizes some of the measured or calculated properties associated with various high-k dielectric material constituents. One notes the tradeoff between the band gap (and therefore the conduction/valence-band offsets to those of Si) for these dielectrics and the associated dielectric constant, as seen in Fig. 27.23 [27.149].

The compatibility of alternative dielectrics with metal gate electrodes is also an important consideration [27.14, 30, 166]. The interfacial reactions between some gate electrode metals and gate dielectric is thought to lead to extrinsic states due to Fermi-level pinning, which shifts the threshold voltages for transistors to a fixed value. Another clear challenge is compatibility with other *gate-first* process steps that entail substantial thermal budgets ($\approx 1000\,^{\circ}\mathrm{C}$, ≤ 10 s) for conventional CMOS. Indeed, it was found that the development of a *replacement gate last* process was key for high-k dielectric integration in high-volume manufacturing [27.1]. A key innovation in the deposition process for the high-k dielectric was also employed: atomic layer deposition (ALD). This deposition process enables atomic layer conformaility over device structures – a key requirement for scaled planar and 3-D transistor (and trech capacitor) geometries utilized currently [27.1].

Mobility Degradation for Transistors with High-k Dielectrics

In the case of many of the alternate gate dielectric materials (mainly metal oxides) currently under consideration, the polarizability of the metal–oxygen (*ionic*) bond is responsible for the observed low-frequency permittivity enhancement. Such highly polarizable bonds are described to be *soft* relative to the less polarizable *stiff* Si−O bonds associated with SiO_2. Unlike the relatively stiff Si−O bond, the polarization frequency dependence of the M−O bond is predicted to result in an enhanced scattering coupling strength for electrons with the associated low-energy and surface optical phonons. This scattering mechanism can therefore degrade the electron mobility in the inversion layer associated with MOSFET devices. A theoretical examination of this effect is provided by *Fischetti* et al. where calculations of the magnitude of the effect indicate that pure metal–oxide systems, such as ZrO_2 and HfO_2, suffer the worst degradation, whereas materials which incorporate Si−O bonds, such as silicates, fare better [27.167]. In that work, it is also noted that the

presence of a thin SiO_2 interfacial layer between the Si substrate and the high-k dielectric can help boost the resultant mobility by screening this effect, although the maximum attainable effective mobility is still below that for the ideal SiO_2/Si system. These researchers further suggest that the effect is also minimized by the incorporation of Si−O in the dielectric, as in the case of pseudo-binary systems such as silicates. Indeed, the utilization of a thin, Si-oxide rich interface has demonstrated several advantages, including a higher quality high-k/Si interface [27.1].

At this time, work on *higher-k* dielectric materials are under exploration to enable the roadmap targets presented in Table 27.1. Combinations of ALD high-k layers are often employed to increase the overall gate stack capacitance, while minimizing the thickness within the constraints for leakage current [27.1].

It is also important to note that most of the high-k metal oxides listed in Table 27.4 crystallize at relatively low temperatures ($T \approx 500$–$600\,^{\circ}C$). An exception is Al_2O_3 where crystallization in thin films is observed at $T \approx 800\,^{\circ}C$ [27.168]. In the case of Hf–silicates, film morphology (viz. suppression of crystallization) and diffusion-barrier properties can be controlled through the incorporation of N, as in the case of SiO_2 [27.153, 160–162, 169, 170].

Suppression of crystallization is also observed for aluminates (depending upon the Al content) [27.171], but there are fewer studies of interdiffusion with the Si substrate available at this time. As noted above however for the case of Al_2O_3 thin films, Al penetration into the Si substrate has been reported upon high temperature thermal annealing budgets appropriate for dopant activation [27.172]. Such penetration could be a concern for any high-k dielectric incorporating Al as well if a high temperature gate stack processs is employed.

The morphology of the dielectric film may also impact on the propensity for capping layer constituents (from metal gate material layers) to diffuse through the stack as well. Metal gate materials can include well-known minority-lifetime killers such as Ni (in NiSi) as well as tunable-work-function alloys and layers [27.30, 166, 173, 174]. The potential for the interdiffusion of metals into the channel region is clearly undesirable.

The limits of a useful high-k dielectric constant value have also been examined. For example, the study by *Frank* et al. (Fig. 27.24) suggests that there exist a range of useful permittivity values as planar CMOS transistor structures are scaled [27.21]. It is noted that the physical thickness of the gate insulator should be less than the Si depletion length under the channel region, and that this results in a limited design space that enables further device scaling. Again, one notes that the dielectric constant cannot be arbitrarily increased without careful consideration of the complete transistor design.

27.3 Isolation Dielectrics

Dielectrics are also employed to electrically isolate various regions of an integrated-circuit technology. The dominant material for these applications is SiO_2. A method commonly employed to obtain such isolation in larger-scale IC technologies (generally with gate lengths larger than $0.25\,\mu m$) is the so-called local oxidation of silicon (LOCOS) technique, where regions of Si between various components are preferentially (thermally) oxidized [27.16, 27]. Such isolation oxides are typically several hundred nanometers thick and the tapered shape of the edge of the LOCOS isolation oxide near the transistor gate dielectric and source/drain region (often referred to as the *bird's beak*) is an important region to control during the device fabrication at these gate lengths. Thinning of the dielectrics in this region results in breakdown reliability concerns, as the electric fields in this region can be quite high. A *re-oxidation process* is often performed to improve the thickness and reliability of the SiO_2 in this region as well.

Scaling ICs beyond this gate-length regime however has required the placement of isolated regions utilizing deposited SiO_2 trench structures, as seen in Fig. 27.6. As summarized by *Wolf*, extensive work has been done to control the shape of the trench walls and the SiO_2 layer initially formed on these walls. Chemical vapor deposition methods are normally utilized for the dielectric deposition as this approach provides superior conformality in the trench structure. Filling the trench without void formation, controlling film stress, and chemical mechanical polishing properties are also important aspects that must be addressed in the fabrication process [27.7, 27]. Scaling of integrate circuits will result in a decrease of the area available for these isolation trenches, and so the increasing aspect ratio of the trench depth to width requires considerable attention in regard to trench filling. The control of the shape of the top corner regions of the trench structures is also an area of concern due to high-field reliability as well as the formation of essentially a parasitic

edge transistor. Initially, thermal oxidation methods were employed to round off the shape of the corner, but further scaling will require etch processing methods.

The fabrication of transistor source/drain regions utilizing implantation processes also utilizes a dielectric spacer layer that surrounds the transistor gate region (Fig. 27.6). This spacer provides isolation between the gate and source/drain regions, and also permits the control of the depth (and therefore profile) of the implanted dopant species – a so-called self-aligned dopant implantation process. Dielectrics used for spacer technologies include deposited SiO_2 and Si_3N_4, and the extent of the spacer dimensions from the gate is an important device parameter to control [27.16]. Further scaling of transistor structures will likely result in the need for elevated source/drain regions, and so process compatibility of the spacer material with the source/drain formation processes and high-k dielectrics will become an important consideration [27.7].

27.4 Capacitor Dielectrics

Capacitors are employed in a variety of integrated circuits including storage (memory) circuit elements and input/output coupling circuitry. Clearly, dielectrics are critically important in this application. In contrast to the MIS structure associated with transistors, capacitors are passive devices incorporating a metal–insulator–metal (MIM) structure. Early electrodes were composed of degenerately doped Si while more recent work focuses on integrating metals for modern devices.

27.4.1 Types of IC Memory

A dominant memory technology for the IC industry includes dynamic random-access memory (DRAM) in which capacitors play the essential role of storing charge, and thereby useful information. This type of memory element requires refreshing in order to maintain useful information, and the rate of refresh is fundamentally related to the dielectric associated with the capacitor structure and leakage of charge from that capacitor. As a result, this class of memory devices is called volatile. In contrast, a static random-access memory (SRAM) nonvolatile memory element required a capacitor which stores charge without the refresh requirement, and can preserve charge for many years. Again capacitor design must include the consideration of the dielectric [27.25].

In addition to DRAM capacitors, other types of capacitors are used in the back end of the transistor flow. These devices are MIM capacitors, and they typically reside between levels of metal interconnects, and serve as decoupling or radio-frequency (RF) capacitors for input/output functions. For these applications, the capacitance density is still of critical importance, but other factors must be considered, such as the linearity of the capacitance as a function of voltage and temperature. Memory is also more frequently becoming *embedded* with logic, enabling faster on-chip storage.

27.4.2 Capacitor Dielectric Requirements in View of Scaling

In brief, scaling the capacitor dimensions requires a tradeoff between the amount of stored charge required for a reliable memory element and the area occupied by the capacitor (and the associated transistors for the memory cell). From generation to generation of devices, the amount of stored charge has been kept roughly constant ($\approx 30\,\mathrm{fF/cell}$), even though dimensional scaling occurs, for bit detection (sense amplifier), retention and reliability reasons [27.27, 175].

As noted in (27.6) for a simple parallel-plate capacitor, the area associated with the capacitor as well as the dielectric permittivity play an important role. Maintaining the required capacitance with scaling was (and will be) accomplished by increasing the capacitor area, for a suitable dielectric thickness where leakage currents are severely limited; this can be accomplished by utilizing three-dimensional capacitor structures produced in the Si bulk, such as deep-trench capacitors [27.175, 176]. Clever and intricate processing methods to increase the capacitor area were adopted for several generations for well-established SiO_2 and Si–oxynitride dielectric capacitor materials, such as the implementation of hemispherical-grain (HSG) poly-Si and *crown* structures (Fig. 27.25). Eventually, practical concerns about cost and device yield make manufacturing such structures problematic. Thus, substantially increasing the dielectric constant of the insulating material was considered, and less-complicated structures can be fabricated. At this point, both stacked and trench capacitor structures are dominant in the industry. Indeed, the ability to fabricate deep-trench structures will help guide the need for the incorporation of alternative dielectrics. These structures often require the use of chemical vapor deposition (CVD) methods to ensure conformality over the stacked structure topography or deep within trenches that have large aspect ratios. More recently,

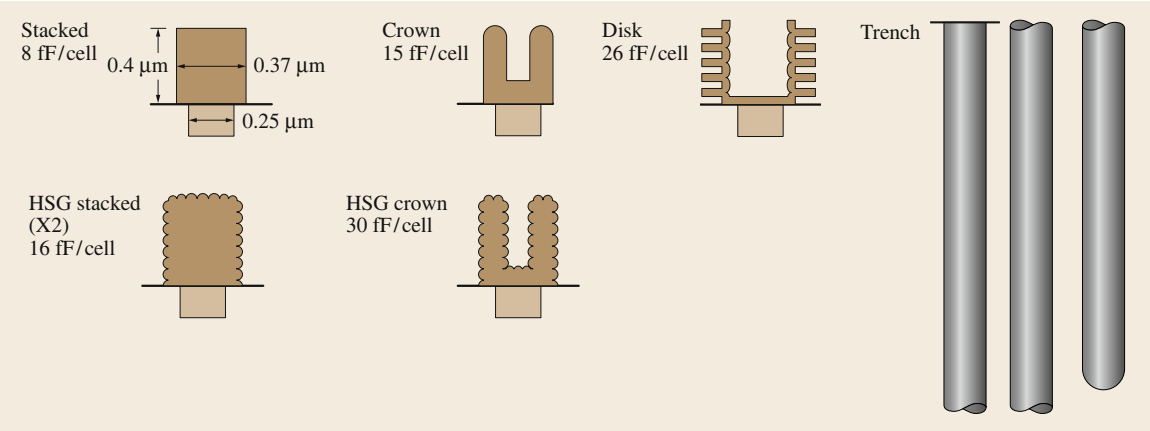

Fig. 27.25 Assorted capacitor structures employed in IC technology. (Courtesy of S. Summerfelt)

atomic-layer CVD processes have been examined for this purpose as well. Although capacitors do not have requirements regarding lateral transport of carriers, as transistors do, capacitors have much more rigorous charge-storage-capacity requirements when they serve as memory elements. This additional constraint results in projected limitations.

27.4.3 Dielectrics for Volatile Memory Capacitors

Capacitor dielectric properties for dynamic random-access memory (DRAM) applications have been important since these devices were introduced commercially in the early 1970s for volatile memory [27.177]. *Fazan* provides some rules of thumb that provide guidance for the selection of desirable materials (and electrical) properties for DRAM capacitor dielectrics [27.175]. In addition to the desire to maintain the storage capacitance around 30 fF/cell (in spite of shrinking dimensions), leakage of charge from the storage capacitor must be kept to a current density of less than $0.1\,\mu A/cm^2$ so that less than $\approx 10\%$ of the capacitor charge is lost during the associated refresh (recharge) cycle. Scaling the DRAM cell size has necessarily resulted in the consideration of a variety of dielectric materials for some time [27.7, 25, 27].

SiO_2 and SiO_xN_y

The earliest DRAM planar capacitors utilized SiO_2 as the dielectric. Subsequent scaling into the Mbit regime required an increased capacitance density, and thus a higher dielectric constant. So-called oxide/nitride (ON) or oxide/nitride/oxide (ONO) dielectric stacks were incorporated [27.16]. As the names imply, the dielectric consisted of a stack of SiO_2 and Si_3N_4 layers. The incorporation of the Si nitride layer, typically by a deposition method such as chemical vapor deposition, results in an overall increase in the dielectric constant of the stack. Scaling has required the consideration of high-k materials in currrent DRAM technologies.

$ZrO_2/Al_2O_3/ZrO_2$

Scaling metal-insulator-metal capacitors required the development of alternative dielectrics (e.g., Al_2O_3 and ZrO_2) and their integration into DRAM processes [27.7, 178]. The stack provides useful dielectric constants in the range of $k \approx 20-50$ for adequate charge storage and leakage performance.

Perovskites

Considerable effort has also been exerted in the search for CMOS-compatible *ultra high-k* dielectrics. Such materials are envisioned to be required for capacitor scaling at and beyond the 10 nm node [27.7]. Perovskite materials, with a $k > 50-100$ have been a focus for this application. The movement of the Ti atom (ion) in the perovskite lattice structure results in a substantial contribution to the polarization of this materials system. Utilization of perovskite has required the use of noble-metal electrodes including Pt, Ru (RuO_2) and Ir to control interfacial reactions. As a result, considerable process complexity is introduced into the manufacturing process.

27.4.4 Dielectrics for Nonvolatile Memory

As the name implies, nonvolatile memory devices retain their state whether power is applied to the device or not. A thorough description of such devices is provided by *Hori* [27.16]. For example, the electrically erasable programmable read-only memory (EEPROM) device requires an erase operation prior to programming (*writing*) new data to the device. To accomplish this,

Table 27.5 Comparison of non-volatile memory technologies. (After [27.179])

Specifications	FRAM	SRAM	EEPROM	Flash
Non-volatile Retains data w/o power	Yes	No	Yes	Yes
Write speed (13 KB)	10 ms	< 10 ms	2 s	1 s
Average active power (μA/MHz) 16 bit word access by the CPU	100	< 60	> 50 000	230
Write endurance	10^{15}	Unlimited	100 000	10 000
Soft errors	Below measurable limits	Yes	Yes	Yes
Bit-wise programmable	Yes	Yes	No	No
Unified memory Flexible code and data partitioning	Yes	No		

a stacked-gate MOS structure is utilized where the intermediate gate is embedded in a dielectric – a so-called *floating gate*. The placement of a higher electric field to permit Fowler–Nordheim tunneling through such dielectrics to the floating gate is utilized to program arrays of these elements – called *flash memory*. Scaling and the reliability required for such nonvolatile memory devices has required the evolution from using SiO_2 to SiO_xN_y.

SiO_2 and SiO_xN_y

For flash memory elements, the formation of nitrided SiO_2 enables a suitable dielectric for reliable operation. The nitridation process, as described earlier, entails the exposure of an SiO_2 dielectric to anneals with N_2, NH_3, or N_2O (or combinations of these), often under rapid thermal annealing conditions. Details of this process have been summarized by *Hori* [27.16]. Subsequent reoxidation of the dielectric is also employed to improve reliability properties. So-called silicon oxide nitride oxide silicon (SONOS) structures are under examination to improve the scaling limitations of the dielectric thickness and tunneling properties [27.181].

Further scaling of transistors presents significant challenges for flash memory. The thickness of the dielectric is again a key constraint given the need for reliable operation under high-electric-field conditions. Memories based on Si nanocrystals embedded within SiO_2 are currently under development to address this challenge [27.182].

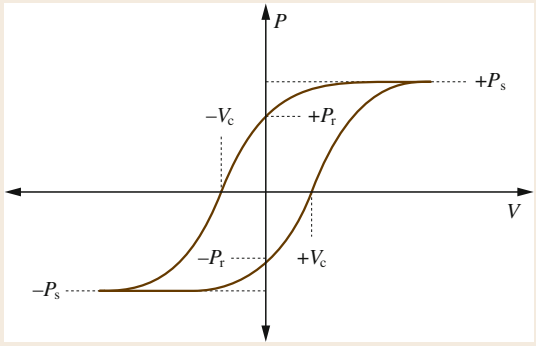

Fig. 27.26 Polarization–voltage curve for a ferroelectric material. (After [27.180], © 2004 IEEE, with permission)

Ferroelectrics

Ferroelectric materials, such as $PbZr_{1-x}Ti_xO_3$ (PZT) or $SrBi_2Ta_2O_9$ (SBT) have been utilized for some time as dielectrics for non-volatile memory elements based upon the ferroelectric effect [27.24]. In storage capacitors incorporating such materials, the polarization state of the ferroelectric is preserved (once poled) without the presence of an electric field [27.23]. This state is then sensed by associated circuitry and can therefore be used as a memory device. The technology has been successfully incorporated in smart card applications as well as microcontroller embeded random access memory – so called ferroelectric RAM (FeRAM or FRAM) [27.179]. A comparison of various memory technologies is provided in Table 27.5.

Principles. Ferroelectricity describes the spontaneous alignment of dipoles in a dielectric as the result of an externally applied electric field. This alignment behavior has thermal constraints in that heating the dielectric above the Curie temperature results in a phase transformation to a paraelectric state. Therefore, capacitors and circuits which utilize the ferroelectric effect must contain materials that have a relatively high Curie temperature compared to that experienced during operation and reliability testing (generally > 200 °C). As shown in Fig. 27.26, the polarization response of these materials to an externally applied electric field exhibits a hysteresis behavior [27.180]. (This behavior is analogous to that observed in ferromagnetic materials, hence the name. Note however that ferroelectric materials contain no iron.) Upon increasing the voltage across the ferroelectric above a coercive value (V_c), the polarization of the material is limited to the spontaneous value (P_s), corresponding to maximum domain align-

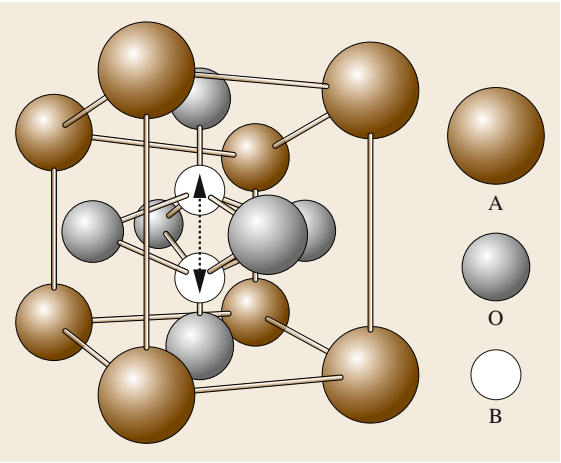

Fig. 27.27 Perovskite ABO unit cell showing motion of the B ion in the cell among the equilibrium positions, resulting in ferroelectric polarization behavior. (After [27.180], © 2004 IEEE, with permission)

ment. Removal of the electric field results in a decrease of the polarization to the remnant value (P_r), which can be sensed accordingly. The time required for the polarization to be switched is on the order of nanoseconds for these devices. Moreover, this can be accomplished in low-power circuits, making these materials attractive, in principle, for scaled CMOS.

Materials. In addition to the perovskite PZT and SBT materials mentioned above, other materials investigated for nonvolatile memory applications include $BaTiO_3$, $PbTiO_3$, $Pb_{1-x}La_xZr_{1-y}Ti_yO_3$ (PLZT), $PbMg_{1-x}Nb_xO_3$ (PMN), $SrBi_2Nb_2O_9$ (SBN), and $SrBi_2(Ta_{1-x}Nb_x)_2O_9$ (SBTN). These materials generally have the cubic structure ABO_3 shown in Fig. 27.27, with the larger (A) cations in the corner of the cubic unit cell, and the smaller (B) cations (e.g., Ti, Zr, Mg, Nb, Ta) located in the center of the unit cell. The oxygen anions are located at the face-centered-cube positions. The distortion of the unit cell in response to the externally applied electric field results in the observed polarization. In particular, the movement of the B cation (e.g., Ti) in the associated lattice between the equilibrium positions results in substantial distortion and therefore polarization [27.24, 180].

Issues for Ferroelectric Materials. Substantial research has been performed to understand the reliability issues associated with ferroelectric memory devices, as their integration tends to occur at the back end of (fabrication) line (BEOL) stage of the typical chip fabrication process. The retention of the polarization state is one area of investigation. It is observed that the polarization state decreases slowly over time (*log-time* decay behavior), even in the absence of an electric field, and the reasons are still not understood. Another area of concern is *imprint*, where a polarization state, if repeatedly poled to the same state, becomes preferred. Subsequent switching to the opposite state can result in relatively poor retention times. Again, the physical mechanism associated with this phenomenon is poorly understood. The role of hydrogen exposure is another area of investigation, where exposure of ferroelectric random-access memory (FeRAM) elements to hydrogen, commonly from forming gas during CMOS back-end processing, can result in the suppression of the remnant polarization [27.183–185]. Barriers for hydrogen (and moisture) permeation into the ferroelectric, such as ALD Al_2O_3, are important for reproducible and reliable operation [27.186–188].

27.5 Interconnect Dielectrics

As noted in Fig. 27.1, the performance of the integrated circuit, as measured by the time delay for signal propagation, also depends upon the interconnections between circuit elements. The scaling of CMOS has resulted in a substantial increase in interconnect metal lines throughout the IC chip, which make a major contribution to the delay time. The industry segments these levels into *local* (interconnection between neighboring devices), *intermediate* (metal 1 interconnection between neighboring circuits), and *global* (interconnection across the chip), as shown in Fig. 27.28. A cross section of a 65 nm-node IC is shown in Fig. 27.29 where eight layers of metallization and the associated dielectric isolation are evident.

As discussed in Sect. 27.1.1, the *RC* time delay for the interconnect contribution to performance can be attributed to the metal lines and their isolation dielectrics (see Fig. 27.1). The resistivity of the lines has been reduced in the industry by recently adopting copper metallization processes in lieu of aluminium metallization in 1998. Further reductions in the delay time then require the consideration of the dielectric between the lines, as these essentially form a parasitic capacitor structure, and therefore low-*k* dielectrics are required. Examples of such interconnect dielectrics are presented in Table 27.6. Reviews of interconnect technology for CMOS are available [27.189]. It is noted that for the global interconnect level, new

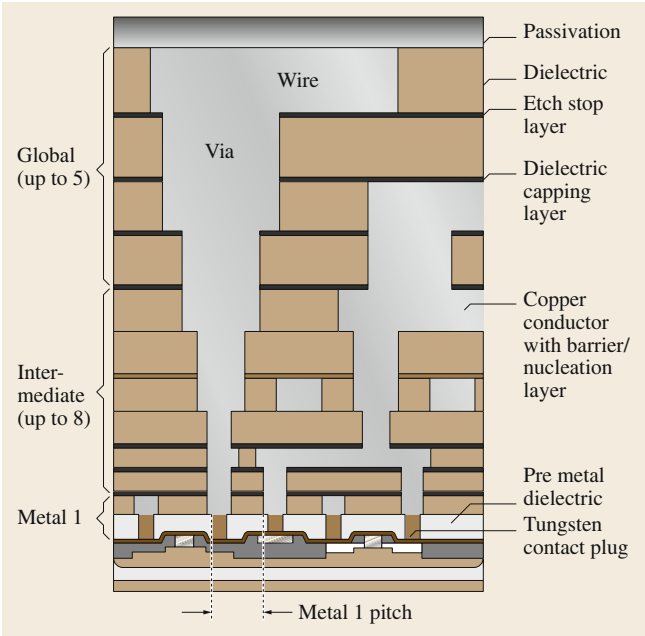

Fig. 27.28 Schematic of a typical chip cross section showing key interconnect metallization and dielectric layers. (From [27.7])

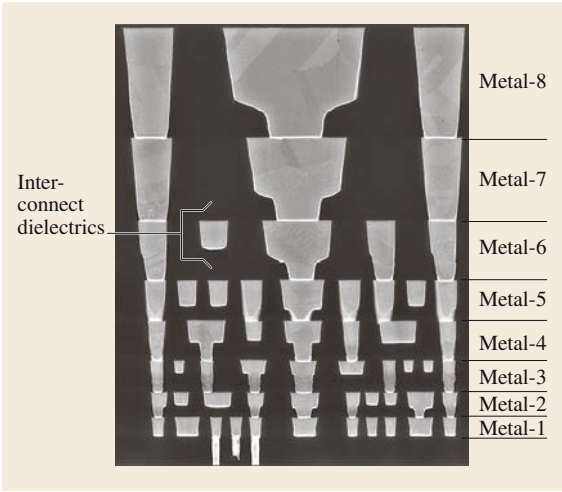

Fig. 27.29 Cross section of a 65 nm node IC chip from 2005 showing eight levels of metal interconnects isolated by low-k dielectrics. (Courtesy of Intel)

concepts such as RF or optical communication, will likely be needed to address extreme CMOS scaling.

27.5.1 Tetraethoxysilane (TEOS)

For many years, CVD-deposited SiO_2 provided adequate isolation for interconnection of ICs. This was frequently accomplished through the deposition of tetraethoxysilane (TEOS) and subsequent densification thermal treatments to render a dielectric constant of $k \approx 4$. Films produced in this manner were relatively easy to process and provided good mechanical strength. The incorporation of fluorine into these films (fluorinated silicate glass or FSG) succeeded in a reduction of the dielectric constant to $k \approx 3.5–3.7$ after considerable efforts. As F is among the most electronegative elements, the incorporation of F into the silica matrix renders the film less polarizable due to Si−F bond formation, and therefore results in a lower permittivity. Scaling CMOS however has driven the industry to consider interconnect dielectric materials with $k \ll 4$.

Table 27.6 Interconnect dielectric materials. (After [27.7, 27])

Dielectric constant	Material
3.5–3.7	FSG
3.0–3.6	Polyimides
2.7–3.1	Spin-on glass
2.6–2.9	Organo-silicate glasses (OSGs)
2.6–2.8	Parylene-based polymers
2.5–3.2	Methyl/hydrogen silsesquioxane (MSQ/HSQ)
1.8–2.4	Porous MSQ, parylene-based polymers
1.1–2.2	Silica aerogels
1.5–2.2	Silica xerogels

27.5.2 Low-k Dielectrics

As seen in Figures 27.28 and 27.29, several levels of dielectrics must be incorporated with the metallization schemes associated with ICs. As can be seen, dielectrics utilized in this back end of (fabrication) line (BEOL) portion of the IC fabrication process are also segmented into pre-, inter- and intra-metal dielectrics. Additionally, dielectric layers are employed to facilitate etching control for Cu metal patterning of the various interconnection lines. This requires materials integration with barrier layers (that control Cu diffusion), etch stop layers, CMP (chemical mechanical polishing) stop layers as well as overall mechanical stability. Additionally, for the local and metal 1 layers, the future incorporation of metal gate and/or NiSi materials may require extensive limitations on processing temperatures ($< 500\,^{\circ}C$).

Several materials have been explored for the low-k application, and some of these are summarized in Table 27.5 [27.7, 27]. Most consist of polymeric (low-Z) materials with varying porosity to enable a sufficiently low dielectric constant for interconnect applications. At this point, films are deposited by either CVD or spin-on methods. Desirable properties for low-k dielectrics include thermal stability (to $\approx 500\,^{\circ}C$), mechanical

stability (to withstand packaging), electrical isolation stability/reliability (similar to SiO_2), chemical stability (minimal moisture absorption, resistance to process chemicals, resist compatibility), compatibility with BEOL materials (e.g., diffusion barriers) and processes (etching, cleaning, post-metallization and forming-gas anneals, chemical mechanical polishing, etc.) and of course low cost. As noted by Wolf, thermal properties of low-*k* materials are important for effective power dissipation in high-performance applications. According to the 2013 ITRS Roadmap, a lack of progress on low-*k* dielectric scaling presents a significant challenge to the industry where innovative solutions would be very welcome [27.7].

27.6 Summary

It should be evident that IC technology is critically dependent upon suitable dielectrics throughout the entire chip. Materials properties, and their resultant electrical properties, must be carefully evaluated throughout the research and development process associated with integrated circuit technology.

Recent years and roadmap predictions clearly place an emphasis on the development of new materials for the various dielectrics employed to achieve scaling. Researchers and technologists engaged in this endeavor must be able to span several disciplines to enable the successful integration of these new dielectric materials.

28. Thin Films

Robert D. Gould†, Safa Kasap, Asim K. Ray

This chapter provides an extended introduction to the basic principles of thin-film technology, including deposition processes, structure, and some optical and electrical properties relevant to this volume. The material is accessible to scientists and engineers with no previous experience in this field, and contains extensive references to both the primary literature and earlier review articles. Although it is impossible to provide full coverage of all areas or of the most recent developments in this survey, references are included to enable the reader to access the information elsewhere, while the coverage of fundamentals will allow this to be appreciated.

Deposition of thin films by the main physical deposition methods of vacuum evaporation, molecular-beam epitaxy and sputtering are described in some detail, as are those by the chemical deposition methods of electrodeposition, chemical vapour deposition and the Langmuir–Blodgett technique. Examples of structural features of some thin films are given, including their crystallography, larger-scale structure and film morphology. The dependence of these features on the deposition conditions are stressed, including those required for the growth of epitaxial films and the use of zone models in the classification of the morphological characteristics. The main optical properties of thin films are reviewed, including the use of Fresnel coefficients at media boundaries, reflectance and transmittance, matrix methods and the application of these techniques to the design of antireflection coatings, mirrors and filters. The dependence of electrical conductivity (or resistivity) and the temperature coefficient of resistivity in metallic thin films is discussed, in particular the models of Thomson, Fuchs–Sondheimer and the grain-boundary model of Mayadas–Shatzkes. For insulating and semiconducting thin films the origin and effects of several high-field conduction processes are examined, including space-charge-limited conductivity, the Poole–Frenkel effect, hopping, tunnelling and the Schottky effect. Finally, some speculations regarding future developments are made.

28.1 **Deposition Methods** 647
28.1.1 Physical Deposition Methods 647
28.1.2 Chemical Deposition Methods 662
28.1.3 Sol–Gel Method 667
28.2 **Structure** 669
28.2.1 Crystallography 669
28.2.2 Film Structure 670
28.2.3 Morphology 676
28.2.4 Raman Spectroscopy 678
28.3 **Properties** 680
28.3.1 Optical Properties 680
28.3.2 Optical Absorption 684
28.3.3 Electrical Properties 685
28.4 **Concluding Remarks** 699
References 702

The earliest use of thin films by mankind is probably in the application of glazes to brickwork and pottery. Tin glazing was discovered by the Assyrians and was used to coat decorative brickwork. Glazed brick panels have been recovered from various archeological sites, with a fragment from Nimrud being dated to about 890 B.C. Various alternative types of glaze have since been developed, and are used both to overcome the effects of porosity in pottery and for decorative purposes. The importance of thin films in optics was first recognised in the 17th century by Hooke, Newton and others. In 1675 Newton described observations of colours in thin films of transparent material and from geometrical considerations was able to calculate effective film thickness and correlate this with the periodicity of observed colours. The films in question were typically of air or water in the space between two glass surfaces having different radii of curvature. The phenomena described are seen most conveniently as *Newton's rings*, where an optically flat glass surface is in contact with

a convex glass surface having a large radius of curvature. Under monochromatic illumination in reflection, a series of concentric coloured rings were observed, the radii being proportional to $\sqrt{1}$, $\sqrt{2}$, $\sqrt{3}$, etc. Although the wave nature of light and interference phenomena were not universally accepted at that time (especially by Newton) these observations, and others where the radii of the rings were seen to be larger for red than for violet light, established one of the most important properties of thin films. Since these early observations of thin film properties, they have been found to display not only characteristic and distinctive optical behaviour, but also mechanical, electrical and magnetic properties. These properties underpin many of their present-day industrial applications, such as antireflection coatings and optical filters, surface acoustic wave devices, electronic components (both discrete and integrated) such as resistors, capacitors, thin-film transistors and other active devices, magnetic data storage and superconductors.

Notwithstanding this wide range of properties and applications, it should be stressed that there is no watertight definition of the thickness below which a film becomes thin. The reason for this is primarily because different properties scale differently with thickness. *Eckertová* [28.1] has pointed out that it is permissible to say in general that the physical limit is determined by the thickness below which certain described anomalies appear, but that this differs for different physical phenomena. For instance a film which is optically thin may be of the order of the wavelength of light ($\approx 500\,\mathrm{nm}$) although some electrical properties are determined by the mean free path of conduction electrons ($\approx 50\,\mathrm{nm}$ for metals) or by the thickness at which a given applied voltage produces an electric field which leads to high-field (nonlinear) behaviour. Generally speaking a thin film has a thickness of less than $1\,\mu\mathrm{m}$, and is deposited on the surface of a substrate by one of several distinct deposition methods [28.2]. In keeping with the remit of this Handbook, the emphasis in this chapter is on the electrical and optical properties of thin films, as these are clearly the most important in the field of electronic and optoelectronic materials. It is not the intention to dismiss thermal and mechanical properties as irrelevant in this sphere, but to stress that, although they may both also have an influence on the electrical and optical properties, they are both mainly dependent on the material itself. Mechanical properties of thin films have been reviewed by *Hoffman* [28.3] and also by *Campbell* [28.4]. However, the *structure* of thin films often has a crucial effect in determining other thin-film properties and, unlike the thermal and mechanical properties, is very largely determined by the film deposition method and conditions. For these reasons sections on both the structure and deposition methods of thin films are included in this review.

The basic structure of the chapter, following this brief introduction, covers the various aspects of thin films starting from their deposition methods, through their structures to their optical and electrical properties. There is no attempt to cover all of these aspects comprehensively; in a chapter such as this there is sufficient space to cover only the most important techniques and properties. In Sect. 28.1 the major deposition methods are described, such as physical processes like evaporation and sputtering, and chemical methods including chemical vapour deposition (CVD) and the Langmuir–Blodgett technique for molecular films. In Sect. 28.2 some examples of the crystalline structure of various types of films are examined. These can be relatively simple in the case of evaporated metal films, whereas compound films (such as compound semiconductors) can exhibit a variety of different structural forms depending on the deposition conditions and the thickness. Films prepared from larger molecules, such as the organic phthalocyanines having molecular weights of the order of 500, can also show several quite complex structures. In addition to the crystal structure per se, which is normally determined using X-ray, electron or neutron diffraction techniques, the morphologies of thin films often show interesting features, which are observed using electron microscopy or one of the newer scanning-probe imaging techniques such as scanning–tunnelling microscopy (STM) or atomic force microscopy (AFM). Section 28.3 covers the basic optical and electrical properties of thin films. The optical properties covered in Sect. 28.3.1 are largely the result of the electromagnetic wave nature of light, leading to the interference phenomena which were first observed in the 17th century. Films of suitable thickness and refractive index may be used in simple antireflection coatings, and quite complex multilayer film structures are used as optical filters. In Sect. 28.3.3 electrical properties are described. These include electrical conductivity (or resistivity) in relatively high-conductivity materials such as metals, where the conductivity depends not only on the carrier concentration and bulk mean free path, but is also modified by the effects of scattering at one or both of the film surfaces and internal grain boundaries. Lateral conduction in discontinuous (island) films where there are significant potential barriers between highly conducting regions has been investigated by *Neugebauer* and *Webb* [28.5], although this not discussed in the present work. This mechanism is reviewed elsewhere in the literature [28.1, 6]. Various nonlinear conduction processes arise as the result of the high electric fields that can be applied across thin films; for example a film of thickness 100 nm having a poten-

tial difference of only 1 V applied between its surfaces, would experience a field of 1×10^7 V/m, which approaches the dielectric breakdown strength of many materials. Finally in Sect. 28.4 the main points or the discussion are summarised and some speculations concerning future trends are given.

Much of the technology associated with thin-film deposition and growth is explicitly excluded from this discussion. The measurement of film thickness, both during deposition (monitoring) or post-deposition, is not covered, although good accounts are given in the literature [28.7, 8]. Furthermore the condensation and growth mechanisms of thin films are also omitted [28.9, 10], although the structure and other properties are largely influenced by these. Many of the up-to-date materials properties and device applications are covered elsewhere in this volume. The reader is referred to Chap. 14 for details of epitaxial growth techniques and to Chap. 17 for structural characterisation. Optical properties and characterisation are discussed in Chap. 3, while the corresponding materials and devices are addressed in Chap. 35. Sensors and transducers, which are frequently based on various thin-film techniques (both inorganic and organic) are described in Chap. 37 and 52. In the area of electronics, much current effort is in the areas of molecular electronics as described in Chap. 51. Indeed the present author has predicted that many of the high-field conduction effects commonly observed in thin films will, in due course, also be detected in nanostructures in a suitably modified form [28.11].

Many of the topics coved in this chapter are explained in more detail in various books. The *Handbook of Thin Film Technology* [28.12], although published over three decades ago, has an enormous amount of detail concerning basic thin-film phenomena, most of which is still of interest today. Another very useful resource is the series of volumes originally entitled *Physics of Thin Films* and later simply *Thin Films* (recent volumes retitled *Thin Films and Nanotechnology*) published by Academic Press. Volume 25 of this series [28.13] contains an index for all the earlier volumes covering the years 1963–1998. Detailed references to several articles from both these sources are given in the references. Also of particular interest in the materials field is the *Handbook of Thin Film Materials* [28.14]. The reader is also referred to several other books covering the general field of thin films and technology [28.1, 15–19]. Other books covering more restricted areas of thin-film technology (e.g., optical properties, electronics) are referred to in the appropriate sections.

The SI system of units is used throughout, and where original work was presented in non-SI units, these have normally been converted. Other customary units, such as the electronvolt, are used where appropriate. The main emphasis in this chapter is on the physics of the deposition processes and the optical and electrical properties, and on their relationships with film structure, while keeping mathematical details to a minimum. As mentioned earlier, only the most important methods and properties are covered, although references to techniques omitted and fundamental factors are included to aid the acquisition of a deeper understanding, where this is required, and to appreciate the applications of thin films in those areas not covered elsewhere in this volume.

28.1 Deposition Methods

The deposition methods described in this section are those most commonly used. The physical methods of vacuum evaporation and sputtering are perhaps the most controllable, giving the best-quality films. In particular, molecular-beam epitaxy (MBE) is capable of providing very high-quality films. Examples of chemical methods, which are somewhat less flexible and limited to particular types of films, are also given. Perhaps the most important of these is CVD, but as will be seen the particular route chosen depends on the chemical properties of the material to be deposited.

28.1.1 Physical Deposition Methods

These could perhaps be described as physical vapour deposition (PVD) methods, since they involve direct deposition from the vapour phase, normally under reduced pressure. There are two main classes which are considered. The first of these is vacuum evaporation, which takes place at a low background pressure, i. e., high vacuum (HV) of the order of 10^{-4} Pa, although MBE systems normally operate at pressures significantly below this level. Secondly we have sputtering, which relies on the ejection of atoms or molecules from the surface of a material target by a mechanism of momentum transfer involving an impact from (usually) ionised inert gas atoms such as argon; in order for this to occur a sufficient inert gas pressure is required to sustain a discharge, and thus the typical operating pressure is of the order of 1 Pa. Thus evaporated films are liable to have a higher intrinsic purity than sputtered films, which are prone to the incorporation of sputtering gas

atoms. However, as these are generally inert there is often no deleterious effect on the film properties.

Vacuum Evaporation

During evaporation the evaporant is heated in vacuum by, for example, employing a high current through a refractory boat in which the evaporant is placed, or by using a high-current electron beam focussed on the evaporant. The purpose of this heating is to convert the condensed phase of the evaporant into the vapour phase, which then condenses elsewhere in the system in the form of a thin film. At a given absolute temperature T, there will in general be some of the evaporant in a condensed phase and some in the vapour phase. In thermodynamic equilibrium the Clausius–Clapeyron equation, relating the equilibrium vapour pressure p^* to the temperature T may be applied

$$\frac{\mathrm{d}p^*}{\mathrm{d}T} = \frac{L}{T(v_\mathrm{g} - v_\mathrm{c})}\,, \tag{28.1}$$

where L is the latent heat of vaporisation, representing the amount of energy required to convert a quantity of the condensed phase (liquid or solid) into the vapour phase at the given temperature. If L is expressed in J/mol, then v_g and v_c represent the molar volumes of the gaseous and condensed phases respectively. Although evaporation is not an equilibrium process, the importance of the equilibrium vapour pressure to evaporation is that maximum evaporation rates are dependent on the vapour pressure. Expressions for p^* may be obtained from (28.1) provided the temperature dependence of L is known. For the simplest assumption, where L is independent of T, we assume that the vapour obeys the ideal gas law. For one mole of the vapour

$$p^* v_\mathrm{g} = RT\,, \tag{28.2}$$

where R is the universal gas constant. Further assuming that the volume of the vapour phase is very much greater than that of the condensed phase ($v_\mathrm{g} \gg v_\mathrm{c}$), combining the above two equations and integrating, an expression for p^* is obtained. This can be expressed in logarithmic form as

$$\log_{10} p^* = AT^{-1} + B\,, \tag{28.3}$$

where $A = -(L/R)\log_{10}\mathrm{e}$ and B is a constant of integration. The constants A and B are tabulated by *Dushman* and *Lafferty* [28.20] for various metals using non-SI units, although in a slightly different form from the definitions of (28.3). In many cases such an expression for determining equilibrium vapour pressure is inadequate. The main reason for this is that the assumption of a constant latent heat L is invalid, particularly over a wide temperature range. When temperature variations in L are taken into account, (28.3) is modified by the addition of several additional terms, which may be determined from standard thermodynamic enthalpy and entropy data [28.21]. Tabulated values of coefficients for a logarithmic p^*–T expression involving four coefficients are given by *Kubaschewski* et al. [28.22] for various elements and compounds over defined temperature ranges in both the liquid and solid phases. Even more helpful are direct tabulated and graphical data of the p^*–T relationship in the case of various solid and liquid elements [28.21, 23, 24]. Examples of the p^*–T dependence are given in Fig. 28.1 for several elements using the data of *Honig* and *Kramer* [28.24]. From this figure it is clear that p^* increases very rapidly with temperature, and that most metals require temperatures of up to about 1500 K to attain significant vapour pressures; however, the refractory metals (Pt, Ta, W, etc.) require far higher temperatures for evaporation and thus they are not normally deposited by this method, although they are very useful materials for evaporation boat materials, which require very low vapour pressures and high melting points.

It is a well-known result from the kinetic theory of gases, that the molecules of a gas at a pressure p impinge on surfaces at a rate

$$N_\mathrm{i} = \frac{p}{(2\pi m k_\mathrm{B} T)^{1/2}} \tag{28.4}$$

where N_i ($\mathrm{m^{-2}s^{-1}}$) is termed the impingement rate, m is the mass of a gas molecule, k_B is Boltzmann's con-

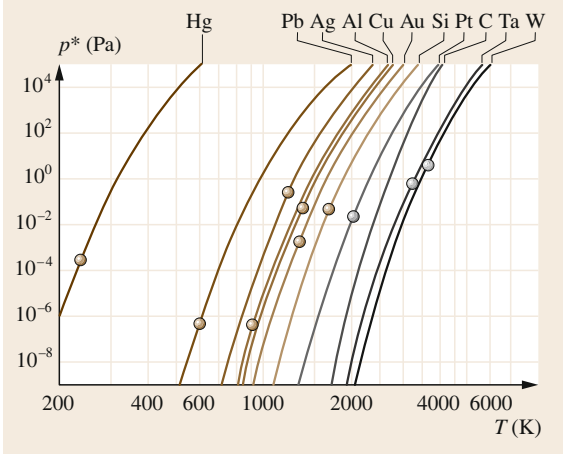

Fig. 28.1 Experimental dependence of the equilibrium vapour pressure p^* on absolute temperature T for several elements, derived from the compilation of *Honig* and *Kramer* [28.24]. The *point* (•) on each *curve* indicates the melting point, except for that of carbon, which sublimes

stant and T is the absolute temperature. In principle this equation applies equally well to residual gas molecules (N_2 and O_2) in an evaporation chamber, as well as to evaporant molecules in the vapour phase. It was noted previously that the equilibrium vapour pressure of a material largely determines the maximum evaporation rate. Hertz [28.25] observed for the case of mercury that evaporation rates were proportional to the difference between the equilibrium vapour pressure p^* and the reverse hydrostatic pressure p_h exerted at the surface of the evaporant. The *maximum* evaporation rate occurs when $p_h = 0$, and is equal to the impingement rate a vapour of the evaporant would exert at its equilibrium vapour pressure. This is given by an expression similar to (28.4), with pressure p^*, evaporation temperature T_e and mass of evaporant molecule m_e. This rate is rarely achieved, not only due to the hydrostatic pressure p_h, but also to a molecular reflection phenomenon proposed by *Knudsen* [28.26], which takes place at the evaporant surface. It was proposed that only a certain fraction α_v (the evaporation coefficient) of molecules make the transition from the condensed to the vapour phase. The net *molecular evaporation rate*, N_e, is then given by the *Hertz–Knudsen equation*

$$N_e = \frac{\alpha_v\,(p^* - p_h)}{(2\pi m_e k_B T_e)^{1/2}}. \tag{28.5}$$

Under equilibrium conditions $p_h = p^*$ and there is no net evaporation; however, under nonequilibrium conditions, especially when $p_h \ll p^*$, the evaporation rate can be considerable. Values of the coefficient α_v have been tabulated in the literature for a selection of different elements and compounds [28.27].

Equipped with vapour pressure and evaporation coefficient data, it is straightforward to estimate the evaporation rate using (28.5). The molecular deposition rate N_R represents the number of evaporated molecules deposited on the substrate per unit area per second. It is clearly proportional to the evaporation rate N_e, depending on the geometry of the evaporation/deposition system. N_R is simply related to the thickness deposition rate R (m/s) by

$$N_R = \frac{\rho R}{m_e}\,, \tag{28.6}$$

where ρ is the density of the depositing film. An indication of the film quality is given by the impingement ratio K, representing the ratio of the rate at which ambient gas molecules impinge on the substrate to the rate of evaporated molecules depositing on the substrate. Hence

$$K = \frac{N_i}{N_R} \tag{28.7}$$

From (28.4) and (28.6) it is clear that $K \propto p/R$ for a given material. In order to reduce contamination by gas incorporation into the film, it is therefore necessary to operate at a low background gas pressure with a relatively high deposition rate. A simple calculation for copper shows that for $R = 1\,\text{nm/s}$, $N_R \approx 8.5\times10^{19}\,\text{m}^{-2}\,\text{s}^{-1}$. If we require $K < 10^{-3}$ for impinging oxygen molecules then the maximum value of N_i allowed is $8.5\times10^{16}\,\text{m}^{-2}\,\text{s}^{-1}$, which from (28.4) corresponds at room temperature to a pressure of about $3\times10^{-6}\,\text{Pa}$. Such a pressure is in the range of ultrahigh vacuum (UHV), and is not attainable in normal vacuum deposition systems. Increasing the deposition rate is the normal method of lowering K without moving into UHV, as is used in MBE. This may in principle be achieved either by increasing the evaporation rate by increasing T_e to raise p^*, or by increasing the proportionality constant between N_e and N_R by shortening the distance between the evaporant and the substrate. A useful table of values of K for various combinations of chamber pressure and deposition rate is given by *Eckertová* [28.1].

There is in principle a second limitation on the level of the background pressure in a vacuum system which is also derived from kinetic theory. By using a Maxwell–Boltzmann distribution function for the molecular velocities in a gas, it can be shown that the mean free path between collisions in the gas λ is given by [28.21]

$$\lambda = \frac{k_B T}{p\pi\delta^2\sqrt{2}}\,, \tag{28.8}$$

where δ is the effective molecular diameter of a gas molecule. Values of δ are tabulated in the literature [28.20], and range from about 0.22 (He) to 0.49 nm (Xe). From (28.8) λ is inversely proportional to the pressure p, and this general relationship is shown for He, O_2 and Xe in Fig. 28.2. Since the values of δ do not vary greatly for different gases, the λ values for all common gases fall within a narrow range, as illustrated in the figure. The proportion of molecules $F(x)$ which have not suffered an intermolecular collision as a function of distance x since their last collision is given by

$$F(x) = \exp\left(-\frac{x}{\lambda}\right). \tag{28.9}$$

From this expression it is evident that for a deposition chamber size of about $\lambda/10$, less than 10% of molecules suffer a collision before hitting the walls of the chamber or the substrate, e.g., in a large vacuum chamber of dimensions about 1 m where the mean free path is about 10 m. From Fig. 28.2 a pressure of $10^{-4}\,\text{Pa}$ is sufficiently low to ensure that $\lambda > 10\,\text{m}$. In evaporation processes we require that the evaporant molecules

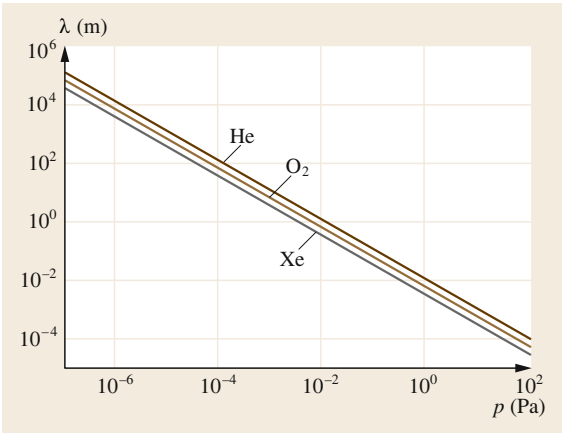

Fig. 28.2 The dependence of mean free path λ on pressure p for helium, oxygen and xenon at 300 K. Mean free paths are calculated from (28.8) using values of molecular diameter δ from *Dushman* and *Lafferty* [28.20]

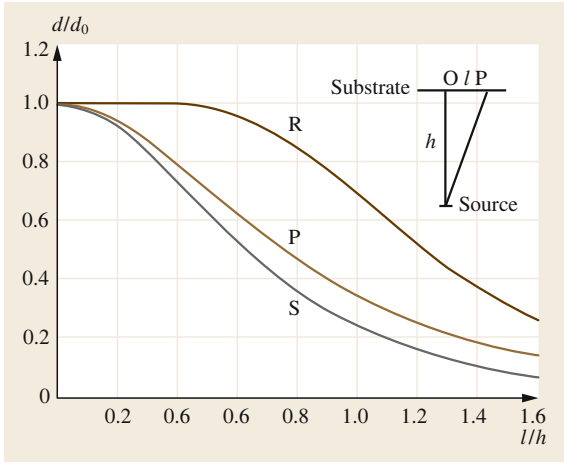

Fig. 28.3 Film thickness profiles calculated for evaporation from various sources onto a flat parallel substrate. Thickness ratio d/d_0 is given as a function of the ratio l/h, as shown in the *inset*. Sources include the small surface source (S), the point source (P) and a thin ring source (R) of radius b, where $b/h = 0.75$. Profiles are calculated, respectively, from (28.11), (28.10) and from an expression given by *Glang* [28.21]

are not significantly dispersed by collisions with gas molecules en route to the substrate, and since the mean free path is relatively insensitive to the molecular diameter, λ is a suitable criterion to determine this. Thus smaller deposition chambers will not require as low a residual gas pressure as larger ones.

The geometry of the evaporation source and its positioning with respect to the substrate is an important consideration in determining the uniformity of a thin-film deposit. Expressions for the film thickness variation over the substrate for various types of source have been derived by *Holland* and *Steckelmacher* [28.28]. Traditionally the *point source* and the small *surface source* are used. It is assumed that the evaporation source, of either type, is located a distance h below the centre of a flat substrate, as shown in the inset to Fig. 28.3. It is obvious that the film thickness deposited directly above the source at the point O will be thicker than elsewhere, since this is the closest point of the source to the substrate. For the case of the point source, molecules are emitted uniformly in all directions, and the ratio of the film thickness d deposited at the point P a distance l from O to the thickness d_0 deposited at O is given by

$$\frac{d}{d_0} = \frac{1}{[1 + (l/h)^2]^{3/2}} \,. \tag{28.10}$$

For a small surface source, the emission follows a cosine law, and the thickness distribution is given by

$$\frac{d}{d_0} = \frac{1}{[1 + (l/h)^2]^2} \,. \tag{28.11}$$

Plots of these two functions are shown on Fig. 28.3 for the point source P and the small surface source S. For both sources, there is a rapid diminution in the thickness ratio d/d_0, which falls off to 0.985 and 0.98 respectively for the point and surface sources at a value of $l/h = 0.1$. When the substrate is relatively small, the thickness uniformity is thus better than 2%. Uniformity can be enhanced, for these two small sources, by increasing the source–substrate distance h, but at the expense of consuming more evaporant material. It has also been shown that a substantially uniform deposit will be obtained for a point source if the source is placed at the centre of a sphere and the substrates placed on the surface. For a surface source a uniform thickness distribution is obtained if both the source and the substrates are placed on the surface of a sphere [28.28].

Other systems for obtaining uniform thickness are based on the use of either extended sources, or substrates rotating around a central axis with respect to an off-centre source, such that variations in the thickness average out. *Holland* and *Steckelmacher* [28.28] have addressed ring sources in addition to strip and cylindrical sources evaporating onto a plane-parallel substrate. The ring source has also been treated by *von Hippel* [28.29] and the small surface source evaporating onto a rotating plane parallel substrate has been discussed by *Macleod* [28.30]. Expressions for ring and large surface sources are given by *Glang* [28.21]. A ring source can be considered to be a narrow ring of radius b, which is usually placed parallel to a flat substrate. This introduces an additional controllable

variable which influences the thickness distribution. Thickness distributions may be obtained by calculating the distribution arising from an element of the ring source and then summing over all elements in the ring. For small b/h the thickness distribution reduces to that of the small surface source. For b/h larger than about unity the uniformity is also poor as the maximum in the distribution moves away from the central axis towards the source radius. However, for intermediate ranges, in particular b/h of about 0.7–0.8 there is considerable uniformity in thickness up to l/h of about 0.6. This is also illustrated in Fig. 28.3, where the curve R shows the thickness distribution for a narrow ring source with $b/h = 0.75$, calculated from the formula given by *Glang* [28.21]. Extended disc source thickness distributions may be obtained by integrating the thickness distribution derived for a narrow ring source from radius zero to radius b, but in general the thickness uniformity is not as good as for ring sources. Expressions for ring source of finite width can be determined by subtracting the disc source distribution for the inner radius from that of the outer radius. Diagrams illustrating the thickness distributions for several sets of ring and disc sources are given by *Glang* [28.21]. *Behrndt* [28.7] gives further details and references for such sources, and a discussion of the results of using combinations of several rod-like sources. Further attempts to minimise thickness variations have resulted in the evolution of various *planetary* deposition systems, so called because the rotating substrate plane is itself rotated around a vertical axis. A typical example of such a system and its performance is given in the literature [28.31].

Before describing the practical details of the evaporation process, it should be mentioned that, whatever type of evaporation process is used, some consideration needs to be given to the substrate. There are three basic types of substrate commonly used: glasses, single crystals and polycrystalline ceramics. Ceramics are particularly useful for high-temperature deposition processes. Although the substrate material may be predetermined (e.g., silicon wafers for microelectronics, optical glass for coatings on lenses, etc.), there are frequently factors which can be selected to increase the probability of obtaining good-quality films. The substrate planarity is important, in order to reduce the effect of defects. Electrical resistivity should in general be high in order to minimise surface leakage currents. Thermal properties include a consideration of the coefficient of expansion, which should be comparable to that of the deposited film to reduce the probability of thermally induced stresses in the films. Thermal conductivity should be high for films whose applications will entail significant power dissipation. A full description of thin-film substrates and the associated problems of substrate cleaning are discussed in detail by *Brown* [28.32].

Resistive evaporation is the most commonly used evaporation technique, although it is unfortunately not suitable for certain applications. It entails the resistive heating of an evaporation source, by passing a high current either through the source itself or through an adjacent heater. There are a large number of practical evaporation sources for various applications which are described in the literature [28.1, 21, 28]. The main requirement for any evaporation source is that the source itself will not emit its own vapour at the operating temperature. If metallic sources are used, the equilibrium vapour pressure of the metal must be negligible in comparison to that of the evaporant. A glance at Fig. 28.1 shows that the refractory metals (such as Pt, Ta and W) have equilibrium vapour pressures very low compared to about 1 Pa at temperatures up to about 2000 K, and are therefore suitable for evaporation of many materials. Carbon and oxides of aluminum or magnesium may also be used in evaporation, although owing to their low electrical conductivity refractory metal heaters are often used in conjunction with these. However, at elevated temperatures the oxides themselves may dissociate, with the liberated oxygen reacting with the evaporant to form its own oxide. For this reason the refractory metals cannot themselves be evaporated from oxide crucibles. Furthermore carbon may react with metals to form carbides well below 2000 K. Having chosen a suitable evaporation source, the vacuum deposition chamber is pumped down to the required background pressure and deposition may commence. The temperature of the source is increased such that the vapour pressure increases to a value consistent with a reasonable evaporation and hence deposition rate. The substrate is normally shielded using a metallic shutter until the required deposition rate is established, when the shutter is removed. The deposition rate is usually monitored by one of several methods [28.7, 21]. The quartz crystal method entails depositing the evaporant material on a vibrating quartz crystal, whose frequency varies linearly with the thickness of material deposited [28.33, 34]; the deposition rate is obtained by electronically differentiating the thickness signal with respect to time. Optical thickness monitoring methods are also used, particularly in applications where films are required for optical purposes, and require films having an optical thickness of multiples of $\lambda/4$, where λ is the wavelength for which the optical film is designed [28.7, 21]. These thickness multiples correspond to maxima and minima in reflected light intensity, which can easily be monitored during deposition. When the required film thickness is attained, a shutter is again used to

curtail further film deposition and the evaporation process is stopped. Sequences of several film layers may be deposited by using a suitable sequential masking system [28.35].

Apart from simple vacuum evaporation there are also several other types of evaporation, which entail using alternative methods to heat the evaporant, or cater for various problems encountered in the deposition of alloys and compounds. In electron-beam evaporation the evaporant material is placed in a ceramic hearth, which is bombarded by high-energy electrons The main advantage of this method is that considerably higher temperatures of above 3000 K may be obtained than with resistive evaporation methods. This allows evaporation of the refractory metals and also elements such as boron and carbon (which sublimes). Other advantages are the evaporation of reactive metals such as Al, which are prone to contamination due to alloying, and situations where high purity is required.

For non-elemental (multicomponent) films there are several methods which may be employed. The main problem with such films is that, because of differences between the vapour pressures of the evaporant components, the Hertz–Knudsen expression of (28.5) predicts that the compound will evaporate noncongruently, i. e., with different evaporation rates for each element, and the deposited film will not in general replicate the composition of the evaporant. The problem is compounded because the proportion of each component present will therefore vary throughout the evaporation process, and the overall composition of the deposited films will vary throughout its thickness. In the evaporation of alloys, each component establishes its own vapour pressure at a given temperature, which may be predicted by *Raoult's law* for an ideal solution. This states that the vapour pressure established by each individual component is proportional to the mole fraction of the component present. Under these circumstances it is relatively simple to adjust the proportions of the alloy components to achieve the required film composition. However, complications occur in nonideal solutions, where the interactions between different types of atoms vary and an empirical parameter known as the activity coefficient, a, is defined. Knowing this it is possible to determine the vapour pressure for the component and hence the evaporation and deposition rates. Activity coefficients for various important systems, such as nichrome (a Ni-Cr alloy), are given in the literature [28.36]. However, as noted previously the mole fractions present in the evaporant are time-dependent and the composition of the films will vary during deposition. A parameter K has been determined, which if maintained close to unity should result in congruent evaporation throughout the entire deposition process. Further details are given by *Zinsmeister* [28.37]. Additional comments on the evaporation of both nichrome and permalloy alloys are given by *Glang* [28.21].

On evaporation of compounds, a wealth of chemical reactions can occur, which leads to a variety of different evaporation mechanisms. Frequently more than one reaction may operate simultaneously. Four simple generic reactions have been listed by *Glang* [28.21], which include many of the materials which can be successfully evaporated. We consider only compounds AB composed of the elements A and B, and denote the phase of the material by s (solid), l (liquid) or g (gas). Some compounds (solids or liquids) do not dissociate on evaporation and the reaction can be expressed simply as

$$\mathrm{AB(s,l)} \rightarrow \mathrm{AB(g)}\,. \tag{28.12}$$

There is then only the single vapour phase AB(g) produced. Other compounds dissociate on evaporation into two different vapour species. One reaction which is typical of the evaporation of chalcogenides and some simple oxides is given by

$$\mathrm{AB(s)} \rightarrow \mathrm{A(g)} + \frac{1}{2}\mathrm{B_2(g)} \tag{28.13}$$

whereas the group IV dioxides tend to dissociate according to the reaction

$$\mathrm{AB_2(s)} \rightarrow \mathrm{AB(g)} + \frac{1}{2}\mathrm{B_2(g)}\,. \tag{28.14}$$

In compounds of elements whose volatilities are significantly different, frequently one element enters the vapour phase while the other remains in the solid (or possibly liquid) phase. The compound decomposes into its different elements, with the simplest reaction of this type being

$$\mathrm{AB(s)} \rightarrow \mathrm{A(s)} + \frac{1}{2}\mathrm{B_2(g)}\,. \tag{28.15}$$

Examples of materials evaporating without dissociation following (28.12) are the simple oxides GeO, SiO, SnO, the fluorides CaF_2 and MgF_2, and PbS. In general the evaporation of these materials can therefore be considered as analogous to those of the elements, and where available simple p^*–T data give the vapour pressure. Materials which follow (28.13) are primarily the II–VI chalcogenides, in particular the cadmium compounds CdS, CdSe and CdTe, and several simple oxides such as BaO, BeO, CaO, MgO, NiO and SrO. A full review of the electrical and structural properties of the cadmium chalcogenides is given by *Gould* [28.38].

Equation (28.14) is followed by many of the group IV dioxides, such as SiO_2, SnO_2, TiO_2 and ZrO_2, which dissociate into their lower oxides and molecular oxygen. Decomposition, as described by (28.15) is followed by most of the metallic borides, carbides and nitrides [28.21]. Other modes of decomposition, such as those for the technologically important III–V compounds, are also described in this reference.

Provided the relevant reaction for the evaporation process is known (e.g., as given by (28.12)–(28.15)) it is possible to determine the equilibrium vapour pressure using standard thermodynamic tables. The law of mass action may be used to determine the equilibrium state of the chemical reaction, and for evaporation, the pressures of the various phases present contribute to a temperature-dependent equilibrium constant K_p, which is given by

$$K_\mathrm{p} = \prod_i (P_i)^{\nu_\mathrm{i}} \qquad (28.16)$$

where P_i represents the vapour pressure for each of the various components of the vapour expressed in standard atmospheres and the ν_i are the molecular coefficients. K_p is related to the thermodynamic parameter ΔG^0, the standard change in Gibbs free energy per mole for the reaction, by the expression

$$\Delta G^0 = -RT \ln K_\mathrm{p} \,, \qquad (28.17)$$

where R is the universal gas constant. Free-energy data is tabulated for many materials in the literature [28.22, 39] and the use of (28.16) and (28.17) allows realistic estimates of the equilibrium vapour pressures to be determined and the evaporation rates estimated. Further discussions are given by *Glang* [28.21]. Nevertheless, although the theoretical framework is in place for the controlled evaporation of compounds, the exact type of dissociation and decomposition are not known in all cases, and for compounds consisting of three or more elements this problem is compounded. Some materials are therefore not amenable to direct evaporation from a single source.

For these cases various special evaporation techniques have been developed, all of which aim to replicate the composition of the evaporant in the deposited film, by ensuring that the different molecules arrive at the substrate in the desired proportions and at a constant rate. Reactive evaporation is a process whereby one component of the desired film is evaporated resistively in the normal manner, while the other component is present in the evaporation chamber in the form of a gas. This method is most commonly used where oxide films are required and oxygen gas present in the chamber combines with a metal at the substrate to form the oxide. The impingement ratio K, given by (28.7) is optimised so that evaporant and gas molecules reach the substrate in a predetermined ratio. Oxides of the common metals have been deposited by this method, including those of Al, Cr, Cu and Fe; additionally tantalum and titanium oxides have been prepared for dielectric applications. Reactive evaporation has also been used for compounds other than oxides. For instance, stoichiometric CdS films have been obtained by the evaporation of CdS in a sulphur vapour [28.40]. The sulphur vapour has the effect of discouraging the appearance of nonstoichiometric Cd-rich films which occur when CdS is evaporated alone. Nitrides may also be deposited in some cases by the use of a nitrogen atmosphere. The utility of this technique has been demonstrated in the reactive evaporation of silicon oxide, SiO_x, by *Timson* and *Hogarth* [28.41]. The evaporant is a mixture of the monoxide, the dioxide and possibly also free silicon. A sequence of films, varying in composition between SiO and SiO_2 as determined by electron spin resonance studies were obtained, depending on the ratio of the deposition rate to the oxygen pressure R/p. A useful nomogram for use in reactive evaporation is given by *Glang* [28.21].

Co-evaporation, sometimes known as the three-temperature technique, involves the simultaneous evaporation of two or more materials from separate evaporation sources. The essential feature of this process is that the rate of molecular arrival at the substrate may be controlled by individually controlling the temperatures of the evaporation sources. A major advantage of this method is that materials with widely different vapour pressures at a given temperature may be co-deposited by increasing the temperature of the less-volatile material. This method has found applications in the deposition of II–VI compounds such as CdS and CdSe, and also the III–V compounds such as AlSb, GaAs, InAs and InSb. It is also used for the deposition of alloy films.

Flash evaporation is another technique used for deposition of layers whose components have widely different vapour pressures. The evaporation is constrained so that only very small amounts of the compound completely vaporise almost instantaneously. The various components normally evaporate noncongruently, but because only very small quantities are evaporated rapidly, any inhomogeneity in the deposited films is limited to a few atomic layers. The process is repeated by evaporating further small quantities of evaporant. Several alternative arrangements have been developed to evaporate small particles, by continuously feeding powdered evaporant from a hopper into a heated evaporation source. The rate of delivery needs to be

controlled such that at any given time there will be a number of evaporant particles in the source at various stages of the evaporation process. This ensures that the vapour emerging from the source contains contributions from many individual particles, resulting in an overall vapour composition which approximates to that of the evaporant powder. The method has been used particularly for III–V compound semiconductors such as GaAs.

Finally, the method of molecular-beam epitaxy (MBE) should be included here as a particularly sophisticated example of evaporation (or co-evaporation). In MBE the background pressure is considerably lower than in the case of the simpler evaporation techniques, i. e., well into the UHV range. This effectively eliminates the effects of background gas impingement, drastically improving the purity of the films. Several sources (effusion ovens) may be used simultaneously, each of which is separately controlled. These permit the deposition of compounds and precisely controlled doping of semiconductors. Sophisticated monitoring and isolation techniques are employed, and deposition sequences are usually under computer control. MBE is used particularly for the preparation of III–V compounds [28.42, 43] and silicon [28.44]. Figure 28.4 illustrates a typical MBE system for use in the deposition of III–V compounds [28.42]. A full description of MBE, together with other epitaxial growth techniques is given elsewhere in this volume in Chap. 14.

Sputtering

The technique of sputtering in its various forms is of secondary importance only to evaporation for the deposition of thin films, offering certain advantages for the deposition of high-melting-point and dielectric materials. Sputtering is essentially the removal of particles from the surface of a *target* of the deposition material, by the action of incident energetic particles (normally positive ions). It is generally considered that the sputtering mechanism is the result of the transfer of momentum from the incident particles to the target atoms, some of which become dislodged. Energy acquired by other atoms interacting with the dislodged atoms can be sufficient to overcome the surface binding energy potential barrier. The net effect of a large number of atomic interactions is for a certain proportion of the target to be released (or sputtered) from the surface. Sputtered atoms typically have energies much higher than their evaporated counterparts. For low-energy sputtering with incident energy 1 keV, an ejected particle may have an energy of 10 eV, since typically 1% of the incident energy is transferred to each sputtered atom. In contrast, the thermal ($k_B T$) energy of an atom evaporated from a source at 2000 K is less than 0.2 eV. Such considerations have implications regarding the sticking coefficients for deposited materials (i. e., the probability that an atom reaching the substrate condenses on it), which is generally higher for higher-energy atoms.

Sputtering is limited by a threshold energy, below which it will not occur for a given ion/target combination. Threshold energies for a wide range of incident ions and target materials are of the order of 20–30 eV; experimental values for some common ion/target combinations are given by *Wehner* and *Anderson* [28.45]. These workers have pointed out that the threshold energy appears to be approximately four times the latent heat of sublimation per atom, equivalent to the surface

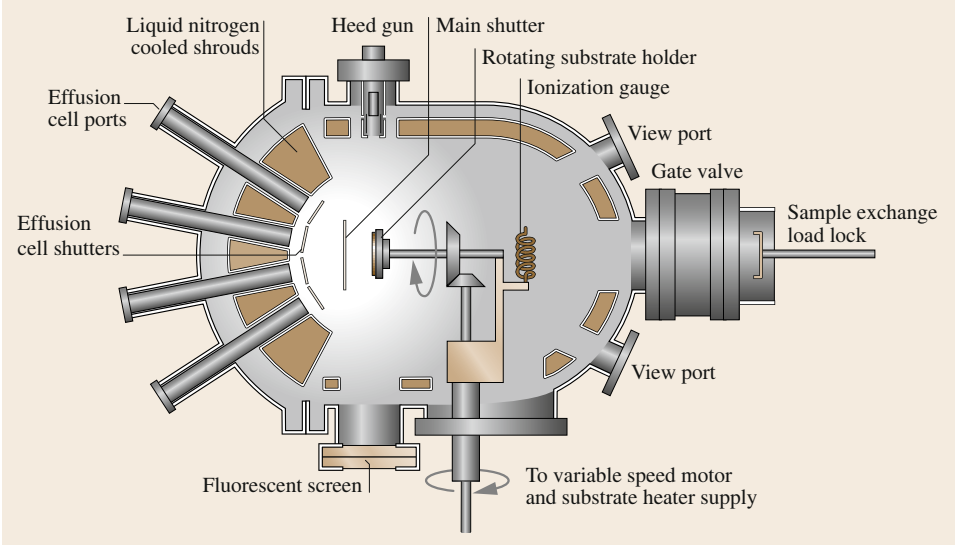

Fig. 28.4 Schematic diagram of a molecular-beam epitaxy (MBE) system for the deposition of III–V semiconductor compounds. (After [28.42] with permission from Elsevier Science)

binding energy. However, for practical sputtering considerations, incident energies are normally at least a few hundred electronvolts, well above the threshold energy. The efficiency of sputtering, measured by the sputtering yield, is also very low at low incident ion energies.

The sputtering yield is the most important sputtering parameter, and its variation with the target material and the incident ion energies is of major concern in both theories of sputtering and in practical sputtering deposition techniques. Sputtering yield $S(E)$ is defined as the ratio of the number of sputtered atoms to the number of incident ions. Hence

$$S(E) = \frac{N_s}{N_{ion}} , \tag{28.18}$$

where N_{ion} is the impingement rate of incident ions and N_s is the sputtering rate of the target. Its primary variation is with the incident ion energy E. However, it also depends on the atomic properties of the incident ions and the target atoms. In the following discussion Z_1 and m_1 refer to the atomic number and mass of the incident ions, and Z_2 and m_2 refer to the corresponding quantities for the target material. The dependence of sputtering yield on the atomic number of the incident ions is quite striking, as shown in Fig. 28.5 [28.46]. This shows the variations of $S(E)$ for 45 keV incident ions onto targets of silver, copper and tantalum. Maxima in $S(E)$ occur corresponding to the noble gases Ne, Ar, Kr, and Xe. This dependence is one reason why the noble gases are most commonly used as the incident ion species, the second being that their inclusion into deposited films is unlikely to cause significant problems, due to their chemically inactive nature.

A number of theories have been developed to predict the dependence of sputtering yield $S(E)$ on the incident beam energy E. *Keywell* [28.47] assumed that the incident ions interacted with the sputtering target as if they were hard spheres, with the incident ion energy decreasing exponentially with the number of collisions. A discussion of this and other early models is given in the literature [28.45, 48]. More recent models [28.49, 50] have taken account of the scattering of incident ions by the atomic nucleus, and screening effects due to the electron cloud are also included, based on the Thomas–Fermi potential. This predicts a characteristic screening length a, which depends on the atomic numbers of the incident and target atoms, Z_1 and Z_2, respectively. The screening length is given by

$$a = \frac{a_0}{\left(Z_1^{2/3} + Z_2^{2/3}\right)^{1/2}} , \tag{28.19}$$

where $a_0 = 5.29 \times 10^{-11}$ m is the Bohr radius of the ground state of the hydrogen atom. Another parameter which is often invoked in sputtering models is the energy transfer coefficient, γ. For an incident ion of

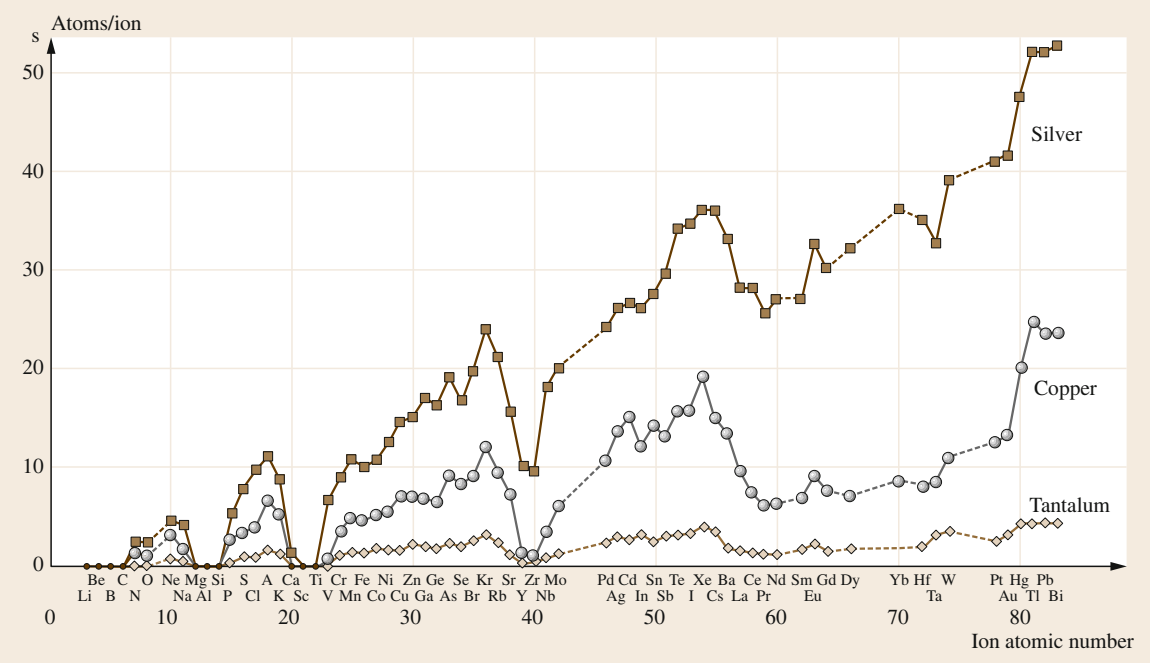

Fig. 28.5 Sputtering ratios of silver, copper and tantalum targets for different ions of energy 45 keV. (After [28.46] with permission from Elsevier Science)

mass m_1 and energy E, impacting on a stationary target atom of mass m_2, the maximum energy E_{max} the target atom will attain is given by

$$E_{max} = \gamma E \,, \tag{28.20}$$

where

$$\gamma = \frac{4m_1m_2}{(m_1+m_2)^2} \,. \tag{28.21}$$

In most collisions the incident ion will lose some energy to the target lattice, resulting in the acquisition of an energy less than E_{max} by the target atom. γ has a maximum value of unity for $m_1 = m_2$, but this is neither a sufficient nor a practical condition for obtaining high sputtering yields owing to the impracticability of having identical sputtering ions and target material as well as the striking periodic dependence of $S(E)$ on Z_1 noted earlier. Two well-known sputtering models are now outlined, both of which have been reasonably successful in predicting sputtering yields.

In the model of *Pease* [28.49], which is also outlined elsewhere in the literature [28.51], ions are considered to interact with the target atoms near to the surface, which if displaced from their lattice sites are termed *primary knock-ons*. The mean energy of primary knock-ons before further interactions is denoted by $\overline{E}$. The threshold energy for displacement of a target atom, either by an incident ion or by a primary knock-on is denoted by E_d. Collisions with stationary atoms result in slowing down of displaced atoms, and in some cases a reversal of momentum and escape from the target surface, providing they still retain energy greater than E_s, the surface binding energy per atom. The number of atomic layers which contribute to the sputtering process is established by considering the average number of collisions n that a primary knock-on of energy $\overline{E}$ will make before its kinetic energy is reduced to less than that required to leave the target surface, i.e E_s. This is given by $2^n = \overline{E}/E_s$ or

$$n = \frac{\ln(\overline{E}/E_s)}{\ln 2} \,. \tag{28.22}$$

While engaged in n collisions the primary knock-ons diffuse on average $n^{1/2}$ atomic layers toward the surface, and thus $(1+n^{1/2})$ layers are involved in sputtering of material liberated by primary knock-ons only. The total number of atomic layers involved in sputtering is also equal to this expression. We also have to consider the probability of interaction in a given atomic layer, and denote the number of atoms per unit volume in the target by N. If these atoms are considered to be arranged in uniform crystallographic layers in three dimensions, the atoms in each layer will have an area density of $N^{2/3}$. If σ_p denotes the cross section for interaction between incident ions and target atoms, the probability of interaction in a given atomic layer is given by the product of the number of atoms per unit area and their interaction cross sections, or $\sigma_p N^{2/3}$. The total probability of producing a primary knock-on which can contribute to the sputtering process is then given by the product of the probability of interaction in a given atomic layer and the number of layers involved in sputtering, i.e., $\sigma_p N^{2/3}(1+n^{1/2})$. An estimate of the number of atoms displaced per primary knock-on is $\overline{E}/(2E_d)$ [28.52] of which half, or $\overline{E}/(4E_d)$, will be directed towards the surface. The total sputtering yield $S(E)$ is then given by the product of the probability of producing primary knock-ons and the number of displaced atoms produced by each. Hence

$$S(E) = \sigma_p \overline{E} N^{2/3} \frac{1}{4E_d} \left[1 + \left(\frac{\ln(E/E_s)}{\ln 2}\right)^{2/3}\right] \tag{28.23}$$

where the expression for n in (28.22) has been substituted.

In (28.23) for the sputtering yield, N, E_d and E_s are constants depending on the target material and E_d is normally determined from radiation damage experiments. However, σ_p and $\overline{E}$ are energy-dependent variables, which depend on the atomic numbers Z_1 and Z_2, the Thomas–Fermi screening length a, and the maximum target-atom energy E_{max}. It is not appropriate to give these expressions here, but it is worth mentioning that different expressions are applicable in different incident ion energy ranges, defined by $E < L_A$, $L_A < E < L_B$, and $L_B < E$. Further details concerning the threshold energies L_A and L_B are given in [28.49, 51]. Calculations of sputtering yield predicted by this model are reasonably consistent with experiment, showing a sharp increase above a certain threshold energy which is determined by E_s, a broad maximum and a relatively slow decrease at higher energies [28.49].

The model of *Sigmund* [28.50] represents a comprehensive theory of sputtering, particularly for single-element solids, although this has led to a certain degree of complexity in its general form. The model has been revised and extended [28.48] and tested against a considerable amount of data produced by many different workers [28.53]. The emphasis in this section is to briefly outline the model, to provide a basis for the calculation of $S(E)$ at normal incidence for low- and high-energy sputtering, and to give useful references to the required data. Various approximations made and some of the conditions of validity are omitted. Being

a multiple-collision process, sputtering may be treated by using the formalism of transport theory, and in the Sigmund model the Boltzmann transport equation is solved. The sputtering yield at normal incidence is given by

$$S(E) = \Lambda\alpha N S_n(E) \,, \tag{28.24}$$

where Λ is termed the material factor, and depends only on the target material. α is a dimensionless factor, effectively depending only on the ratio of the target atom to incident ion masses m_2/m_1. The factor α is given for various different conditions in the literature [28.48, 50]. As in the model of *Pease* [28.49], N represents the number of atoms per unit volume in the target. $S_n(E)$ is the nuclear scattering cross section, depending on the interaction probability between the incident ions and the target atoms at a given energy.

The material factor Λ arises in the sputtering yield expression as a result of integrating the number of sputtered atoms emitted in all directions with all possible energies. According to Sigmund, the material factor

$$\Lambda = \frac{3}{4\pi^2}\frac{1}{NC_0E_s} \,, \tag{28.25}$$

where $C_0 = \frac{1}{2}\pi\lambda_0 a_{BM}^2$, λ_0 is a constant approximately equal to 24, and $a_{BM} = 2.19\times10^{-11}$ m is the Born–Meyer potential characteristic screening radius. E_s represents the surface barrier energy, as in the model of Pease. Making these substitutions into (28.24) gives a more useful formula for the sputtering yield [28.45] as

$$S(E) = \frac{1}{16}\frac{\alpha S_n(E)}{\pi^3 a_{BM}^2 E_s} \tag{28.26}$$

which applies both for low- and high-energy sputtering. An expression for E^*, the boundary between low-energy and high-energy sputtering, is given in the literature [28.50], and is typically a few hundred electronvolts, depending on the atomic masses and atomic numbers of the incident ions and the target atoms. For low-energy sputtering ($E < E^*$) the nuclear scattering cross section can be approximated by

$$S_n(E) = C_0E_{max} = \tfrac{1}{2}\pi\lambda_0 a_{BM}^2 E_{max} \,, \tag{28.27}$$

where $E_{max} = \gamma E$ from (28.20). Substituting into (28.26) yields

$$S(E) = \frac{3}{4}\frac{\alpha\gamma E}{\pi^2 E_s} \,. \tag{28.28}$$

Hence for low-energy sputtering $S(E)$ is directly proportional to the sputtering energy, where α and γ effectively depend only on the ratio m_2/m_1 and E_s is a constant for the target material.

For higher incident ion energies ($E > E^*$) the Thomas–Fermi, rather than the Born–Mayer interaction potential is applicable, and a simple approximation for $S_n(E)$ is not available. It is therefore necessary to determine its value from tables or graphical data, calculating $S(E)$ directly from (28.26). Incident ion energies E and nuclear scattering cross sections $S_n(E)$ may be expressed in terms of reduced or Thomas–Fermi variables ε and $s_n(\varepsilon)$ [28.48, 50]. $s_n(\varepsilon)$ is a universal function of ε, depending on the details of the screened Coulomb function used [28.48]. The detailed dependence of $s_n(\varepsilon)$ on ε utilised in the Sigmund model is that given by *Lindhard* et al. [28.54]. For ease of computation E_{TF}, the Thomas–Fermi energy unit has been calculated for various incident ion/target combinations [28.48]. E_{TF} represents the ratio E/ε, and thus ε and hence $s_n(\varepsilon)$ may be obtained. $S_n(E)$ may then be determined from the reduced value.

Agreement between predicted and measured sputtering yields as a function of incident ion energy are good. *Andersen* and *Bay* [28.53] have reviewed sputtering yield measurements at normal incidence for a considerable number of incident ion and target species, and generally concluded that sputtering yields for high-yield materials (e.g., Ag, Au, Cu, Zn) are predicted well by the theory, while for low-yield materials (e.g., Nb, Ta, Ti, W) it was over-estimated by a factor of up to three. A fuller discussion, to which the reader is referred, shows that the model breaks down for certain combinations of Z_1, Z_2 and E due to the existence of inelastic collisions, nonisotropic and nonlinear effects (spikes) in the collision cascade and unallowed-for surface effects. The regions of validity of the model are neatly presented in terms of a three-dimensional (Z_1, Z_2, E) space, and illustrate the fact that (28.26) is an amazingly good prediction for a large number of (Z_1, Z_2, E) combinations of practical interest.

Sputtering yields may be determined experimentally by measuring the decrease in mass of a sputtering target. Normally such experiments are performed using ion-beam sputtering, in a fairly high-vacuum environment. The target area bombarded by the beam is small, and fairly low sputtering rates are achieved, but it has the advantage that ion energies are accurately given by the accelerating potential. The methods of sputtering normally used for the preparation of thin films are based on the establishment of a population of positive ions in a low-pressure gaseous environment. Such techniques depend on the establishment of a glow discharge, and require a considerably higher operating pressure, whereas ion-beam sputtering does not require the presence of gas molecules in the deposition cham-

ber, and can therefore be used under UHV conditions, where gaseous contamination effects are minimised. A complicating factor, which often has to be taken into account, is that some incident ions may become embedded in the target, thus tending to increase its mass. The net loss of material from the target Δm is then the difference between the mass of material sputtered and the mass gain of the target. If N_{ion} and N_{s} are the incident ion impingement rate and the atomic sputtering rate of the target respectively (28.18), and m_1 and m_2 are the incident ion and target atom masses, it is simple to calculate the mass loss and increase of a given target with bombarded area A sputtered for a time t. The loss of mass is given by $N_{\text{s}} m_2 A t$, and the increase in mass is given by $N_{\text{ion}} \Gamma m_1 A t$, where Γ is the probability that an incident ion becomes embedded in the target. Hence

$$\Delta m = N_{\text{s}} m_2 A t - N_{\text{ion}} \Gamma m_1 A t \qquad (28.29)$$

or

$$S(E) = \frac{N_{\text{s}}}{N_{\text{ion}}} = \frac{\Delta m}{m_2 N_{\text{ion}} A t} + \Gamma \frac{m_1}{m_2} \,. \qquad (28.30)$$

Frequently the second term on the right-hand side of this equation is negligible, and the sputtering yield is then given by the first term only. This is particularly applicable for large ion doses, while for intermediate doses a detailed empirical knowledge of the value of Γ is required. For low ion doses the approximation $\Gamma = 1 - R_0$, where R_0 is an ion reflection coefficient, may be used [28.53]. It is often useful to express the sputtering yield in terms of the ion current at the cathode $I_{\text{c}} = e N_{\text{ion}} A$, where e is the electronic charge and the sputtering yield is then given by [28.1]

$$S(E) \approx \frac{e \Delta m}{m_2 I_{\text{c}} t} \,. \qquad (28.31)$$

Measurements of the ion current, target mass loss and the sputtering time are then all that are necessary to calculate $S(E)$. Although strictly speaking the above expressions are only applicable for sputtering performed with ions of a single energy, they may also be applied to a first approximation for practical sputtering methods using the glow discharge.

Although ion-beam sputtering is a very useful technique for measuring sputtering yields and comparing with theoretical predictions, it is not normally used for routine film deposition, owing to the need for UHV conditions, the low sputtering rate obtained and the associated expense. Virtually all sputtering methods used for the deposition of thin films utilise the glow discharge phenomenon. When a gas at reduced pressure is subjected to an applied voltage, usually in the range of a few hundred to several kilovolts, any free electrons will be accelerated in the field, acquiring energy and ionising the gas molecules to produce a plasma. Under the influence of the field the positively ionised gas molecules are accelerated towards the cathode and free electrons towards the anode. The gas pressure required for the establishment of such a discharge is of the order of a few pascals, which in turn is determined by the molecular concentration required to maintain the mean free path within suitable limits to initiate and sustain the discharge. The basic principles of the glow discharge are well known and documented [28.55, 56] and need not concern us here. However, it should be noted that the positive ions tend to accumulate in front of the cathode (the cathode-fall region), across which most of the applied voltage is dropped. Thus the electric field between the cathode and the anode is distinctly nonlinear, and most of the energy acquired by the ions in their journey to the cathode is obtained in the cathode-fall region.

It is relatively simple to set up a self-sustained glow discharge, although the behaviour of the discharge depends in a fairly complex manner on the pressure, the applied voltage and the geometry of the system. Inert gases such as argon are generally used, unless the sputtered film relies on a reaction between the sputtering gas and the sputtered material to produce the required compound film. Once the discharge is established, the cathode is continuously bombarded by energetic ions, and provided the energy of these ions is sufficient, sputtering of the cathode will occur. Thus if the target is sufficiently conductive, all that is necessary is to make the cathode of the target material. Substrates on which deposition will occur are normally placed parallel to the target at the anode so that the sputtered atoms need only cover a short distance before deposition. The energy of the sputtered atoms when they reach the substrate is considerably higher than in the case of evaporation, leading to better adhesion. Furthermore, sputtered compounds are normally deposited without dissociation, and therefore the stoichiometry of the target material is usually preserved in the deposited film. This basic form of sputtering is normally termed *diode sputtering*, since only two electrical connections are required.

Basic diode sputtering operates reasonably satisfactorily, but has a major disadvantage in that the sputtering rate N_{s} depends directly on the impingement rate of the incident ions N_{ion} and thus also on the discharge current. At low gas pressures the supply of ions is limited and thus the discharge current and the sputtering rate are low. Moreover, at sufficiently low pressures the electrons do not ionise a sufficient number of gas atoms to sustain the glow discharge. This low-pressure limit is in fact a major drawback in diode sputter-

ing, since enforced operation at higher pressures above about 3 Pa results in significant film contamination. For this reason sputtering was for many years rejected in favour of evaporation for thin-film deposition. A major improvement in sputtering technology, which enabled sputtering to be performed at lower pressures was the introduction of *triode sputtering*. In this technique, the discharge is maintained by using an additional source of electrons, so that it is not totally dependent on secondary electron emission from the cathode. Electrons are supplied by an additional thermionic emitter, consisting of a filament through which a current is passed. The electron concentration in the plasma can be readily controlled by varying the anode potential or the filament current, while the ion current is directly controlled by the target potential. A further innovation usually employed in triode sputtering systems is the use of a coil to set up a magnetic field, which forces electrons from the emitter to travel in spiral paths, thus greatly increasing the distance travelled from the emitter before they are collected by the anode. This enhances the ionisation probability α, and thus the supply of positive ions.

It should be emphasised that both diode and triode sputtering may not be used for the sputtering of insulators – a very important class of materials. Since positive ions are responsible for the sputtering process, these need to be neutralised by electrons from the external circuit. In the case of insulators a positive charge builds up at the surface of the target, and this charge cannot leak away through the insulator. Sputtering ceases when the positive charge causes the potential at the target surface to approach that of the plasma. Various methods, such as bombarding the target surface with electrons, have been attempted to solve this problem, but in general with little success. Glow discharge sputtering of insulators is generally therefore performed reactively, or with alternating radio-frequency (RF) fields, as described later.

As with evaporated films, there are a number of problems associated with the deposition of alloys and compounds. The best theories of sputtering yields are typically inaccurate by a factor of two or so. Empirical determinations are normally required for films of controlled composition to be deposited. Nevertheless, sputtering of multicomponent or compound targets is frequently all that is necessary to obtain films varying only marginally from the target composition. *Maissel* [28.57] suggests that during the initial sputtering run an *altered region* is formed on the surface of the target, which is deficient in the target component having the highest sputtering yield. Thus although stoichiometric films will not normally be deposited during the initial sputtering run, such films may generally be deposited during subsequent runs, since the deficiency in the higher sputtering rate material compensates for its greater removal rate [28.51, 57]. Minor differences between the compositions of the film and target do still occur, but are normally the result of oxidation or of the evaporation of one component at high temperatures. When compounds are sputtered the incident ion energies are often sufficient to break the chemical bonds, again leading to a deficiency in one component. *Reactive sputtering* and *co-sputtering* are specifically designed to give greater flexibility during the deposition of multicomponent films.

Reactive sputtering involves the sputtering of a target using a sputtering gas which is amenable to chemical combination with the target material. The gas used may be either solely the reactive species, or a mixture of the reactive species and an inert sputtering gas, such as argon. Clearly the process is suitable for preparation of certain insulators which cannot be prepared by the previously mentioned sputtering techniques. Deposition rate depends primarily on the target sputtering yield, through the energy of the incident sputtering ions, the gas pressure and the distance between the target and the substrate. For example, *Perny* et al. [28.58] have concluded that the deposition rate is primarily determined by a reduced electric field E^*, given by E/p, where E is the mean electric field between the cathode and the anode, and p is the gas pressure. When a copper target was sputtered in a mixture of oxygen and argon, either Cu_2O, CuO or Cu were deposited depending on the value of E^* and the oxygen concentration [28.59]. Reactive sputtering has been used mainly to deposit oxide films which have insulating or semiconducting properties. Among the common oxides that have been studied are those of aluminium, cadmium, copper, iron, silicon, tantalum, tin and titanium. Oxides of niobium, thorium, vanadium and zirconium have also been investigated, as have the rare-earth oxides of hafnium, lanthanum and yttrium. The other major non-oxide compounds which have been investigated are the nitrides, with silicon nitride, Si_3N_4, receiving most attention due to its utility both as an insulator and in variants of the silicon planar process for integrated-circuit fabrication. This material has been prepared using a Si_3N_4 target and a mixture of argon and nitrogen as the sputtering gas [28.60]. Carbides and sulphides have also been sputtered reactively. In all cases it is imperative that the stoichiometry of the deposited films is determined using the normal chemical techniques, and the deposition parameters adjusted until the required composition is attained. A very useful review of reactive sputtering, covering both the mechanisms and the primary reactive sputtering techniques, has been given by *Westwood* [28.61].

Co-sputtering has certain advantages from the point of view of the preparation of films whose components

have different sputtering yields. Segregation of components on cooling can lead to a nonstoichiometric composition of material in the target, and differences in sticking coefficients between components can lead to the deposited composition differing from that arriving at the substrate. Co-sputtering has the advantage that the proportion of each sputtered components may be controlled during deposition, and may readily be adjusted in response to varying conditions to ensure stoichiometry of the deposited film. Co-sputtering may be performed with two or more conventional sputtering targets operating simultaneously for each component, each directed towards a common substrate. Another method of co-sputtering is again to use conventional targets, but with the substrate alternately subjected to the sputtered material from each target. This may be achieved by mounting the substrate on a disc which rotates in front of the targets. Alternatively a specially designed target assembly may be used such that the components arrive at the substrate in their stoichiometric proportions; the potentials of the components may be independently controlled to compensate for differing sputtering yields and sticking coefficients. Generally a plane-parallel substrate arrangement, with the target large in comparison to the target–substrate distance is employed, which maximises the uniformity of the film thickness. *Sinclair* and *Peters* [28.62] have described some target-electrode assemblies which have proven suitable for co-sputtering, including a concentric ring and disc assembly and an interdigitated design. Each of these allows independent control of the voltage applied to the two parts of the electrode assemblies and thus control over the composition of the sputtered films. Although the spatial dependence of the electric field in such assemblies is complex, and the deposition rate of one component may be influenced by the potential applied to the electrode for the other component, it is relatively straightforward to calibrate such a source for different materials, and to compensate for such effects by varying the acceleration potentials accordingly.

It is clear that, in general, impurities present in the gaseous phase may be incorporated into the deposited films. The fraction f_i of the impurity species i trapped within a film is given by [28.57]

$$f_i = \frac{s_i N_\mathrm{i}}{s_i N_\mathrm{i} + N_\mathrm{R}} \qquad (28.32)$$

where s_i and N_i ($\mathrm{m}^{-2}\,\mathrm{s}^{-1}$) are respectively the sticking coefficient and impingement rate of the impurity species and N_R is the molecular deposition rate of the required film material; f_i can be reduced by increasing N_R, or by decreasing either or both of s_i or N_i. In *bias sputtering* the phenomenon of re-sputtering is employed, i. e., components of the sputtered film are re-sputtered by ions from the plasma. This is achieved by applying an additional small negative potential to the substrate. Preferential sputtering of the impurities takes place, providing the binding energy of the impurities is lower than that of the host film material. This leads to an effective reduction in f_i, below that predicted by (28.32) [28.63]. The value of s_i in the expression is effectively reduced by re-sputtering of impurities from the film surface. *Asymmetric alternating current (AC) sputtering* [28.64] achieves similar objectives to bias sputtering, i. e., bombardment of the cathode target by ions to cause sputtering and bombardment of the films by lower-energy ions to preferentially re-sputter the impurities. These are accomplished by establishing an alternating current between the substrate and cathode and the use of a simple diode-resistance network. During the negative half-cycle the full negative potential is applied to the cathode, allowing sputtering to take place. In the following positive half-cycle, a relatively small positive potential (limited by the resistance) is applied to the cathode. This allows low-voltage sputtering of the films, which is sufficient to remove only the gaseous impurities. In this technique, again the value of s_i is effectively reduced, leading to a decrease in f_i. In *getter sputtering*, the gettering action of a freshly deposited thin film is utilised to purge the chamber of unwanted active gases. The concentration of impurities in thin films has been observed to decrease as the film thickness increases, and is attributed to the trapping (or gettering) action of the film material. In getter sputtering systems this action is exploited so that the majority of impurities are trapped in a film region deposited between the gas entry point and the substrates, while the required film is deposited elsewhere in the chamber where the gas impurity concentration will already have been depleted by the gettering action. The design of a typical getter sputtering system is described by *Theuerer* and *Hauser* [28.65]. In the case of getter sputtering, N_i is effectively reduced in (28.32), lowering the value of f_i.

Trapping of inert gas molecules in the films is also a possibility, and their concentration should be given by (28.32). However, at thermal energies the sticking coefficient is effectively zero, and thus trapping ought not to be of great concern. Nevertheless, for sputtering systems using argon, concentrations of 0.1% have been observed [28.66], generally for ion energies greater than 100 eV. Although not a major problem for many applications the possibility of inert-gas contamination should not therefore be discounted.

It has been mentioned earlier that simple direct current (DC) discharges as used in the diode and triode sputtering techniques described above, are unable to

deposit insulating films. Although reactive sputtering may be used, the deposition of films by this method requires careful control of sputtering rates and gas pressure, and often calibrations of individual systems and materials. The use of *radio-frequency (RF) sputtering*, allows insulators to be sputtered directly [28.67]. When a high-frequency (typically several MHz) alternating signal is applied to a metal plate, on which an insulating (dielectric) target is mounted and is placed within an auxiliary low-pressure discharge, the positive charge which accumulates on the target is neutralised during half of each cycle. Owing to the much higher mobility of the electrons than the ions in the plasma, the plasma potential becomes positive with respect to the target. RF sputtering was first employed by *Davidse* and *Maissel* [28.68], who found that a self-sustained discharge could be started and maintained by the application of RF power to the electrode only. The mechanism by which sputtering takes place requires the frequency to be in the radio-frequency range [28.16]. The electron mobility is several orders of magnitude greater than that of the ions which have difficulty in keeping up with the field variations, and at high frequencies the ions accumulate in front of the target, in the same way that they do in a DC discharge. Because the number of electrons arriving at the target during the positive half-cycle are not matched by the number of ions arriving during the negative half cycle, the front of the target acquires a negative charge, which repels most of the electrons that would arrive at the surface during the positive half-cycle. The plasma itself is said to be positively *self-biassed* with respect to the target. It is therefore possible to both feed energy into the plasma, while also giving the ions sufficient energy to cause sputtering. The RF discharge is self-sustained, and Davidse and Maissel found that an externally generated plasma is not required. A schematic diagram of the RF sputtering equipment is shown in Fig. 28.6 [28.69] while more detailed discussion of the RF sputtering process is given in previous reviews [28.16, 57]. These authors point out that a major difference between diode and RF sputtering is a requirement for an impedance matching network or *match box* [28.70] in the RF case. The matching network is inserted between the power supply and the discharge chamber, its purpose being to maximise the power that can be delivered to the plasma. Typically a network containing an inductor and a capacitor is used. An example is shown in the literature [28.71]. A blocking capacitor is normally inserted in the network to ensure that the build up of the self-bias voltage proceeds satisfactorily. Although the target itself will normally perform this function in the case of insulator sputtering, the inclusion of a blocking capacitor allows RF sputtering to be used for the deposition of conductors as well as insulators, so semiconductors and metals are also easily deposited by this technique. Mainly for this reason RF sputtering has become a versatile technique which is used near-universally for semiconductor production as well as for insulators and metals [28.70]. A significant increase in the sputtering rate is also observed in RF systems.

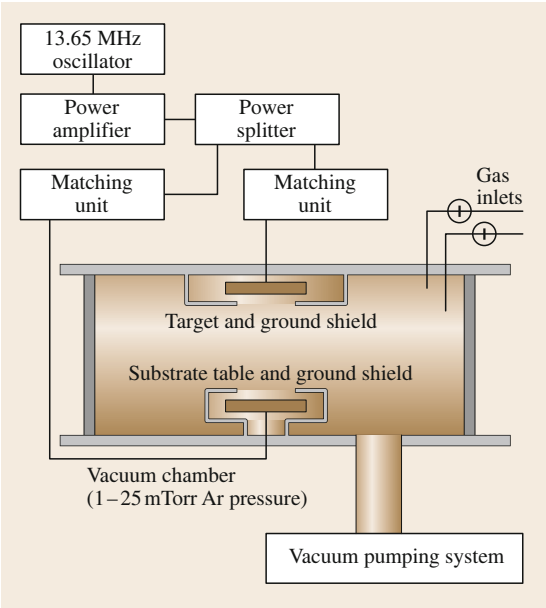

Fig. 28.6 A typical radio-frequency (RF) sputtering system. (After [28.69] with permission from Oxford Univ. Press)

Finally, a technique used to increase the sputtering rate still further is that of *magnetron sputtering*. In this technique, a magnetic field is applied between the target and the substrate. Electrons in the plasma then experience the Lorentz force from the magnetic field in addition to that derived from the electric field, so that the total force on the electron is given by

$$\boldsymbol{F} = m\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = e\boldsymbol{E} + e\boldsymbol{v}\times\boldsymbol{B}\,, \tag{28.33}$$

where $\boldsymbol{F}$ is the total force experienced by the electron, m and e are the electron mass and charge respectively, $\boldsymbol{v}$ is the electron velocity, $\boldsymbol{E}$ is the electric field and $\boldsymbol{B}$ is the magnetic field [28.19, 72]. The effect of the two fields is to cause the electrons to move in spiral rather than linear paths, and therefore to greatly increase the distance travelled by the electrons in the plasma. This substantially increases the time the electrons are within the plasma, and thus the probability of their causing secondary ionisation is also significantly enhanced. In turn this leads to increased current flow and crucially increased deposition rates. The magnetron sputtering

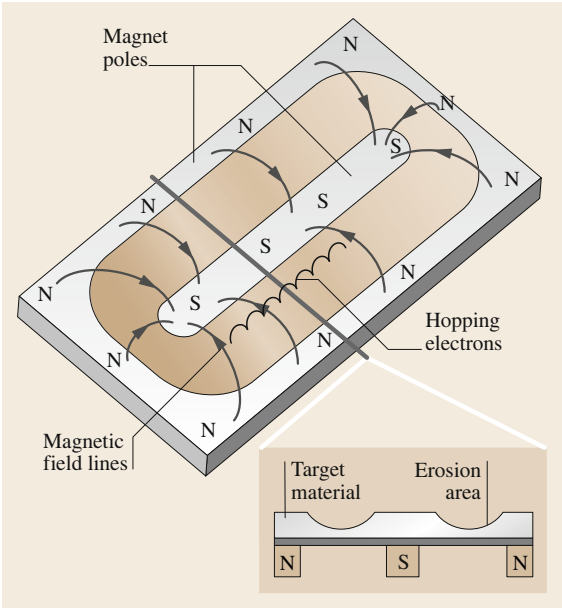

Fig. 28.7 The technique of magnetron sputtering, showing the hopping electrons of the target confined to a *racetrack* region by the magnetic fields from the magnets under the target. (After [28.69] with permission from Oxford Univ. Press)

source is constructed by mounting a powerful magnet below the target, with one pole concentric with the other as shown in Fig. 28.7 [28.69]. This establishes a magnetic field across the target surface; the direction of the magnetic field is perpendicular to the electric field at the furthest extent of the magnetic force lines from the target. The result of the two interacting fields is to confine the electrons for a significant period within a region termed the *racetrack* at the surface of the target, where the electrons effectively hop across the surface. Ionisation of the sputtering gas occurs mainly above the racetrack, and erosion of the target takes place preferentially in this region. In addition to the enhanced deposition rate, magnetron sputtering also has several other advantages. Since the ionisation region is effectively confined to the racetrack, unwanted sputtering from the substrate and the walls of the chamber are reduced, as is the substrate temperature. The gas pressure required to sustain the discharge is also reduced, owing to the greater ionisation efficiency.

A further improvement in the technique of magnetron sputtering may be obtained by the use of an unbalanced magnetron, as described by *Window* and *Savvides* [28.73]. In spite of its excellent high deposition rate, magnetron sputtering generally produces films which have a columnar structure. This leads to the presence of voids, both within grains and at grain boundaries. Low-energy ion bombardment has been shown to improve adatom mobility, allowing atoms to migrate on the depositing surface and filling some of the voids [28.72]. Various computer simulations described in this reference have illustrated the importance of ion beams in depositing dense, void-free films. It is possible to generate an ion current in the plasma by using an unbalanced magnetron where the inner and outer magnets are deliberately unbalanced from the ideal magnetron configuration. Further details concerning the field characteristics of unbalanced magnetrons and of the unbalanced magnetron technique are given in the literature [28.72, 73]. The method has been used to successfully deposit various types of film, including those intended for electrical and optical applications, corrosion protection, and wear and abrasion resistance. A fuller discussion of materials prepared using this method is given by *Rohde* [28.72].

Magnetron sputtering may also be used in conjunction with other sputtering techniques. A combination of RF and magnetron sputtering is frequently used, for example for Co:M alloys where M represents Al, Si, Ti, Cr, Fe, Ni, Cu, Zr, Nb, Mo, Ag, Ta or W [28.74], and also for the deposition of silicon nitride films [28.60].

Thus sputtering has developed from a relatively simple DC technique capable only of the deposition of conductors at a relatively low rate, to encompass both conductors and insulators (RF sputtering) and with sputtering rates suitable for high-throughput industrial processes (magnetron sputtering). Improvements in film morphology have been accomplished by the use of unbalanced magnetron sputtering.

28.1.2 Chemical Deposition Methods

There are many different chemical methods for preparing thin films, but by their nature many of these are restricted to one or perhaps a few different materials, related to a specific chemical reaction or series of reactions. It is therefore only possible to categorise some general techniques and to give examples for various particular materials. *Campbell* [28.75] divided chemical methods into two classes: those depending on an electrical source of ions, such as electroplating and anodisation, and those requiring a chemical reaction, usually, but not exclusively involving a chemical vapour as in the CVD method. A further technique, which has found favour in recent years, is the deposition of molecular films using the Langmuir–Blodgett technique. Brief examples of these are given below.

Electrodeposition

By electrodeposition, we include all methods which involve passing an electric current through a solution such

that a film of a material, usually a metal or an oxide, is deposited on one of the electrodes immersed in the solution. Electrolytic deposition, or *electroplating*, is the deposition of a metal by this method. According to *Campbell* [28.75, 76], of the 70 metallic elements, 33 can be electroplated successfully, although of these only 14 are deposited commercially. The metallic film is deposited on the cathode, and its thickness and the time in which this occurs are determined by the two laws of electrolysis:

1. The mass of the deposit is proportional to the quantity of electricity passed.
2. The mass of material deposited by the same quantity of electricity is proportional to the electrochemical equivalent, E.

This can be expressed as

$$\frac{W}{A} = JtE\alpha \,, \tag{28.34}$$

where W is the mass deposited on a cathode of surface area A, J is the current density, t is the time of deposition and α is the *current efficiency*, or ratio of the expected to the theoretical mass deposited. Its value is generally in the range 0.5−1.0. The previous expression can be rewritten in terms of the film deposition rate, R (or thickness d per unit time t), by noting that the film density $\rho = W/(Ad)$. Combining this with (28.34) gives

$$R = \frac{d}{t} = \frac{JE\alpha}{\rho} \,. \tag{28.35}$$

When a high current is passed through a suitable electrolyte, metallic ions move towards the cathode under the influence of the applied electric field. The mass deposited, and the deposition rate are given by (28.34) and (28.35), and may easily be estimated if E and ρ are known. These are tabulated for the 14 metals commonly deposited by this method [28.75]. Deposition rates can be very high, depending on the current drawn through the electrolyte. For example, silver will deposit at a rate of about 1 nm/s for a current density of 10 A/m^2, rising to 1 μm/s at 10 000 A/m^2 [28.75]. Further details of the deposition of alloys are given in a standard text [28.77], while the growth and structures of electrodeposits are described by *Lawless* [28.78].

A second technique which is used for the deposition of oxides (or less commonly for other compounds such as nitrides), is that of *anodisation*. As its name implies, films are deposited on the anode of the parent metal, following a chemical reaction. The chemical equations describing the anodisation process are given below [28.75]

$$\begin{aligned} &\mathrm{M} + n\mathrm{H_2O} \rightarrow \mathrm{MO}_n + 2n\mathrm{H}^+ + 2n\mathrm{e}^- \text{ (at the anode)} \,, \\ &2n\mathrm{e}^- + 2n\mathrm{H_2O} \rightarrow n\mathrm{H_2}\uparrow + 2n\mathrm{OH}^- \text{ (at the cathode)} \,, \end{aligned} \tag{28.36}$$

where M represents the metal and n is an integer specifying the oxide deposited. The oxide grows in an amorphous form at the metallic anode surface, while hydrogen is evolved at the cathode. The electrolyte is typically an aqueous solution of water containing a dilute acid.

In general a constant current is passed through the cell and film thickness is proportional to the time elapsed. Films grown under constant-voltage conditions, show a decreasing deposition rate with time, as the current falls to zero when the voltage dropped across the film increases to the total applied voltage. Thus the maximum thickness of the film is determined by the voltage used. Growth rates for anodic films under constant-current conditions are of the same order as those for the PVD methods of evaporation and sputtering. Aluminum and tantalum anodisation at a current density of 20 A/m^2 gives growth rates of the order of 1 nm/s [28.76]. Considerably more detailed discussions of anodic oxide films in particular are given in the literature [28.79, 80]. These cover considerably more details of the types of films that may be successfully prepared, their structures, characterisation methods and copious references to related work.

Chemical Vapour Deposition (CVD)

Chemical vapour deposition is a method whereby a volatile compound reacts, with other gas species, to produce the required compound on the substrate. CVD does not require operation under vacuum, as with the PVD processes of evaporation, MBE and sputtering. Moreover, it is capable of producing both silicon and gallium arsenide (GaAs) semiconductor films, and to grow these on substrates of the same material as high-quality epitaxial layers (homoepitaxy). For these reasons it has found wide acceptance in semiconductor processing. High deposition rates relative to PVD deposition methods are possible, and controlled doping performed during the deposition process is relatively straightforward. Objects having quite complex shapes can be coated relatively easily, since the film deposition does not depend on line-of-sight geometry as in the case of evaporation and to a lesser extent sputtering. There are however some formidable disadvantages with the technique. Generally much higher substrate temperatures are required in CVD than for the other methods. The reactive gases used in the deposition

process and/or the reaction products can be extremely toxic, explosive or corrosive, requiring considerable investment in safety features. This may well be justified in high-throughput semiconductor production processes, but uneconomic for smaller-scale development work, where PVD methods are preferable. Corrosion and effects of unwanted diffusion, alloying and chemical reactions at the substrate surface may occur under the high operating temperatures, and masking of substrates is particularly difficult [28.81].

In principle CVD may utilise any chemical reaction which produces the required material, and therefore the equipment used for the production of a given material is likely to differ from that required for another material. Nevertheless, there are several different classes of reaction which are used in CVD processes which are described in the literature [28.16, 18, 19, 75, 76]. Some of these are outlined below.

Pyrolysis or thermal decomposition of a gaseous compound entails passing a vapour over a heated substrate, which causes decomposition and the condensation of a stable solid. This has been used primarily in the production of silicon from SiH_4 and nickel from nickel carbonyl. *Oxidation* is frequently employed to provide SiO_2 in silicon processing. Halides of the required metal oxide are reacted with steam to give the oxide and a hydrogen halide. In *nitriding* the steam is replaced with ammonia (NH_3), and nitrides such as Si_3N_4 may be generated. *Reduction* reactions use hydrogen gas instead of steam or ammonia in the preparation of silicon and refractive metals such as tantalum or molybdenum from their halides. In *disproportionation*, a reversible reaction of the type

$$A + AB_2 \rightleftharpoons 2AB \qquad (28.37)$$

is usually employed [28.76], where A represents a metal, B is usually a halide and both AB and AB_2 are gases. The higher valence state is more stable at lower temperatures so, if the hot gas AB is passed into a colder region, AB_2 will be formed and A deposited. In *transfer reactions* for the preparation of compounds, two different strategies may be employed. Either a compound can be used as the source material, or the source comprises a volatile compound of one of the elements of the required compound. Gallium arsenide (GaAs) can be prepared by both methods [28.16, 83]. In Fig. 28.8 [28.82] a typical CVD system is shown which uses a transfer reactor of the second type to produce GaAs. Highly purified arsenous chloride ($AsCl_3$) and Ga are the source materials. Purified hydrogen is bubbled through the $AsCl_3$ and passed through the furnace. In zone 1 of the furnace, the following reaction takes place

$$2AsCl_3 + 3H_2 \rightarrow 6HCl + \frac{1}{2}As_4 \,. \qquad (28.38)$$

The arsenic vapour is completely absorbed by the Ga source in zone 2 until saturation occurs at 2.25 at. % As. No free arsenic condenses beyond the furnace, but gallium is transported as a lower chloride. Deposition of GaAs occurs in zone 3, when hydrogen is diverted to bypass the bubbler.

Tables of materials which can be deposited by CVD and the associated reactions are given in the literature [28.19, 75]. However, several modifications to the basic CVD process are also in current use. These seek to overcome some of the deficiencies associated with CVD, such as the operation at atmospheric pressure and the use of very high temperatures often involved. Systems employing organic precursors also have certain advantages for the deposition of various materials.

We first discuss low-pressure CVD or LPCVD. Typical pressures of the order of 100 Pa are used, approximately a thousandfold reduction from atmospheric pressure. Contamination is normally lower than for atmospheric CVD and film stoichiometry is often improved. To compensate for the reduced pressure, the

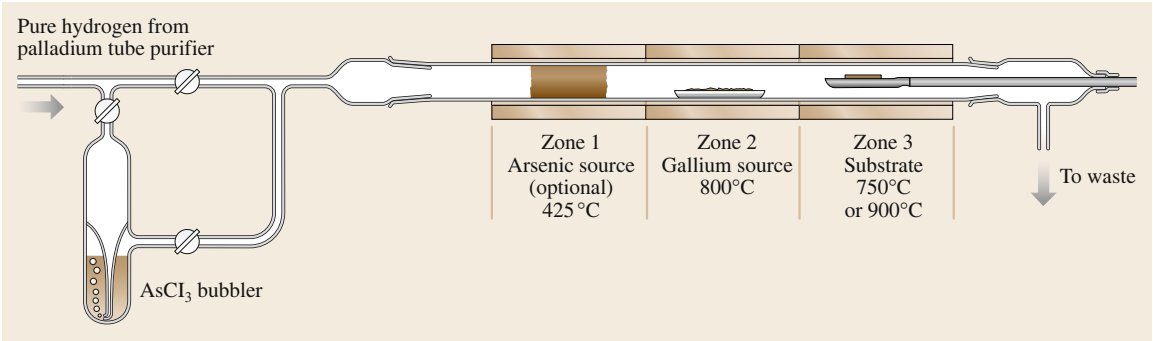

Fig. 28.8 Epitaxial growth apparatus for the production of GaAs using chemical vapour deposition (CVD). (After [28.82] with permission from Elsevier Science)

input reactant gas concentrations are increased, the gas flow velocity is increased, but the gas density is reduced. Because the mean free path of the gas molecules increases due to the reduced pressure, substrates can be placed closer together, giving a higher throughput in commercial applications. Silicon and dielectric films are generally prepared by this method. The operating temperatures required for LPCVD remain high, however.

In plasma-enhanced CVD (PECVD) a glow discharge is initiated inside the chamber where the reaction occurs. A comprehensive review of the PECVD technique is given by *Ojha* [28.84]. Dissociation of the gas in the plasma takes place, owing to the nonequilibrium nature of the plasma, which has a high electron temperature but a low gas temperature. The main advantage of this technique is that the plasma decomposition allows film deposition to take place at much lower temperatures than those employed in atmospheric CVD using decomposition reactions and also in LPCVD. In PECVD, as in LPCVD, the pressure is reduced considerably below atmospheric pressure, although the range of pressures employed varies over a wider range, and can be as high as a few hundred Pa. The discharge is usually excited by an RF field, although both DC and microwave frequency fields have also been used. Average electron energies are of the order of several eV, which is sufficient to cause ionisation and decomposition of the gas molecules. A major application of PECVD is in the deposition of silicon nitride films, an important dielectric used in semiconductor processing for microelectronic passivation. Here the temperatures may not exceed about 300 °C, otherwise damage to the circuitry can result, and so atmospheric CVD and indeed LPCVD are not suitable techniques. For details of the chemical reactions involved, and a comparison of the properties of silicon nitride prepared by LPCVD and by PECVD the reader is referred to the literature [28.19, 85]. The former reference also includes a table giving details for the deposition of many other thin-film materials, including silicon, germanium and other semiconductors, as well as various oxides, nitrides and carbides. PECVD systems operating at microwave frequencies utilise the phenomenon of electron cyclotron resonance (ECR); this deposition method is known as electron cyclotron PECVD (or ECRPECVD). Frequencies are of the order of 1−10 GHz and the ECR plasma may be generated at pressures of about 10^{-3}−10^{-1} Pa, leading to a degree of ionisation up to about 1000 times that achieved in an RF plasma [28.19]. High deposition rates, low-pressure operation and absence of contamination have made ECRPECVD a very attractive technique for film deposition. A full review of this technique has been given by *Popov* [28.86].

Finally we briefly mention the technique of metalorganic CVD (MOCVD), which is becoming an increasingly important method of film deposition. The technique is essentially the same as CVD, except that at least one of the precursors is a volatile metalorganic compound, such as a metal alkyl. The formation of the required compound takes place by pyrolysis of the metalorganic compound with another (inorganic or organic) gaseous precursor. The main advantage of MOCVD is the relatively high volatility of the organic compounds at moderate temperatures, and the fact that, since all these are in the vapour phase, precise control of gas flow rates and partial pressures are possible [28.19]. The compound semiconductors such as GaAs, GaP and InP may be prepared using, for example, trimethyl-Ga ($(CH_3)_3Ga$) or trimethyl-In ($(CH_3)_3In$) as precursors. The basic reaction is with a Group V hydride, e.g., AsH_3 or PH_3 for the compounds listed above. A short table of some film materials which have been successfully generated by MOCVD is given in the literature [28.19]. In addition to its applications in preparing compound semiconductor films MOCVD has also been applied to the deposition of high-temperature superconducting thin films, with quite complex structures [28.87].

Langmuir–Blodgett Film Deposition

The Langmuir–Blodgett technique of film deposition entails the coating of solid substrates with molecular layers. *Langmuir* [28.88] first described the transfer of fatty-acid organic monolayers from the surface of water to a rigid substrate, while *Blodgett* [28.89] extended the work to show that the process could be repeated so that monolayers were sequentially transferred to form multilayer films. The early history of Langmuir–Blodgett films has been briefly described in the preface to the Proceedings of the First International Conference on Langmuir–Blodgett Films [28.90]. In the basic deposition process, a fatty-acid film is spread over the surface of a subphase (usually purified water). Most molecular-film materials have a molecular structure where one end of the molecule is hydrophilic, which seeks out the water subphase, while the other end of the molecule is hydrophobic and attempts to point away from the water subphase. We therefore have the situation where the hydrophilic end of the molecule is oriented downwards towards the water, with the hydrophobic end oriented upwards. In Langmuir–Blodgett deposition, the required molecules are dispersed in a volatile solution, which eventually evaporates, leaving the molecules with their hydrophilic ends immersed in the water, but with their axes randomly oriented [28.91]. A compressive surface-barrier system is employed to compress the molecules so that they are close-packed and oriented perpendicu-

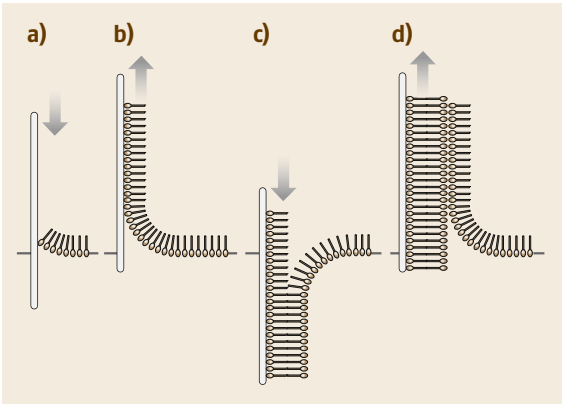

Fig. 28.9a–d Langmuir film deposition: **(a)** immersion of a hydrophilic substrate without film deposition; **(b)** withdrawal of the hydrophilic substrate; **(c)** repeated immersion with film deposition; **(d)** continuation of the process. (After [28.91] with permission from Elsevier Science)

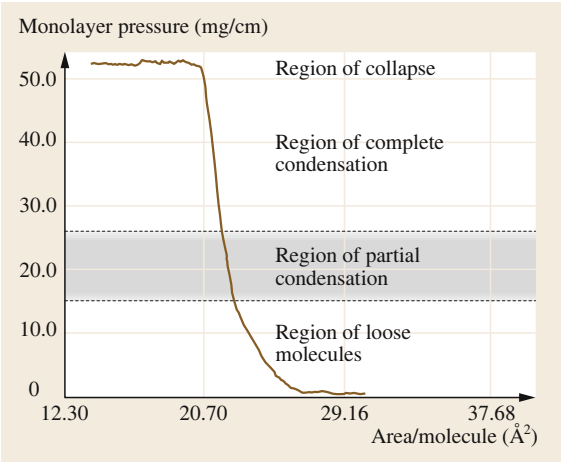

Fig. 28.10 The pressure–area relationship for a cadmium stearate molecular layer obtained at a temperature of 22 °C at pH 5.6. Film deposition should be carried out in the linear region of the curve, i. e., the region of complete condensation without collapse. (After [28.91] with permission from Elsevier Science)

lar to the surface of the subphase, with their hydrophilic ends pointing vertically downwards. The molecules can then be transferred to either a hydrophilic or hydrophobic substrate by slowly dipping into the subphase. The basis process is shown in Fig. 28.9 [28.91], for the case of a hydrophilic substrate. On the initial introduction of the substrate into the subphase no coating takes place (a), but on removing it a film attaches to the substrate by polar-bond formation (b). The substrate is then effective hydrophobic, and on dipping for a second time, the hydrophobic ends of the molecules on the subphase form van der Waals bonds with the hydrophobic substrate surface, thus again making the surface hydrophilic (c). On withdrawing the substrate for a second time a further molecular layer is deposited, with the hydrophobic ends of the molecules at the surface (d). Repeated dipping cycles then establish multilayer films with an odd number of layers. The use of an initially hydrophobic substrate gives an even number of molecular layers for each completed dipping cycle.

It is evident that we have a mechanism whereby a predicted number of molecular layers may be deposited, and knowing the molecule dimensions (i. e., the length of the molecule between its hydrophilic and hydrophobic ends) together with the number of dipping cycles, it is easy to accurately calculate the film thickness. It is important, however, that the surface pressure is maintained within a fixed range of values during deposition. If it is too high the surface film collapses in localised regions, giving a transferred layer thickness greater than one monolayer; conversely, if the pressure is too low, there may be voids in the film surface, which transfer on to the substrate. This is illustrated in Fig. 28.10 [28.91], which shows a pressure–area isotherm for a cadmium stearate molecular layer. It is normal to use a feedback system during deposition to control a moveable barrier on the film surface to maintain the surface pressure within a narrow range while the dipping process takes place. Here the molecular area remains effectively constant for a large change in pressure (region of complete condensation in the figure), ensuring that small changes in pressure do not cause the deposited film to fold over or break up.

There are, however, some limitations to the use of the Langmuir–Blodgett deposition method. The material must satisfy the following requirements [28.91]. The molecular chain structure needs to be hydrophilic at one end and hydrophobic at the other. Furthermore, it should be insoluble in water, but soluble in a suitable solvent in order to give a spreading solution. Some materials which are insoluble can, however, be modified by chemical substitution of molecular end groups. For example, metal-free phthalocyanine is normally insoluble, but the chemical addition of $C(CH_3)_3$ end groups to the molecule renders it soluble in some aromatic solutions such as toluene. This type of chemical modification allows the deposition of materials which cannot normally be deposited to be deposited in a substituted form [28.92]. Many other substituted organic compounds may also be deposited, including dyes, porphyrins, fullerenes, charge-transfer complexes and polymers [28.93]. It is also possible to prepare Langmuir–Blodgett film layers with alternating monolayer structures, by dividing the Langmuir–Blodgett trough into two compartments, one for each type of

monolayer, separated by a surface barrier [28.94, 95]. Deposition then takes place by alternately removing the substrate from the surfaces of the two compartments, by passing the substrate through the subphase under the surface barrier between deposition of each of the materials.

The advantages of the Langmuir–Blodgett technique over other thin-film deposition methods lie primarily in the low temperature at which deposition takes place (close to room temperature), and on the feasibility of depositing very thin mono-moleculer layers of known thickness. Several types of electronic devices incorporating Langmuir–Blodgett films have been discussed [28.96] as has the writing of very fine lines of width less than 10 nm separated by 20 nm in manganese stearate films [28.97]. Further work on the deposition of other materials by this method may well lead to novel device structures and to improved processing methods. An excellent discussion on the preparation and major properties of Langmuir–Blodgett films is given by *Petty* [28.93].

28.1.3 Sol–Gel Method

The sol–gel process is regarded as being a cost-effective and simple technique to synthesize primarily oxide ceramics. Among several significant advantages, products with a high degree of purity can be obtained by purifying precursors via either distillation, crystallization, or electrolysis [28.98]. In this process, the solution (sol) undergoes a sol–gel transition in which the gel becomes a relatively rigid, porous mass. This involves the use of metal alkoxides as precursors for the preparation of a colloidal solution [28.99]. Metal alkoxides have organic ligands attached to metal atoms and react readily with water. The most common precursor is silicon tetraethylorthosilicate (TEOS). In a two-phase system solid silica SiO_2 and solvent-filled pores are formed from the polymerization of $Si(OC_2H_5)_4$. Hydrolysis of TEOS takes place in the presence of water mixed with ethanol (C_2H_5OH) solvent according to the following chemical reaction

$$\mathrm{Si(OC_2H_5)_4 + xH_2O \xrightarrow{C_2H_5OH} Si(OC_2H_5)_{4-x}(OH)_x + xC_2H_5OH\,.} \qquad (28.39)$$

It is to be noted that no additional catalyst is required for the hydrolysis of TEOS in C_2H_5OH.

Depending upon amounts of water and catalyst present, complete hydrolysis may take place with conversion from $Si(OC_2H_5)_4$ to $Si(OH)_4$ producing silicic acid.

For partial hydrolysis, a siloxane Si–O–Si group is formed through possible condensation of the two silanol groups with elimination of water and ethanol

$$\mathrm{Si(OC_2H_5)_{4-x}(OH)_x + Si(OC_2H_5)_{4-x}(OH)_x \rightarrow Si(OC_2H_5)_{4-x}(OH)_{x-1}OSi(OH)_{x-1}(OC_2H_5)_{4-x} + H_2O} \qquad (28.40)$$

Intermediary Si–OH silanol groups may be formed as a result of partial hydrolysis [28.100].

Equations (28.39) and (28.40) describe the chemical reactions during the sol–gel process

The condensation process is dynamic, and may be manoeuvered in the desired direction by adjusting parameters like types of precursor, catalyst and solvent, reactant concentrations, and ratio of water to alkoxide. When the ratio of water to alkoxide = 1, hydrolysis becomes complete without condensation. A ratio greater than unity increases condensation. A precise control over the stoichiometry of the deposited film is achieved by exploiting polycondensation reactions of molecular precursor metal alkoxides in a solution over a very large pH range. Slow hydrolysis produces cross-linked linear molecules in acidic, low pH conditions. These molecules entangle and form additional branches resulting in gelation. The minimal reaction rate for hydrolysis is at pH 7, and for condensation at around pH 4.5. However, basic conditions at high pH levels promote the formation of more highly branched silica clusters as discrete species. Gelation occurs by linking these clusters. As the sol aggregates the viscosity will increase until a gel is formed. The pH where the particle is neutral is called the point of zero charge (PZC). The size of the surface potential depends on the difference between pH and PZC. The sol–gel transition (gel point) is reached when a continuous network is formed. The gel time is determined as the time at which it is possible to turn the container upside down [28.101]. All fluid is kept in the gel, and the volume is maintained. If the solvent from the pores is removed by drying, capillary forces will result in shrinkage and the gel network will collapse, forming a xerogel. The network structure may be retained with supercritical evaporation which yields low density ($0.085\,g/cm^3$) aerogels with a specific surface area of $700\,m^2/g$ and a large pore volume ($3.29\,cm^3/g$) [28.102].

Sol–gel processing allows materials to have any oxide composition. Uniform thin films of a large number of metal oxides can be deposited on a variety of substrates at room temperature in a hydro-alcoholic medium in the presence of a basic or acidic catalyst. Thin films of titania TiO_2 produced using sol–gel methods have been extensively investigated for various device applications due to the low fabrication cost. Sol–gel coatings may result from dipping, spin coating, or spray-

ing a sol precursor onto a substrate. The formation of a thin film through spin coating consists of four stages:

1. Deposition, which is the dispersion of the solution on the surface of the substrate
2. Spin-up, in which the solution flows toward the edges of the substrate
3. Spin-off, where the excess amount of solution is spread as droplets and leaves the surface of the substrate, and lastly
4. The evaporation of the solvent.

The alkoxide used during the current work is titanium isopropoxide ($C_{12}H_{28}O_4Ti$) with a purity of 99.99%, which is mixed with absolute ethanol and acetic acid as a catalyst in the molar ratios of 1 : 9 : 0.1. Thin films of TiO_2 were deposited by the method of spin coating using a standard photoresist spinner. In general the films were predominantly polycrystalline with an estimated grain size of a few nanometers. The grain size decreases with an increase in spin speed. The room temperature conductivity is an order of magnitude higher than that of TiO_2 films prepared from a similar solution by dip coating [28.103].

One promising transparent oxide that can be used as an insulating, semiconducting or metallic layer, is the zeolite-like calcium aluminate $12CaO \cdot 7Al_2O_3$ (C12A7) binary compound. This novel oxide exhibits physically interesting characteristics by exploiting its high-density intrinsic defect nanostructure. The pulsed laser deposition method has been extensively used for preparation of C12A7 thin films. The technique is relatively costly and requires a C12A7 target as the starting material for the deposition of the film. For the sol–gel process, C12A7 sol is synthesized through hydrolysis of two separate solutions. Aluminum oxide hydroxide (AlOOH) sol is prepared using aluminum sec-butoxide $Al(OBu)_3$ as the precursor. In order to avoid precipitation this precursor is modified using ethyl acetoacetate (etac). $Al(OBu)_3$ is hydrolytically unstable and its hydrolysis leads to immediate precipitation. However, modifying $Al(OBu)_3$ using ethyl acetoacetate (etac) mediates the hydrolysis of Al^{3+} ions, through substitution of monodentate butoxy ligands of $Al(OBu)_3$ with etac groups. Etac groups will be bonded to Al atoms in an enolic form (Fig. 28.11).

$Al(OBu)_3$ is mixed with etac at a molar ratio of $Al(OBu)_2$: etac = 1 : 1. The mixture is magnetically stirred for 30 min followed by 1 h of ultrasonic mixing. Ultrasonic mixing provides better dispersion compared to our previous work. Through this stage the $Al(OBu)_2$(etac) complex is formed. This new precursor is diluted with ethanol ($Al(OBu)_2$: ethanol = 1 : 4) prior to hydrolysis. In the final step ethanol is diluted with distilled water followed by pH regulation using hydrogen chloride (HCl) acid ($Al(OBu)_3$: H_2O : HCl = 1 : 3 : 0.075). Diluted distilled water is then added to the $Al(OBu)_2$(etac) solution initiating the hydrolysis process. The hydrolysis is performed under vigorous stirring using an ultrasonic bath, followed by gentle stirring at room temperature for 24 h using the magnetic stirrer. During hydrolysis of the modified $Al(OBu)_2$(etac) compound, etac groups will be separated from the compound in both enolic and ketonic forms. Following the separation of butoxy ligands, AlO bonding will be exposed to OH bonding of water, resulting in the formation of boehmite (γ-AlO(OH)). The reaction to this water content may be derived as

$$\begin{aligned} &Al(OC_4H_9)_2(\text{etac}) + 3H_2O \rightarrow \\ &AlOOH(H_2O) + \text{etac} + 2C_4H_9OH\,. \end{aligned} \qquad (28.41)$$

The molar ratio $Al(OBu)_3$: HCl = 1 : 0.15 was chosen for acid concentration used in the synthesis of AlOOH particles, thereby reducing the pH of the solution from 10.4 to 8, well below the isoelectric point of boehmite particles. Such acid regulation will reduce the chance of agglomeration due to columbic interactions between particles. The final product was AlOOH particles dissolved in ethanol.

A second solution was prepared using $Ca(NO_3)_2 \cdot 4H_2O$ dissolved in ethanol. Additional water was added to the solution ($Ca(NO_3)_2 \cdot 4H_2O$: H_2O = 3 : 4) to initiate partial hydrolysis. Addition of water expels some salt ions to form HNO_3, decreasing the pH of the solution to 4. The dispersion of calcium nitrate in the solvent was facilitated using an ultrasonic bath followed by 24 h of magnetic stirring. The solution formed required no further acid addition since HNO_3 was formed inside the solution.

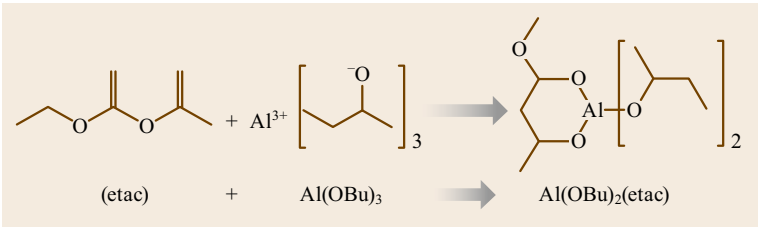

Fig. 28.11 Enolic bonding of etac groups to Al atoms

The sol–gel process starts with a homogenous solution of AlOOH and $Ca(NO_3)_2$ in ethanol solvent with the concentrations meeting the nominal composition of C12A7 compound. The AlOOH solution and $Ca(NO_3)_2$ were mixed allowing the formation of homogenous C12A7 amorphous solution. C12A7 nanoparticles were prepared by dispensing a thin layer of sol in a Petri dish followed by a 72 h drying process at room temperature. During drying, evaporation of ethanol progressively facilitates the formation of the amorphous phase from the solution [28.104].

Sol–gel processing has been widely employed for the synthesis of inorganic–organic hybrid materials.

The high-temperature synthesis route to ceramic materials is not suitable for the incorporation of thermally labile organic moieties. Two different routes are used for incorporation of organic groups: (1) embedding organic compounds into gel without chemical bonding and (2) covalent bonding of organic compound to gels [28.105]. The sol–gel process is commonly identified as an ecofriendly process compared to traditional routes to ceramics and glasses because the first steps are usually carried out at low temperature. Unlike the high-temperature classical methods, the possibility of chemical interaction between the container and the materials is very small. As the processing takes place in a liquid medium, there is no pollution due to dispersion of dust. Industrial and consumer efforts have been made to recycle various forms of silica gel [28.106].

28.2 Structure

In this section some examples of the structures of various types of thin films are described. By the *structure*, we mean mainly the crystallographic form in which the film is deposited, and also factors associated with this, such as the mean size of crystallites and their orientations. However, the gross morphology of films is also included, and this covers features generally larger than the grain size. The basic type of film, i. e., epitaxial, polycrystalline or amorphous, is usually deduced by diffraction methods (X-ray, electron or neutron), although we will mainly be concerned with the first of these only. Thus a brief description of the method of X-ray crystallography is first given, followed by examples of different types of films that have been observed. Finally some examples of the larger-scale morphology are described.

Several reviews of film structure have been given previously [28.107–109], as well as more generalised discussions in most of the texts covering thin films, to which the reader is referred. However, it should be noted that the large number of variables encountered in thin-film deposition processes (e.g., substrate temperature, deposition rate, angle between vapour stream and substrate) permit films of differing structures to be deposited under nominally similar conditions. It is always wise, therefore, before interpreting measurements of any thin-film properties (such as the electrical or optical properties) to first fully determine the structure of the films, and to take this into account in any interpretation.

28.2.1 Crystallography

In general films tend to deposit from the vapour phase in one or more of their documented bulk-crystal structures. In crystals, the spatial arrangement of the atoms exhibits a symmetry, which can be replicated throughout three-dimensional space by repetition of a basic unit, called the primitive unit cell. The unit cell of any crystal structure may be specified by the magnitudes of three vectors $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{c}$ representing the unit cell lengths, and the angles α, β and γ between the three vectors. Symmetry considerations allow all crystals to be classified into seven crystallographic structures, namely the cubic, tetragonal, orthorhombic, hexagonal, trigonal, monoclinic and triclinic forms, of which only the first three are orthogonal. Conditions on the equality or otherwise of the lengths a, b and c and the angles between them determine into which type the structure of a given material falls. In three dimensions the atoms arrange themselves in planes, with gaps between the planes known as the planar spacing, d_{hkl}. In any perfect crystal there are many sets of crystal planes that may be identified. The possible planar spacings are given by different expressions, depending on the crystal structures. For example, in the cubic structure ($a = b = c$, $\alpha = \beta = \gamma = 90°$)

$$\frac{1}{d_{hkl}^2} = \frac{h^2 + k^2 + l^2}{a^2} \,. \tag{28.42}$$

In the tetragonal structure ($a = b \neq c$, $\alpha = \beta = \gamma = 90°$)

$$\frac{1}{d_{hkl}^2} = \frac{h^2 + k^2}{a^2} + \frac{l^2}{c^2} \tag{28.43}$$

and in the hexagonal structure ($a = b \neq c$, $c \perp a$, $\gamma = 120°$)

$$\frac{1}{d_{hkl}^2} = \frac{4}{3}\left(\frac{h^2 + hk + k^2}{a^2}\right) + \frac{l^2}{c^2} \,. \tag{28.44}$$

In these equations a, b and c represent the lengths of the sides of the primitive unit cell, and h, k and l are integers. Similar, but more complex, equations exist for the other crystal structures which have less symmetry. For bulk crystals having unit cell sides of the order of nanometres, the crystal planes act as three-dimensional diffraction gratings, which reflect an incident beam of radiation according to Bragg's law,

$$\lambda = 2d_{hkl} \sin\theta \,, \tag{28.45}$$

where λ is the wavelength of the radiation, and θ is the angle between the incident beam and the reflecting planes. The values of λ for X-rays, electrons and neutrons may be chosen such that they are of the same order as d_{hkl}, and therefore diffraction will occur at suitable angles. These angles are those which satisfy Bragg's law, and are therefore determined by the radiation wavelength λ and by the integer values (h, k and l) applying to the sets of reflecting planes present. (hkl) then specifies the set of reflecting planes, and also the orientation.

For perfect crystals, reflections only occur at certain well-defined angles. If the crystal is rotated with respect to the incident beam of radiation, the deviation angle between the incident and reflected beam is 2θ. If the material, instead of being perfect, is made up of a large number of differently oriented microcrystallites, i. e., it is polycrystalline, the diffraction method will pick up reflections from a large number of individual crystallites, and therefore provide data on all the reflecting planes present. A particular set of planes will only reflect at a specific value of 2θ, and by observing the reflecting angles the planar spacings d_{hkl} can be determined. By reference to standard tabulated data (such as the *International Tables of Crystallography*), which give details of the reflections and intensities expected for most crystalline materials, a considerable amount of information can be determined. This includes the nature of the phases present, their preferred orientations and a measure of the microcrystallite size.

X-ray diffraction is the most commonly used technique. The penetration depth of X-rays can be quite significant, and if the film is too thin they can penetrate down to the substrate. Thus X-ray diffraction often gives information on the substrate as well as the film. If this is to be avoided, the film thickness needs to be increased or the X-rays directed at a low glancing angle with respect to the substrate surface. Electrons have a considerably lower penetration ability, and therefore give information only on the immediate surface region. Neutron diffraction is used particularly in the investigation of magnetic films.

28.2.2 Film Structure

Apart from the detailed type of crystal structures observed, it is useful to divide the structures of thin films into three main categories, according to their crystallographic perfection (or lack of it). Epitaxial films are essentially perfect films grown on a substrate surface with all the atoms arranged predictably in their correct crystallographic positions. There may be certain defects, such as vacancies, interstitial atoms or impurities, but the deviation from perfection should be relatively small. Furthermore, there may be some slight deviations in the unit cell dimensions from those of the corresponding bulk material, owing to idiosyncrasies of the deposition method or the substrate surface, and in particular to stresses built up in the film during deposition. Various methods have been devised to deposit epitaxial films, such as molecular-beam epitaxy (MBE) and vapour-phase epitaxy, both of which are used in the semiconductor industry for preparation of high-quality films. Non-epitaxial films are frequently polycrystalline, having a large number of grains, oriented in different directions, and separated by grain boundaries. The grain size is heavily influenced by the deposition conditions, and can have a profound effect on secondary properties, such as the electrical conductivity, in which grain boundaries influence the electron mean free path. Finally, amorphous films have no long-range order, being noncrystalline, with only short-range order apparent. Substrate temperature during deposition and subsequent thermal history after deposition can have a profound effect in determining the initial structure, orientation and subsequent phase changes. Some examples of these effects are included in the following discussion.

In the case of epitaxial films, a large number of factors determine whether the film is indeed epitaxial, and if so the crystalline orientation that will result. The main concepts that underlay the growth of epitaxial films are the equilibrium thermodynamics of the growing nuclei, the evaporation process as described by the Hertz–Knudsen expression (28.5), surface kinetics and mobility on the substrate and the growth of defects [28.110]. The interdependence and interaction of these various processes, which are generally all temperature-dependent, lead in many cases to a particular value of temperature (usually called the epitaxial temperature) only above which epitaxy can take place. Depending on the relative difference between the unit cell dimensions of the substrate and the films (often quantified as the *misfit*) there is frequently a considerable stress between them, which is released by a network of imperfections (dislocations). Details of the epitaxial growth are strongly related to various theories of nucleation. There are several of these, based

on the characteristics of microscopic nuclei on the substrate. These grow during the deposition process, and if the conditions are suitable, can result in the deposition of epitaxial films. In the capillarity model [28.9, 27] the nuclei become stable when they reach a particular size (the critical nucleus). Above this size the nucleus is stable and continues to grow. However, in this case the size of the critical nucleus is of the order of 100 atoms or more. An alternative theory of nucleation has been proposed for critical nuclei consisting of only a few atoms [28.111, 112]. In this model certain geometries have been postulated for the critical nucleus under different conditions of supersaturation and substrate temperature. The rate of nucleation is given by

$$I = Ra_0^2 N_0 \left(\frac{R}{\gamma N_0}\right)^{n^*} \times \exp\left(\frac{(n^*+1)Q_{\mathrm{ad}} - Q_{\mathrm{D}} + E_{n^*}}{k_{\mathrm{B}}T}\right). \quad (28.46)$$

In this expression the symbols have the following meanings: R is the impingement rate of atoms on the substrate, a_0 is a characteristic jump distance of the atoms across the substrate surface, N_0 is the concentration of adsorption sites, $\gamma = h/(k_{\mathrm{B}}T)$ is the vibrational frequency, where T is the substrate temperature, and n^* represents the number of atoms in the critical nucleus. The remaining terms in the numerator of the exponential represent energies: Q_{ad} is the binding energy of a single atom to the substrate surface, Q_{D} is the activation energy for surface diffusion of adsorbed atoms and E_{n^*} is the dissociation energy of a critical nucleus containing n^* atoms. By substituting $n^* = 1, 2, 3$, etc., into (28.46), expressions can be obtained for critical nuclei of size 1, 2 or 3 atoms. These correspond to stable nuclei of size $(n^*+1) = 2, 3$ or 4. By simultaneously solving pairs of these equations, it is possible to calculate the temperature at which the size of the critical nucleus changes from one value of n^* to another. For example, the temperature at which the critical nucleus size changes from one to two atoms, T_{12}, is given by

$$T_{12} = -\frac{(Q_{\mathrm{ad}} + E_2)}{k\ln(R/(\gamma N_0))}, \quad (28.47)$$

where E_2 is the dissociation energy of a two-atom nucleus into single atoms. The model has been tested, notably in the case of a face-centred cubic metal (silver) deposited on a high-purity (100)NaCl substrate [28.112]. At low substrate temperatures and high supersaturations, it was found that the nucleation rate I is proportional to R^2, which from (28.46) implies that $n^* = 1$ (the critical nucleus is just one atom). At higher temperatures, critical nuclei were found to have $n^* = 2$ or 3, with stable nuclei adopting the (111) or (100) orientations. Further discussion is given in several later reviews [28.1, 10, 16, 19]. More-sophisticated models of nucleation are based on the kinetic behaviour of nuclei, and involve a set of coupled differential equations, relating growth and dissociation of nuclei. More details are given in the literature [28.113, 114].

Another example of where the occurrence of epitaxy is defined by well-defined temperature ranges, is given in the work of *Kalinkin* et al. [28.115] *Muravjeva* et al. [28.116]. This important work has also been discussed in other reviews [28.117, 118]. These workers made extensive measurements on the evaporation of both cadmium and zinc chalcogenides (sulphides, selenides and tellurides), which were evaporated from Knudsen cells at a pressure of about 10^{-2}–10^{-3} Pa. The substrates used were mica in all cases. It was found that for all three cadmium compounds, and all three zinc compounds, the conditions for epitaxial growth were dependent on both the temperature of the substrate (the epitaxial temperature T_{Ep}) and the evaporator temperature T_{ev}. The latter influenced the evaporation rate N_{e} (28.5) and also the supersaturation ratio of the growing films. For each of the six compounds, different combinations of T_{Ep} and T_{ev} were investigated. We discuss in detail only the cadmium compounds, although the behaviour of the zinc compounds is entirely similar, as can be seen from Fig. 28.12 [28.116]. Below about $T_{\mathrm{Ep}} \approx 310$–$320\,^{\circ}\mathrm{C}$, the evaporator temperature for epitaxy T_{ev} increased approximately linearly with T_{Ep} according to $T_{\mathrm{ev}} = A_1 + T_{\mathrm{Ep}}$, where A_1 is a constant. Above $T_{\mathrm{Ep}} \approx 310$–$320\,^{\circ}\mathrm{C}$, T_{ev} decreased linearly with T_{Ep} according to $T_{\mathrm{ev}} = A_2 - 2T_{\mathrm{Ep}}$, where A_2 is a second constant. These relationships between the epitaxial temperature and the evaporator temperature are illustrated in Fig. 28.12 [28.116]. For the cadmium chalcogenides, values of the range of the constants A_1 and A_2 for which epitaxial behaviour was observed are $A_1 = 800$–$950\,^{\circ}\mathrm{C}$ and $A_2 = 1750$–$1900\,^{\circ}\mathrm{C}$ for CdS, $A_1 = 600$–$750\,^{\circ}\mathrm{C}$ and $A_2 = 1550$–$1700\,^{\circ}\mathrm{C}$ for CdSe, and $A_1 = 400$–$550\,^{\circ}\mathrm{C}$ and $A_2 = 1350$–$1500\,^{\circ}\mathrm{C}$ for CdTe [28.116]. It is evident from these values that for each substance the evaporator temperature T_{ev} lies within a range of about $150\,^{\circ}\mathrm{C}$ for values of T_{Ep} at which epitaxy is possible. In addition, for a given substrate temperature the evaporator temperature required for epitaxial CdS is highest, becoming progressively lower for CdSe and for CdTe. For example for $T_{\mathrm{Ep}} = 320\,^{\circ}\mathrm{C}$, the evaporator temperatures for epitaxy are 1120–$1270\,^{\circ}\mathrm{C}$ for CdS, 920–$1070\,^{\circ}\mathrm{C}$ for CdSe and 720–$870\,^{\circ}\mathrm{C}$ for CdTe. The same sequence is also followed for the zinc chalcogenides. At combinations of temperatures outside the limits given by the values of A_1 and A_2, the films deposited were not epitaxial, being polycrystalline and only partially ordered.

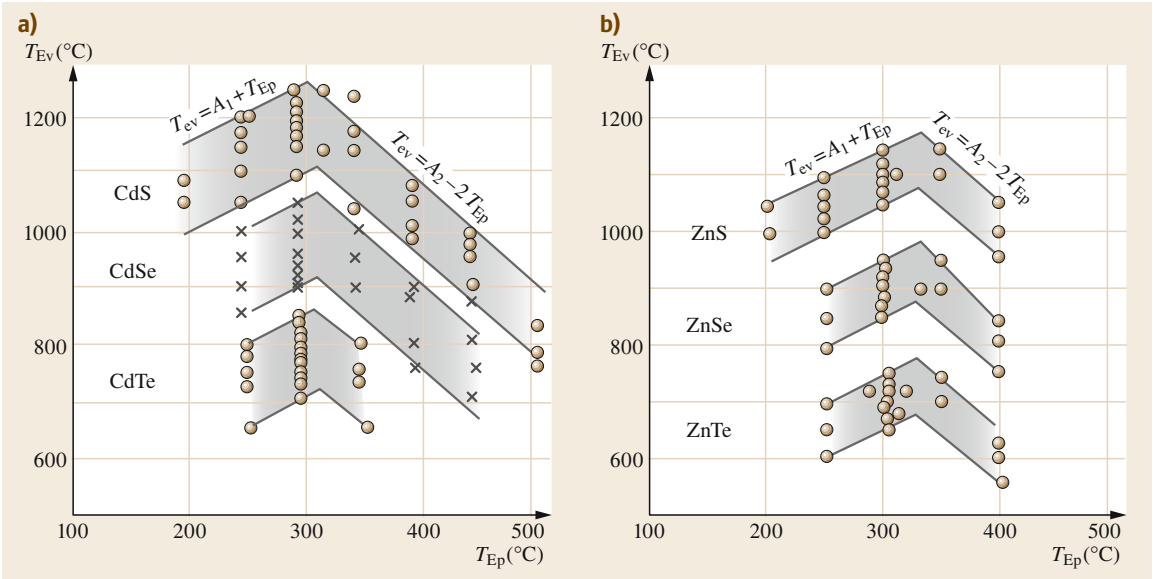

Fig. 28.12 Relationship between the evaporation temperature T_{ev} and the epitaxial temperature T_{Ep} in the growth of cadmium and zinc chalcogenide films on mica. (After [28.116] with permission from Elsevier Science)

We now consider some examples of polycrystalline thin films, and the factors which account for their various crystallographic characteristics. X-ray diffractometry is particularly useful in determining the basic crystal structure adopted by a particular film, particularly when two or more phases are possible. The cadmium chalcogenides have, on average, four valence electrons per atom, which leads to tetrahedral bonding. However, there are two different ways in which tetrahedra formed from each of the constituent atoms can penetrate into each other. This leads to two allowed crystal structures: the hexagonal wurtzite structure and the cubic zinc-blende structure. The planar spacings for these are described by (28.44) and (28.42), respectively. In the evaporant material, which is usually composed of a polycrystalline powder, a large number of diffraction peaks normally occur, which can be indexed using the appropriate planar spacing expression. Figure 28.13a [28.119] shows an example of a diffraction trace obtained from CdS evaporant powder. The diffraction planes are indexed in terms of the hexagonal structure, and rule out the possibility of the material being of the cubic form. More interestingly, Fig. 28.13b shows a trace obtained from a thin film prepared from this material. Although the two peaks shown correspond to those observed for the evaporant powder, it is clear that reflections from most of the crystal planes are missing. If the intensities of the peaks are different from those for a random powder (or more specifically from those tabulated in the *International Tables of Crystallography*), the crystallites are said to be preferentially oriented. In this case it can be seen that virtually all the crystallites must be aligned in the same direction, with the *c*-axis directed perpendicular to the substrate plane, along a preferential orientation in the [002] direction.

Apart from the simple determination of film crystal structures and preferential orientations, it is also possible to monitor changes from one crystal structure to another. For example, the phthalocyanines are organic crystals, which are known to possess several basic crystal structures, of which the α-phase and the β-phase are the most common. There is some controversy over whether the α-phase is orthorhombic or monoclinic, and it was originally identified as tetragonal [28.120]. The β-phase is monoclinic. However, X-ray diffraction has identified most films prepared at lower substrate temperatures as being of the α-structure, while those deposited at higher temperatures are of the β-structure. Both copper phthalocyanine (CuPc) and cobalt phthalocyanine (CoPc) films deposited on to substrates held at room temperature were of the α-structure, but on annealing at 240 °C for an extended period, the CuPc films underwent a phase transition to the β-structure [28.121]; the CoPc films also showed a transition to the β-phase on annealing at temperatures up to 325 °C [28.122]. The α-form films of both materials were preferentially aligned in the [001] direction assuming a tetragonal structure, or the [002] direction assuming an orthorhombic or monoclinic structure. The annealed β-form films were also preferentially oriented, in the [20$\bar{1}$] direction for CuPc

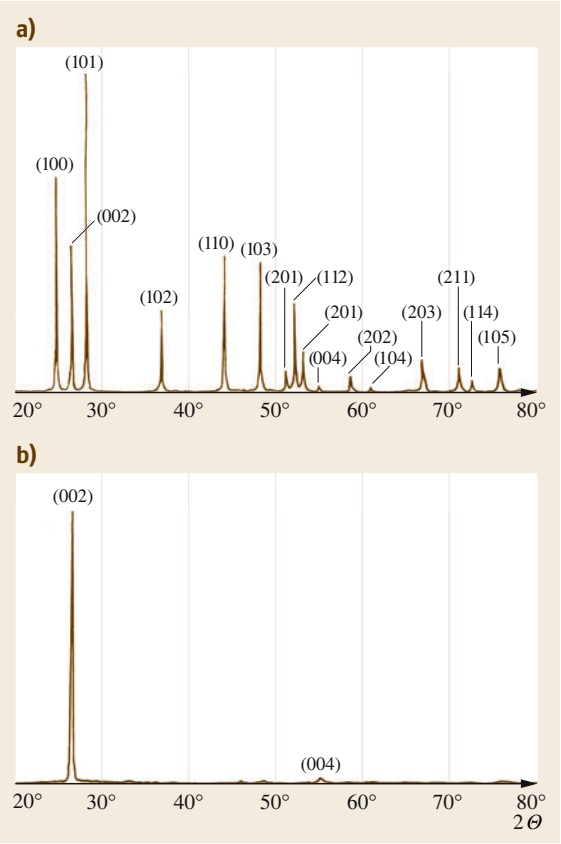

Fig. 28.13a,b X-ray diffraction traces obtained from **(a)** CdS powder, and **(b)** a CdS thin film. (After [28.119] with permission from Wiley-VCH)

and the [001] direction for CoPc. In the latter case it was possible to monitor the dominant peak over the temperature range 200–325 °C where the phase change occurred. d_{hkl} increased slightly with annealing temperature up to 200 °C, then decreased significantly at 250–300 °C. The value of 2θ decreased slightly with T_{ann} up to 200 °C, again followed by a significant *increase* at approximately 250–300 °C. For T_{ann} up to 250 °C d_{hkl} lay in the range 1.271–1.277 nm and 2θ in the range 6.92–6.95°, which is close to those expected for α form CoPc; at higher annealing temperatures d_{hkl} was in the range 1.241–1.246 nm and 2θ in the range 7.09–7.12°, which are in better agreement with those expected for β form CoPc.

X-ray diffraction also allows an estimate of the mean grain size L in polycrystalline films to be obtained, by detailed observation of the peak profiles. The well-known Scherrer equation [28.123]

$$L = \frac{K\lambda}{\eta \cos\theta} \qquad (28.48)$$

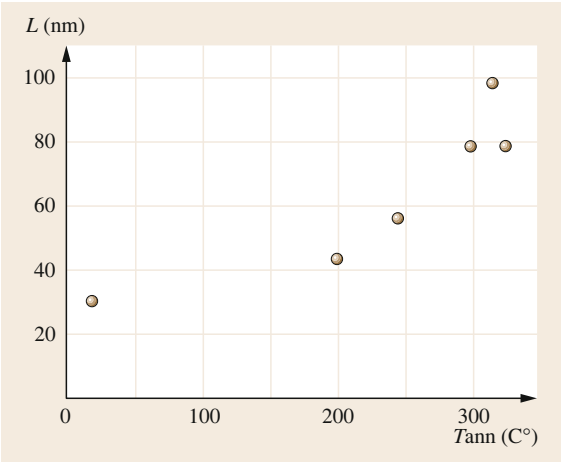

Fig. 28.14 Mean crystallite grain size L as a function of maximum cumulative annealing temperature T_{ann} for a cobalt phthalocyanine film of thickness 0.1 μm. (After [28.122] with permission from Wiley-VCH)

allows an estimate of L to be made from simple details of the peak profiles. In (28.48), λ represents the X-ray wavelength, η the width of a strong peak in radians at half-maximum intensity, and θ is the Bragg angle, where K is a constant which is approximately unity. An example of the use of this method is in the determination of L from the first Bragg peak of α-form CoPc films before annealing [28.122]. The films were subsequently heated to a higher temperature T_{ann} in oxygen-free nitrogen for two hours and the value of L again measured. Measurements were repeated at even higher temperatures until the dependence of L on T_{ann} over the entire temperature range of the α-to-β phase change was determined. These results are illustrated in Fig. 28.14 [28.122]. It is clear that at temperatures up to 200 °C there was an increase in the mean microcrystallite size from about 30 to over 40 nm, although there was no indication of a phase change. *Ashida* et al. [28.124] ascribed this effect in CuPc to preliminary crystallite growth at the early stages of the phase transformation process. Above annealing temperatures of about 200 °C there was a rapid increase in crystallite size to about 100 nm at 315 °C; similar behaviour has also been observed in which α-form CuPc films were heated to 300 °C when the diffraction patterns became sharper and the crystallites larger [28.124].

Some general conclusions concerning the dependence of grain size in vapour-deposited polycrystalline films on various film attributes have been summarised by *Chopra* [28.18]. The major feature determining mean grain size is the surface mobility of adsorbed atoms and clusters during the deposition process. A high surface mobility will allow adsorbed atoms to

move large distances before being incorporated into growing nuclei, resulting in a relatively low concentration of nuclei and thus larger crystallites. The substrate temperature is the most obvious factor contributing to high mobility, and therefore grain size tends to increase with increasing substrate temperature. We have already seen that epitaxy requires a minimum substrate temperature; this too is a consequence of the surface mobility requirement. The total film thickness obviously sets an upper limit on the crystallite size, and therefore the grain size increases in general with film thickness. Subsequent annealing at temperatures greater than the substrate temperature during deposition can also cause an increase in the mean crystallite size as was shown in Fig. 28.14, as surface atoms augment the crystallites and grains coalesce. The dependence of grain size on deposition rate is not consistent between different materials and substrates. Frequently there is an increase with increasing deposition rate [28.18], although a decrease has been observed in some cases, such as in CdTe films where the establishment of a higher concentration of adsorbed nuclei led to the growth of finer grains [28.38].

The interplay between the various deposition parameters can have a profound effect on the structure of the films. This is illustrated particularly well in Fig. 28.15 [28.125], for cadmium arsenide (Cd_3As_2) films evaporated onto mica substrates. Both the substrate temperature T_s and the growth rate v were varied, with the latter covering a wide range. Diffraction patterns indicated that the crystalline films were of the lower temperature tetragonal α-phase of Cd_3As_2; the structure of this phase is documented in the literature [28.126] and the planar spacings are given by (28.43). Amorphous films recrystallised following interaction with the electron beam in the electron microscope and also reverted to a tetragonal structure. The figure shows that, over the substrate temperature and deposition rate ranges investigated, the films could have an amorphous, polycrystalline or well-oriented crystal structure. Below approximately 125–145 °C the films were amorphous, with polycrystalline films resulting when this temperature was exceeded. The amorphous-to-crystalline transition was only weakly dependent on the deposition rate. However, the epitaxial temperature, which delineates polycrystalline and epitaxial films, increased with increasing deposition rate. For deposition rates less than about 4 nm/s (40 Å/s) there was a direct transition from the amorphous to the well-oriented crystalline structure, whereas at higher rates there was a transitional polycrystalline region. The preferred orientation of the films was [001] with the c-axis of the tetragonal structure perpendicular to the plane of the substrate. Also shown on the figure are examples of X-ray diffraction patterns for the crystalline, polycrystalline and amorphous regions. These are characterised, respectively, by discrete reflection points, *spotty* rings and diffuse rings.

Finally, a brief discussion on amorphous films is appropriate. These are films which show no evidence of a regularly repeated crystalline structure, i. e., they do not exhibit long-range order. We have already seen that

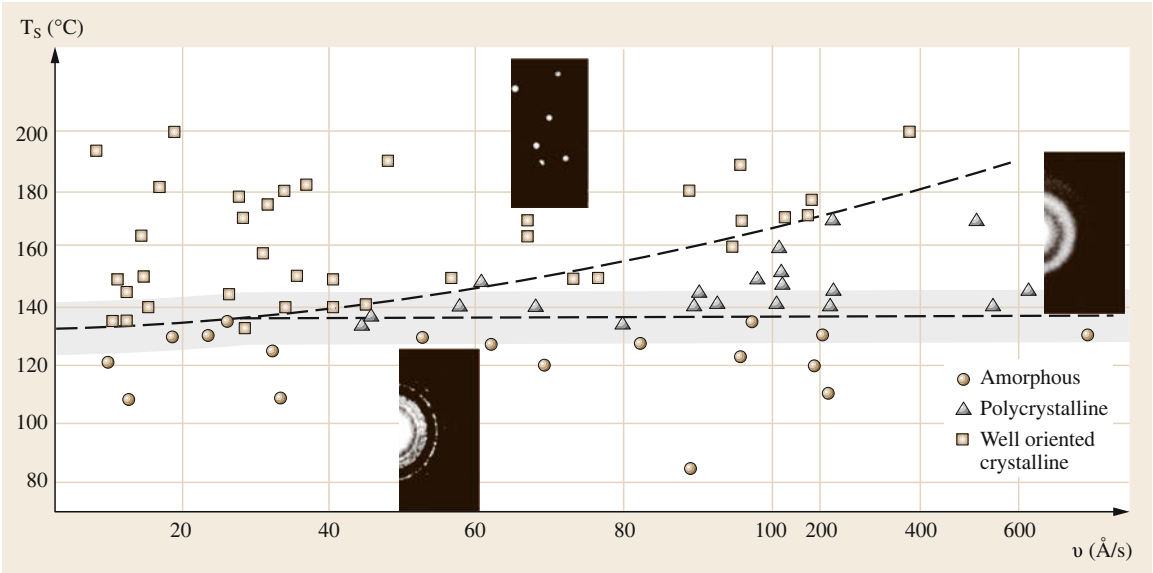

Fig. 28.15 Effects of film growth rate υ and substrate temperature T_s on the structure of Cd_3As_2 films vacuum-evaporated onto mica substrates. (After [28.125] with permission from Elsevier Science)

in Cd_3As_2 films (Fig. 28.15), a relatively low substrate temperature during deposition leads to the growth of amorphous films. This is a general rule, applicable to most materials, and is basically the opposite to the condition for epitaxy – the deposition of amorphous films is encouraged if the surface mobility of atoms on the substrate is low. This causes the adsorbed atoms to be incorporated into the films almost at the point of impact, rather than after diffusion across the substrate surface and joining a growing nucleus. High deposition rates also predispose atoms to remain at their impact position within the growing film – they have only a very limited time to diffuse before they are locked into the growing film structure. These considerations are pertinent to the deposition of amorphous metallic films, which require substrate temperatures to be lowered to liquid-nitrogen temperature or below, and also to elemental chalcogenide and semiconductor films (Ge and Si) and carbon, all of which have a sufficiently low surface mobility at room temperature. A table giving examples of amorphous thin film materials, their preparation methods, and the transition from the amorphous to a crystalline phase is given by *Maissel* and *Francombe* [28.16]. The amorphous state is metastable, requiring some thermal energy to transfer it to a crystalline state.

Another method of producing amorphous films is the incorporation of residual gases during deposition. A relatively high pressure of oxygen ($\approx 10^{-3}$ Pa) can cause oxidation of the evaporant. Large-scale crystallites of metals are then unable to form. The admission of nitrogen during sputtering of refractory metals is also sufficient to result in the deposition of an amorphous phase [28.1].

Since the structure of amorphous materials do not possess any long-range order, it is necessary to describe the short-range order using some function which can be determined directly from diffraction experiments. The radial distribution function $J(r)$ is defined as the number of atoms lying at a distance between r and $r + \mathrm{d}r$ from the centre of an arbitrary atom at the origin [28.127]. It is given by

$$J(r) = 4\pi r^2 \rho(r) \,. \tag{28.49}$$

Here, $\rho(r)$ is an atomic pair correlation function, which is equal to zero at values of $r < r_1$, where r_1 is the average nearest neighbour interatomic separation, $\rho(r)$ is equal to the average value of density ρ^0 at large values of r where the material becomes homogeneous. Between these values $\rho(r)$ is oscillatory, with the peaks in the distribution corresponding to the average interatomic separations [28.127]. $J(r)$ also shows oscillations superimposed on the average density parabola $4\pi r^2 \rho^0$, and the area under a particular peak gives

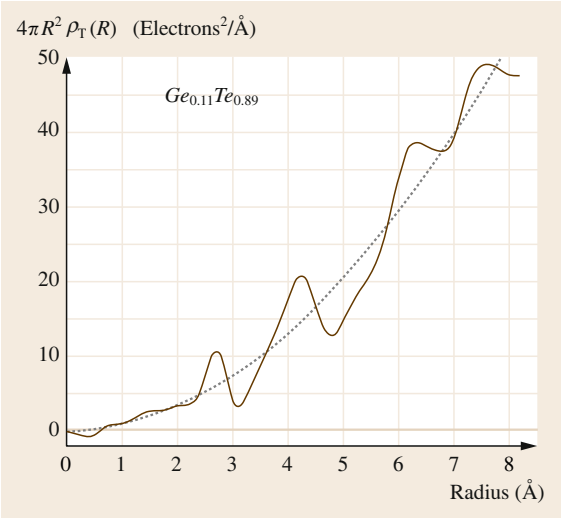

Fig. 28.16 Calculated radial distribution function for a sample of composition $Ge_{0.11}Te_{0.89}$. The *dashed curve* represents the contribution of the average electron density. (After [28.128] with permission from Elsevier Science)

the coordination number for the given shell of atoms. The coordination number represents the number of nearest neighbours in the structure. An example of a radial distribution function, derived from X-ray data, for thin films of the compound Ge_xTe_{1-x} where $x = 0.11$, is shown in Fig. 28.16 [28.128]. For materials having covalent bonds the coordination number is four, whereas for amorphous metals, which generally crystallise in close-packed structures, the coordination number is higher. For covalently bonded materials, the atoms tend to arrange themselves in tetrahedra, which in the amorphous state interconnect at their apexes. However, the apexes themselves interconnect within the material in a random manner, whereas the tetrahedra dimensions are effectively determined by the size of the atoms. Thus there is no long-range order because of the random interconnections, but the short-range order survives, and is similar to that for the corresponding crystalline material. *Bosnell* [28.129] has described the important amorphous semiconducting thin films, and classified them into three major categories: covalent noncrystalline solids, semiconducting oxide glasses and dielectric films. The importance of these materials, in particular their electrical properties, cannot be overestimated. The standard text on this subject [28.130] gives copious information on their electrical properties, as well as their structures and radial distribution functions. Local atomic order in amorphous films is discussed in the literature by *Dove* [28.131], with the primary emphasis being on data derived from electron diffraction. This work also gives the theory behind the radial dis-

tribution function, and provides a wide review of radial distribution functions measured in many systems performed prior to the date of the review.

From the foregoing discussion and examples, it should be clear that the crystallographic structure of thin films, whether epitaxial, polycrystalline or amorphous, depends heavily on the deposition conditions. In turn the film structure strongly influences the mechanical, thermal, optical and electronic properties.

28.2.3 Morphology

Perhaps the most striking morphological characteristic observed in thin films grown by the physical vapour deposition techniques is that of the columnar grain structure. Electron microscopy frequently reveals that high-density regions tend to grow in parallel columns. They tend to develop when the surface mobility of adsorbed atoms is relatively low, so that the area of the base of the columns is small. Further growth of the grains is away from the substrate. The direction of column growth is not necessarily perpendicular to the substrate surface, although it frequently is for depositing material arriving at normal incidence. For oblique incidence it has been observed that the columns are oriented away from the substrate normal and towards the vapour source, although not necessarily pointing directly towards it. If α is the angle between the substrate normal and the vapour stream, and β is the angle between the substrate normal and the direction of the columns, it has been shown experimentally that β is usually less than α. The tangent rule [28.133] relates these two angles and is given by

$$\tan\alpha = 2\tan\beta \qquad (28.50)$$

and was found to be followed for the case of directly evaporated aluminium. In experiments on CdS films, *Hussain* [28.134] deposited films of thickness up to 100 μm with angle of incidence α varying between 0 and 60°. Up to a certain film thickness the *c*-axis of the grains was perpendicular to the direction of vapour incidence, but above this thickness the *c*-axis started to shift towards the substrate normal, eventually becoming aligned with it. Etching of a thin film deposited at oblique incidence confirmed that the top layers of the film had their *c*-axis normal to the substrate, whereas in the bottom layers it was parallel to the direction of vapour incidence. In other work on this material [28.135] similar thickness-dependent orientation effects have been reported. In this case, films of thickness a few tens of nanometres had randomly orientated crystallites, while those of thickness of about 20 μm were aligned with the *c*-axis normal to the substrate.

Evaporated CdS films also show an interesting morphology on a somewhat larger scale, which is illustrated in Fig. 28.17 [28.132]. This illustrates features which are evident in many different types of thin films. The top surface of as-deposited films of thickness 25–30 μm were observed by scanning electron microscopy to consist of partially faceted hills with a height of 5 μm and a width of about 15 μm at the base. These workers also determined the grain size and crystal defect structure using transmission electron microscopy. The grain size was about 2 μm at the top and at the centre of the films, but was only of the order of 10–50 nm at the back surface adjacent to the substrate. Typical dislocation densities were of the order of 10^{13} m^{-2} (10^{9} cm^{-2}). Ultrafine-grain regions of 2–15 μm in diameter were observed. These were thought to be spits of material rapidly ejected from the source. Similar features have also been observed in this laboratory [28.119]. The partially faceted protrusions were reported, and cracks in the films were also present, as a result of differential thermal contraction between the CdS films and the glass substrates during cooling. Larger regions of CdS were seen, which were considered to have been ejected from the evaporation boat during deposition. This phenomenon has been referred to as *spattering* or *splattering* by *Stanley* [28.136], and its elimination is an important goal for deposition processes operating at higher temperatures.

In early work on CdTe films [28.137] photovoltages were measured when there was an angle between the vapour stream and the normal to the substrate. This led

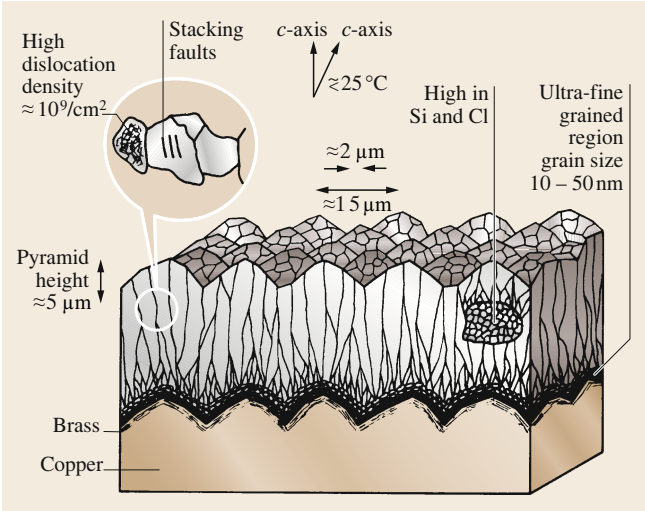

Fig. 28.17 Schematic representation of evaporated CdS film microstructure inferred from scanning electron microscopy studies. (After [28.132] with permission from Elsevier Science)

to the suggestion that in this case the film growth was directionally anisotropic where the nucleating material depositing on a heated substrate has sufficient surface mobility to form islands rather than a uniform thin film. Additional material arrives at an angle, shadowing the far side of the island from the deposition source, and the shadowed side grows relatively slowly and is well ordered, while the exposed face grows towards the vapour source. When islands begin to touch each other there is expected to be a mismatch, leading to a disordered state in the region between the crystallites. Each interface will therefore have an ordered and a disordered side and at the interface between grains a photovoltage develops. Photomicrographs of epitaxial CdTe layers grown by the close-space technique [28.138] revealed smooth epitaxial layers when the deposition was on to (100), (110) and (111)Cd oriented substrates, but large hillocks grew on (111)Te substrate faces. When grown on mica substrates [28.139] it was observed that the morphology was significantly affected by the composition of the incident vapour phase. This was characterised by the ratios γ_{Cd} and γ_{Te}, which depended on the ratio of the actual concentration to the stoichiometric concentration of the Cd atoms or the Te_2 molecules in the gas phase. When $\gamma_{Cd} = 53$ when CdTe and Cd were co-evaporated the films were of high quality consisting of large crystallites with degenerated (111) faces. When CdTe and Te were co-evaporated and $\gamma_{Te} = 12$ formations resembling dendrites were observed.

CdSe film morphologies have been observed by several workers. *Tanaka* [28.140] prepared films using Ar and H_2 sputtering gases; some films were subsequently annealed in Ar. Microscopic examination showed that sputtering in H_2 gas led to uniform grain growth of the films over the whole substrate surface, while films sputtered and annealed using Ar gave rise to geometric pillars and a textured structure. An investigation of the optimum conditions for obtaining CdSe epitaxial layers on (0001) oriented sapphire substrates was performed by *Ratcheva-Stambolieva* et al. [28.141]. For substrate temperatures up to 460 °C the layers were polycrystalline, from 460 to 530 °C a small degree of preferred orientation was observed, with a more significant textured structure for temperatures of 530–570 °C. At higher temperatures of 570–620 °C a monocrystalline structure was obtained, varying in its degree of perfection depending on the actual temperature and the growth rate. Hexagonal pyramids with peaks, regular or irregular facets and flat tops were also identified. RF-sputtered CdSe films [28.142] were porous when deposited at a substrate temperature of 550 °C onto vitreous silica. When deposited onto substrates of single-crystal sapphire the surface appeared shiny, and showed features of hexagonal flat tops and pyramids with edge lengths in the range 1–5 μm.

We finally look at the morphological characteristics of another cadmium compound, Cd_3As_2. Evaporated films of this material have been investigated by *Jurusik* and *Żdanowicz* [28.143] using electron microscopy. It was found that the microstructure of the films was strongly dependent on the substrate temperature T_s. This type of behaviour is frequently addressed in terms of a zone model, and examples of some of these for other materials are discussed by *Ohring* [28.19]. In Cd_3As_2 the microstructures were interpreted in terms of a simple three-zone model in which the structure was correlated with the ratio T_s/T_m, where $T_m = 994$ K is the melting point of Cd_3As_2 [28.143]. They found that for $T_s/T_m \leq 0.4$ the films were amorphous, consisting of spherical or elongated fibrous-like clusters, or were uniform with a large number of pores or cavities. For $0.4 < T_s/T_m < 0.5$ columnar growth was identified, while for $T_s/T_m \geq 0.5$ films with large crystallites and clear grain boundaries were observed. These structures are illustrated in Fig. 28.18 [28.143]. More recently a very detailed study was performed on amorphous Cd_3As_2 films evaporated onto substrates maintained at 293 K [28.144, 145]. It was found that the size of post-nucleation islands was a function of the substrate temperature, type of substrate and the deposition rate. Furthermore the shape and type of growth of the islands varied with these parameters. At a low deposition rate (1 nm/s) the initial nuclei grew until a certain size was reached, and new nuclei started to grow around the original islands. For a moderate deposition rate (3.5 nm/s) the initial nuclei grew into islands which in turn increased in size until the islands had only narrow interfaces between them. Some islands formed polygons. Films deposited at a high rate (50 nm/s) consisted of small islands connected by relatively large low-density areas. Films deposited at low rates were of approximately stoichiometric proportions (i. e., 40 at. % As) while those deposited at higher rates had excess arsenic (typically 51.8 at. % As). It was suggested that the growth process could be considered as a superposition of two growth stages, as shown in Fig. 28.19 [28.144]. The vapour flux onto the substrate is denoted by S_1 and the adatom flux over the substrate surface by S_2. In the first stage of growth the initial nuclei enlarge owing to the adatom flux S_2. The second stage of growth incorporates atoms immediately from the incident flux S_1. This is usually very slow, but increases as the island surface area increases. At this stage branched complex islands or only compact islands grow as the result of a shadowing mechanism. When the islands touch each other the molecular flux S_2 over the substrate surface is eliminated, and the films grow in thickness

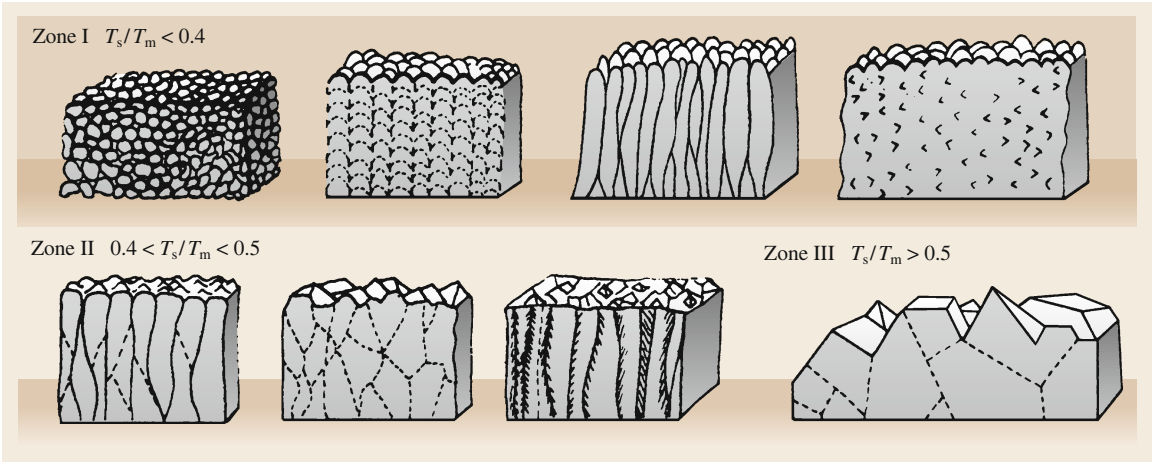

Fig. 28.18 Schematic three-zone model for the temperature dependence of the growth morphology in evaporated Cd_3As_2 films. T_s/T_m represents the ratio of the substrate temperature to the melting point of Cd_3As_2. (After [28.143] with permission from Elsevier Science)

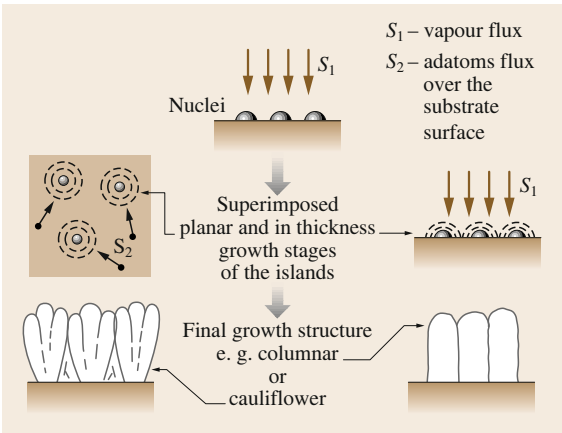

Fig. 28.19 Post-nucleation growth in evaporated Cd_3As_2 films considered as a consequence of two superimposed (planar and thickness) growth stages. (After [28.144] with permission from Elsevier Science)

as the result of the incident flux S_1 and the structure initiated in the earlier stage (i. e., large branched or smaller compact islands). The final growth structure gives rise to cauliflower-like or columnar structures. In later work [28.145] Cd_3As_2 films were evaporated from bulk crystallites of Cd_3As_2 or $CdAs_2$. For films grown from the Cd_3As_2 source a pronounced columnar structure was observed, whereas those evaporated from the $CdAs_2$ source grew uniformly, and the columnar structure was absent. In the latter case the initial island structure was not observed in the early stages of film growth. It was concluded that prerequisites for columnar growth were a limited surface mobility and an oblique component in the deposited flux, particularly where the films are deposited normally to the substrate surface.

In this section some of the morphological characteristics of some cadmium compound films prepared by PVD methods have been described. The emphasis in this discussion of the films was not primarily because of their usefulness as semiconductors in various applications, bur because they exhibit many features typical of a wide range of other film materials. Surface mobility of atomic species on the substrate during deposition is clearly of great importance, as this tends to control the grain size at the substrate interface, while the angle of vapour incidence relative to the substrate normal is an important factor in determining the major direction of crystallite growth and whether a columnar structure develops. Shadowing of the vapour stream by islands during film growth can lead to differential growth rates at different points on the film surface. Bulk diffusion and desorption also contribute to the film morphology variations [28.19]. The morphological characteristics of many materials may be explained using zone models in which the substrate temperature and other variables, such as sputtering gas pressure, conspire to determine the overall morphology via the mechanisms detailed above. The morphology of thin films is particularly rich, and an important factor in influencing film properties.

28.2.4 Raman Spectroscopy

Raman spectroscopy is a nondestructive spectroscopic technique used to study the vibrational, rotational, and other low-frequency modes of a system based on the inelastic scattering of a monochromatic light. A laser

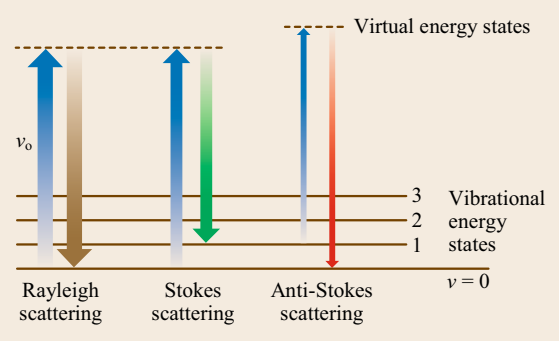

Fig. 28.20 Schematic illustration of the vibrational energy states involved in Raman scattering. The thickness of the *arrows* is a rough indication of the signal strength. (After [28.146])

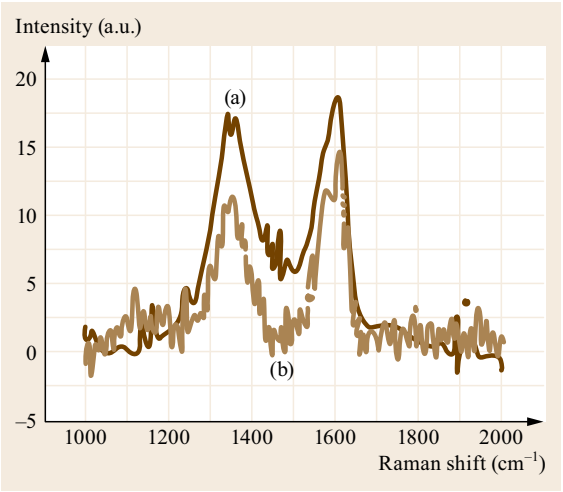

Fig. 28.21 Raman spectrum for the sample (a) freshly prepared before (b) RF hydrogen plasma treatment at 60 W for 30 min

light, usually in the visible, near-infrared or near-ultraviolet range, is used as the incident beam and interacts with molecular vibrations, phonons, and other excitations. The interaction between the laser beam and the electrons and bonds of a molecule results in an excitation of the molecule from the ground state to a virtual energy state. The relaxation of the molecule is accompanied by the emission of a photon and a change in rotational or vibrational state of the molecule. The energy difference between this new state and the original state causes a shift in the emitted photon frequency. A schematic illustration of vibrational energy states involved in Raman scattering is shown in Fig. 28.20.

Raman scattering is regarded as being inelastic because of an energy transfer during the photon–molecule interaction. When the incident photon with a frequency of ν_0 is absorbed by a Raman-active molecule in the ground vibrational state, some of the photon energy with a frequency of ν_m is transferred to the molecule and the scattered light is shifted to the lower frequency of $\nu_0 - \nu_m$. This shift in the frequency is also known as the Stokes shift. If the photon energy is absorbed by a molecule which is already in the excited state, the excess amount of energy is released from the molecule upon relaxation and the resulting frequency of the scattered light is increased to $\nu_0 + \nu_m$, or the anti-Stokes frequency. The Raman shift is typically expressed in wavenumbers. The following formula relates the wavenumbers of shift in the spectrum to the spectral wavelengths [28.106]

$$\Delta\omega = \left(\frac{1}{\lambda_0} - \frac{1}{\lambda_1}\right) \times 10^7 \,, \tag{28.51}$$

where $\Delta\omega$ is the Raman shift in cm^{-1}, and λ_0 and λ_1 are the excitation and Raman spectrum wavelengths in nm, respectively. Since the vibrational information obtained from Raman spectroscopy is specific to the chemical bonds and the symmetry of the molecules, it can be useful in order to identify the chemical composition of the material.

Commercially available graphene oxide (GO) nanoparticles have been utilized to produce solution-processed thin films of GO on silicon substrates. The films were then reduced by 60 W RF hydrogen plasma at room temperature for 30 min in an ordinary laboratory environment. Figure 28.21 shows the Raman spectrum for the samples before and after plasma treatment. The structural changes occurring due to plasma treatment could be evidenced from the Raman spectrum. The characteristic D and G bands corresponding to 1350 and 1578 cm^{-1} were present in both samples.

The D band response is related to defects or any sort of translational disorder, whereas the G band corresponds to scattering from the E_{2g} mode of the sp^2 graphitic domain. It can be seen in the figure that plasma treatment leads to a shift in the D and G band from 1348.3 to 1357.7 cm^{-1} and 1594.7 to 1593.5 cm^{-1}, respectively. The width of the D band seems to change from 76.12 to 130 cm^{-1}, whilst the G band width also changes from 60.25 to 81.693 cm^{-1}. The present sample shows an increase in intensity ratio of both the D and G band from 0.77 to 0.93 with plasma treatment indicating a decrease of the in-plane sp^2 graphitic domain size. This may imply that plasma treatment has induced a decrease in the size of the in-plane sp^2 graphitic domain, an increase in edge planes, and also an increase in disorder in the samples [28.147].

The band at 437 cm^{-1} in the Raman spectra in Fig. 28.22 for spin-coated zinc oxide thin films on

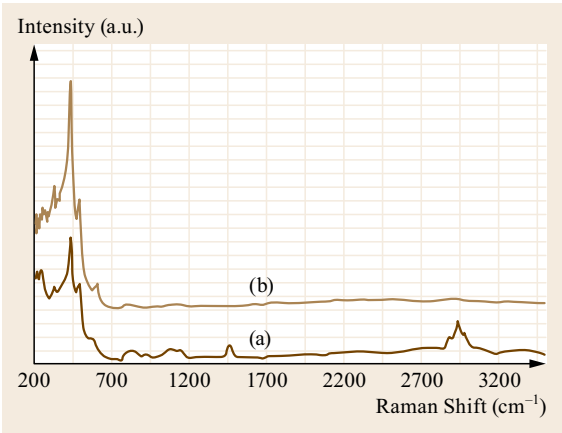

Fig. 28.22 Raman scattering for (a) as-deposited and (b) annealed ZnO coatings

fluorine-doped tin oxide (FTO) coated glass slides may be identified as the nonpolar E_2 mode of the scattering. This marker band became sharper on annealing indicating the dominance of hexagonal crystalline structure of wurtzite ZnO. The polar E_1 mode due to the interaction between electrons and transverse-optical phonons was observed as a shoulder at 549 cm^{-1} for the as-deposited spectrum. The polar A_1 mode bands at 748, 1048, and 1447 cm^{-1} arising from the superimposition of longitudinal-optical and transverse-optical phonons are found to be considerably diminished in intensity on annealing due to the elimination of impurities or defects in the crystals.

Bands in the range 2800 and 3000 cm^{-1} were observed indicating the presence of the hydroxyl groups in the hydrated as-deposited film. The peak at 2943 cm^{-1} disappeared upon annealing of the film [28.148].

28.3 Properties

As mentioned in the introduction, the properties covered in this section are restricted to the optical and electrical properties. Moreover, only the very fundamental properties, which are a direct consequence of the thin-film nature of the material, are covered. Thus the more advanced features, such as those exhibited by specific classes of materials, individual elements or compounds, and electronic, optical and optoelectronic devices are not normally discussed, although many of these are considered elsewhere in this Handbook. The basic thin-film properties, which have been exploited in many of these developments are stressed. Examples include the use of thin films in layers or stacks in antireflection coatings and mirrors [28.30], the contribution of grain boundaries in conducting thin films to the resistivity of tracks and connections in integrated circuits, the importance of high-field conduction in some electronic devices [28.17], and the possible influence of high-field conduction in nanostructures [28.11].

28.3.1 Optical Properties

This section comprises an introduction to the main optical properties of thin films, starting with a discussion of the properties of nonabsorbing single films at normal and non-normal incidence, and then considering modifications due to absorption. Finally a brief discussion of the use of multilayer film stacks is given. Thin-film optics is a particularly wide field, and readers interested in further details and a more in-depth analysis are referred to one of the standard texts [28.30, 149–151], or indeed to most general textbooks on optics, nearly all of which cover thin films in some detail. The general description of optical constants focused on electronic materials and various techniques for their determination in the case of bulk and thin film materials is also given in this handbook in Chap. 3. As mentioned earlier, optical effects in thin films were first recorded in the 17th century, which predates by two centuries the emergence of Maxwell's equations, which encapsulate the behaviour of all electromagnetic radiation, including visible light. The boundary conditions at the interface between two different optical media are derivable directly from Maxwell's equations, and allow us to calculate the reflection and transmission coefficients for the amplitude of the electromagnetic wave at the interface. These are termed the Fresnel coefficients.

Figure 28.23a shows the simplest situation, where a beam of light in a medium having refractive index n_0 is incident at an angle φ_0 to the normal on a film of refractive index n_1. The following expressions for the Fresnel coefficients apply to all individual interfaces in a structure, and for all values of the refractive index. At this stage in the discussion we assume that the materials are isotropic and nonabsorbing. At the interface the electromagnetic radiation is refracted into the medium of index n_1 at an angle φ_1, with a reflected component directed back into the incident medium at an angle φ_0. Conventionally, the coefficients are quoted for components of the light beam resolved parallel (denoted by p) and perpendicular (denoted by s) to the plane of incidence. Therefore there are two reflection coefficients r_{1p} and r_{1s}, and two transmission coefficients, t_{1p} and t_{1s}. The 1 in the subscripts in this notation refers to the first interface, i. e., between the materials with refractive indices n_0 and n_1 in this case. More complex systems will

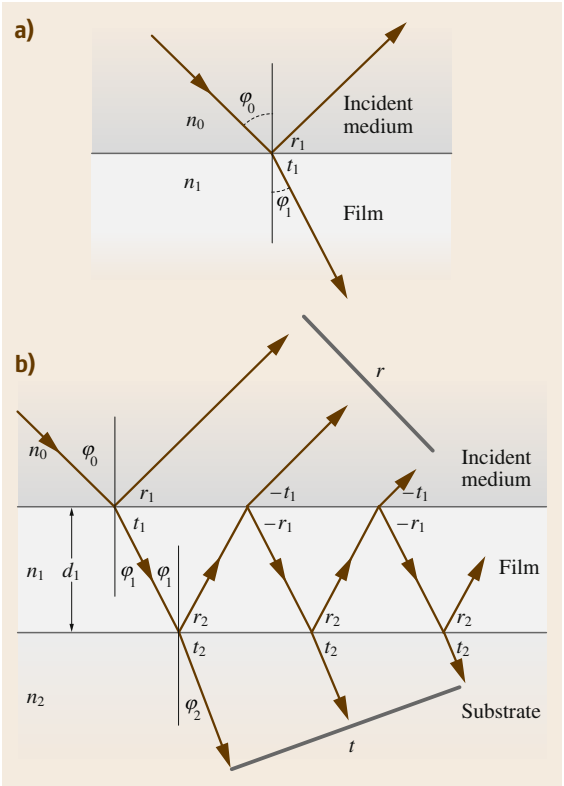

Fig. 28.23 **(a)** Reflection and transmission at a single interface between two media with refractive indices n_0 and n_1. r_1 and t_1 represent the amplitude reflection and transmission coefficients at the interface (the Fresnel coefficients). **(b)** Total reflection and transmission as the result of multiple reflection and transmission through a nonabsorbing thin film of thickness d_1 and refractive index n_1 deposited on a substrate of refractive index n_2. The Fresnel coefficients are indicated at each transit of a boundary, and change sign if the direction of incidence is reversed. r and t represent the total amplitude of reflection and transmission, respectively, each obtained by summing the amplitudes of an infinite number of components, although only three are shown ►

have more than one interface, where 2, 3, etc., signify the second or third interfaces. The Fresnel coefficients for reflection are [28.1, 15]

$$r_{1p} = \frac{n_1 \cos\varphi_0 - n_0 \cos\varphi_1}{n_1 \cos\varphi_0 + n_0 \cos\varphi_1} ,$$

$$r_{1s} = \frac{n_1 \cos\varphi_1 - n_0 \cos\varphi_0}{n_1 \cos\varphi_1 + n_0 \cos\varphi_0} , \qquad (28.52)$$

and those for transmission are

$$t_{1p} = \frac{2n_0 \cos\varphi_0}{n_1 \cos\varphi_0 + n_0 \cos\varphi_1} ,$$

$$t_{1s} = \frac{2n_0 \cos\varphi_0}{n_1 \cos\varphi_1 + n_0 \cos\varphi_0} . \qquad (28.53)$$

Clearly these coefficients reduce to

$$r = \frac{n_1 - n_0}{n_1 + n_0} , \quad t = \frac{2n_0}{n_1 + n_0} \qquad (28.54)$$

for the case of normal incidence where all the cosine terms become unity. There is no difference in this case between the coefficients for the p and s components. An expression for the irradiance (or energy) reflectance at the interface R can be obtained by evaluating rr^*, where r^* is the complex conjugate of r. For nonabsorbing films r is real and this reduces to r^2, and gives for normal incidence

$$R = \left(\frac{n_1 - n_0}{n_1 + n_0}\right)^2 . \qquad (28.55)$$

A similar expression for the irradiance (energy) transmittance T at the boundary can also be derived from t, but in this case the incident and transmitted beams are in different media, and the expression is not simply t^2, but includes the ratio n_1/n_0. Full details are given elsewhere [28.18, 150].

We consider now the slightly more complex situation of a thin film of thickness d_1 and refractive index n_1 deposited on a substrate of refractive index n_2. In this case the value of n_0 for the incident medium will usually be the free-space value of unity. There will be multiple reflections as shown in Fig. 28.23b. It is clear that the total amplitude of the reflected beam is given by summing the amplitudes of the individual reflections into the incident medium, while the total amplitude of the transmitted beam is obtained by summing the amplitudes of the transmitted components into the substrate. In traversing the film of thickness d_1, the radiation undergoes a change in phase, which is accounted for by a *phase thickness* δ_1, given by

$$\delta_1 = \frac{2\pi}{\lambda} n_1 d_1 \cos\varphi_1 , \qquad (28.56)$$

where λ is the wavelength in vacuum. In each case the summations lead to infinite series. These involve $\exp(-i2\delta_1)$ for reflection, where the beam traverses the film an even number of times, and $\exp(-i\delta_1)$ for transmission, where the beam traverses an odd number of times. The results of these summations give the reflection coefficient (sometimes called the reflectance amplitude) r and transmission coefficient t, respectively, as

$$r = \frac{r_1 + r_2 \exp(-2i\delta_1)}{1 + r_1 r_2 \exp(-2i\delta_1)} \qquad (28.57)$$

and

$$t = \frac{t_1 t_2 \exp(-\mathrm{i}\delta_1)}{1 + r_1 r_2 \exp(-2\mathrm{i}\delta_1)} \,. \tag{28.58}$$

(These correspond to (3.86) and (3.87) in Chap. 3. Note also that the three refractive indices were n_1, n_2 and n_3 whereas n_0, n_1 and n_2 are used here.) In this case r_1 and t_1 represent the Fresnel coefficients between n_0 and n_1, and r_2 and t_2 the coefficients between the media n_1 and n_2. Depending on whether we are considering parallel or perpendicular polarisation (p or s) the relevant Fresnel coefficients from (28.52) and (28.53) should be used in these expressions. Equation (28.57) and (28.58) refer to the ratios of the *amplitudes* of the reflected and transmitted beams to that of the incident beam. In terms of the beam irradiances (or beam energies), the reflectance R and the transmittance T may be defined as the ratios of the reflected and transmitted beam energies to that of the incident energy. The energies of the reflected and transmitted beams are given by $n_0 RR^*$ and $n_2 tt^*$ respectively, where r^* and t^* represent the complex conjugates of r and t. We then obtain

$$R = \frac{n_0}{n_0} rr^* = \frac{r_1^2 + r_2^2 + 2r_1 r_2 \cos 2\delta_1}{1 + r_1^2 r_2^2 + 2r_1 r_2 \cos 2\delta_1} \tag{28.59}$$

for the reflectance, and

$$T = \frac{n_2}{n_0} tt^* = \frac{n_2}{n_0} \frac{t_1^2 t_2^2}{\left(1 + 2r_1 r_2 \cos 2\delta_1 + r_1^2 r_2^2\right)} \tag{28.60}$$

for the transmittance. Although these latter two expressions are reasonably compact, when the four Fresnel coefficients are substituted they become somewhat unwieldy. However, for the important case of normal incidence, where (28.54) applies, and where (28.56) simplifies to $\delta_1 = (2\pi/\lambda) n_1 d_1$, they reduce to still fairly long expressions, but involving only the three refractive indices and δ_1, i. e.,

$$\begin{aligned} R = \Big[& \left(n_0^2 + n_1^2\right)\left(n_1^2 + n_2^2\right) - 4n_0 n_1^2 n_2 \\ & + \left(n_0^2 - n_1^2\right)\left(n_1^2 - n_2^2\right)\cos 2\delta_1 \Big] \Big/ \\ & \Big[\left(n_0^2 + n_1^2\right)\left(n_1^2 + n_2^2\right) \\ & + 4n_0 n_1^2 n_2 + \left(n_0^2 - n_1^2\right)\left(n_1^2 - n_2^2\right)\cos 2\delta_1 \Big] \end{aligned} \tag{28.61}$$

and

$$\begin{aligned} T = 8n_0 n_1^2 n_2 \Big/ \Big[& \left(n_0^2 + n_1^2\right)\left(n_1^2 + n_2^2\right) + 4n_0 n_1^2 n_2 \\ & + \left(n_0^2 - n_1^2\right)\left(n_1^2 - n_2^2\right)\cos 2\delta_1 \Big] \,. \end{aligned} \tag{28.62}$$

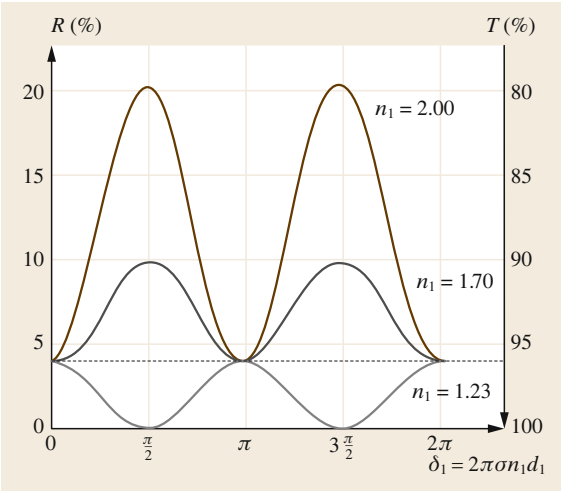

Fig. 28.24 Variation of the energy reflectance R and transmittance T with phase thickness δ_1 for a nonabsorbing film at normal incidence for various film indices n_1, with $n_0 = 1$ and $n_2 = 1.5$. The wavenumber σ is the reciprocal of the wavelength in vacuum λ. (After [28.152] with permission from Elsevier Science)

The variations of R and T with δ_1 are shown in Fig. 28.24 [28.152] for normal incidence, where the refractive index of the incident medium $n_0 = 1$ and that of the substrate $n_2 = 1.5$. These correspond to air and glass respectively. Similar plots of these variations as a function of optical thickness $n_1 d_1$ expressed as multiples of the wavelength λ are also common in the literature [28.1, 16, 150], where an optical thickness equal to the wavelength corresponds to $\delta_1 = 2\pi$. The figure shows curves for three values of the film refractive index of 2.00, 1.70 and 1.23. For the first two of these $n_0 < n_1 > n_2$ and maxima in reflectance occur at $\pi/2$ and $3\pi/2$ with minima at 0, π and 2π, while for the third $n_0 < n_1 < n_2$ and the positions of the maxima and minima are reversed. In general the maximum and minimum reflectance values $R_{\max}$ and $R_{\min}$, depend on the relative values of n_0, n_1 and n_2. For the film index greater or less than those at both its boundaries, i. e., $n_0 < n_1 > n_2$ or $n_0 > n_1 < n_2$, we obtain

$$R_{\max} = \left(\frac{n_1^2 - n_0 n_2}{n_1^2 + n_0 n_2}\right)^2 \,, \quad R_{\min} = \left(\frac{n_2 - n_0}{n_2 + n_0}\right)^2 \tag{28.63}$$

with maxima occurring when δ_1 is an odd multiple of $\pi/2$ (optical thickness $n_1 d_1$ an odd number of quarter-wavelengths) and minima when δ_1 is an even multiple of $\pi/2$ ($n_1 d_1$ an even number of quarter wavelengths). For the film index intermediate between those at its

boundaries, i. e., $n_0 < n_1 < n_2$ or $n_0 > n_1 > n_2$ these results are reversed, and we obtain

$$R_{\max} = \left(\frac{n_2 - n_0}{n_2 + n_0}\right)^2 , \quad R_{\min} = \left(\frac{n_1^2 - n_0 n_2}{n_1^2 + n_0 n_2}\right)^2 \tag{28.64}$$

with maxima occurring when δ_1 is an even multiple of $\pi/2$, and minima at odd multiples (or maxima for $n_1 d_1$ an even number of quarter wavelengths and minima an odd number). Equation (28.64) predicts that zero reflectance occurs when $n_1 = \sqrt{n_0 n_2}$, and for the refractive index values of Fig. 28.24 give $n_1 = 1.23$. Thus a simple *anti-reflection coating* can be made by using a film of this index with optical thickness $\lambda/4$. This is clearly evident from the figure at the points where δ_1 has values of $\pi/2$ and $3\pi/2$. Another point which emerges from the figure is that if the refractive index of the film is the same as that of the glass, the system behaves as if the glass is uncoated. This situation is shown by the dotted line in the figure. Here the reflectance is 4%, exactly as predicted by (28.55) for an uncoated substrate (i. e., $n_0 = 1$ and $n_1 = 1.5$).

If the electromagnetic light wave is attenuated by a film layer, that layer is said to be *absorbing*, in contrast to the *transparent* layers considered previously. Providing the incident light beam is incident *normally* on the surface of the absorbing medium, the theory described above may be applied, with the proviso that the refractive index n is replaced by a *complex refractive index* $\boldsymbol{n} = n - \mathrm{i}k$. The quantity k is called the *extinction coefficient*, and characterises absorption of energy within the film. Substitution of the complex refractive index in the appropriate expressions for the Fresnel coefficient of (28.54), and in the expression for the phase thickness of (28.56) at normal incidence allows the reflection coefficient r to be obtained. The irradiance (energy) reflectance R can be obtained by substituting the complex expressions for r and δ directly into (28.57) and evaluating rr^*. For more than two or three layers the results become intensely unwieldy, and matrix methods as mentioned below are considerably more useful. A simple example of the use of the complex refractive index will suffice. If we take the case of an incident beam in a nonabsorbing medium such as air with refractive index n_0, incident upon an absorbing medium with complex refractive index $\boldsymbol{n}_1 = n_1 - \mathrm{i}k_1$, the reflectance can be determined by replacing n_1 by $n_1 - \mathrm{i}k_1$ in (28.54) and evaluating rr^*. In this case the energy reflectance at the boundary becomes

$$R = \frac{(n_0 - n_1)^2 + k_1^2}{(n_0 + n_1)^2 + k_1^2} \tag{28.65}$$

in contrast to the result of (28.55) for a nonabsorbing medium.

In general, in absorbing films, the planes of constant phase are not parallel to the planes of constant amplitude for the electromagnetic wave disturbances. Only for the special case of normal incidence is this true, and thus in absorbing films it is usual to consider normal incidence only. The general case of oblique incidence is discussed in the standard texts on the optics of thin films [28.149, 150]. The behaviour of the energy reflectance and transmittance depend on the optical constants n and k. We have seen that in transparent films, R and T oscillate with the film thickness due to interference effects. In absorbing films with small k values, the oscillatory behaviour remains, but the amplitudes of the maxima decrease with increasing films thickness. For higher absorption values, particularly in the case of metals, intensity maxima are not observed, and an exponential decrease in transmittance with film thickness is seen.

Of particular use in the case of thin film stacks containing several layers is the matrix formalism, which allows the reflection and transmission properties to be determined. A 2×2 matrix characterises each layer of the stack, and allows the electric and magnetic field strengths to be expressed in terms of those of the adjacent layer. For transparent films this is given for the r-th layer in the form [28.153]

$$\mathbf{M}_r = \begin{pmatrix} \cos\delta_r & \frac{\mathrm{i}\sin\delta_r}{n_r} \\ \mathrm{i}n_r \sin\delta_r & \cos\delta_r \end{pmatrix} , \tag{28.66}$$

where δ_r is the phase thickness and n_r is the refractive index of the r-th layer. The electric and magnetic field intensities in the adjacent $(r-1)$-th layer, E_{r-1} and H_{r-1}, are related to those in the r-th layer E_r and H_r by

$$\begin{pmatrix} E_{r-1} \\ H_{r-1} \end{pmatrix} = \mathbf{M}_r \begin{pmatrix} E_r \\ H_r \end{pmatrix} . \tag{28.67}$$

Repeated application of (28.67) to a stack of layers enables E_0 and H_0 in the incident medium (n_0) to be expressed in terms of the field intensities in any other layer of the stack. Knowing the n values for each of the various layers of the stack, a *characteristic matrix* (also 2×2) for the entire stack is obtained by repeated matrix multiplication of the individual layer matrices, and allows E_0 and H_0 to be obtained in terms of the transmitted field intensities at the opposite side of the stack. The energy reflectance is then easily obtained. Similar matrices to those in (28.66) may also be defined for the case of absorbing films, although it is then usual to work in terms of the layer admittance η, defined as the ratio of the transverse components of the magnetic

to the electric vectors [28.150]. The matrix formalism can be extended even for optically anisotropic thin films [28.154] or magneto-optical multilayers where optical anisotropy is induced by film magnetization or external magnetic field [28.155].

A relatively simple example of an interesting system is a stack of layers of equal optical thickness, but with alternating high (H) and low (L) refractive indices [28.153]. If the optical thicknesses correspond to $\lambda/4$ (a quarter-wave stack), there is a highly reflective region at the wavelength λ, with other highly reflecting regions at 2λ, 3λ, etc. The reflectance value becomes higher the more layers there are in the stack, and approaches unity for a few layers. If the refractive index of the incident medium is n_0, that of the substrate n_S, and those of the high- and low-index regions n_H and n_L, respectively, the energy reflectance for an even number of layers $2s$ (n_L next to substrate) is given by

$$R_{2s} = \left(\frac{n_S f - n_0}{n_S f + n_0}\right)^2 \qquad (28.68)$$

where $f = (n_H/n_L)^{2s}$. For an odd number of layers $(2s+1)$, with n_H next to the substrate, the energy reflectance becomes

$$R_{2s+1} = \left(\frac{n_H^2 f - n_0 n_S}{n_H^2 f + n_0 n_S}\right)^2 . \qquad (28.69)$$

The bandwidth of the highly reflecting region depends on $\sin^{-1}[(n_H - n_L)/(n_L + n_H)]$, and thus is limited by the refractive indices available. Bandwidth can be increased by using a stack with layer thicknesses increasing in geometrical progression.

In addition to antireflection and highly reflecting coatings, various types of optical filters can be designed. Perhaps the simplest is the Fabry–Perot interference filter, which consists of two highly reflecting stacks, separated by a layer of optical thickness $\lambda/2$. This results in a very narrow transmission band at wavelength λ, with a rejection region on either side. Filter designs are usually based on computer evaluations of the optical matrices. These include band-pass, band-stop and edge filters. These are well beyond the scope of the present article and the reader is referred to the literature [28.30, 150, 156, 157]. The general trend in today's design and production of optical interference coatings is towards complex structures with refractive index profiles varying continuously along the structure. Theoretical approaches for the calculation of optical response in such inhomogeneous film stacks is reviewed for example in [28.158].

In this section some of the basic optical properties have been described, with the primary emphasis on non-absorbing films at normal incidence. Several interesting film arrangements have been described, again for non-absorbing films. Implicit to any system there is some absorption, but this can be accounted for if both the optical constants are known. Usually the design process involves the manipulation of several layer matrices, but this is handled effectively by modern computer technology. The optical properties of highly absorbing films are described by *Abelès* [28.159], who also considers inhomogeneous films. Other useful references on the theory and detailed optical properties of various aspects of thin films may be found in the literature: theory and calculations [28.160], antireflection coatings [28.161], filters [28.157, 162, 163] and mirrors [28.164].

28.3.2 Optical Absorption

The interpretation of the optical absorption behavior of thin films is one of the most beneficial methods for gaining a better understanding of the electronic structure of a material and to evaluate the energy band diagram. In 1972, *Tauc* stated a mathematical relation between the absorption tail and band gap of a material, written based on the absorption coefficient [28.165]

$$\alpha_{\text{direct}} = \frac{C}{h\nu}\left(h\nu - E_g\right)^{1/2} \quad \text{Direct band gap},$$
$$\alpha_{\text{indirect}} = \frac{C}{h\nu}\left(h\nu - E_g\right)^{2} \quad \text{Indirect band gap}, \qquad (28.70)$$

where, C is a constant, $h\nu$ is the photon energy, and E_g is the band gap energy. (The constant C is different in the above two equations.)

Direct band gap refers to the excitation in which the momentum energy of electrons is unaffected by excitation from the valence to conduction band, while in the case of indirect band gap some parts of the phonon energy are consumed to change the momentum energy of the electrons. Tauc's law is widely used to calculate the band gap of materials, ranging from bulk to quantum dot size. Further discussions on optical absorption, in particular modifications to the Tauc absorption rules above, can be found in Chap. 3.

Commercially available zinc oxide (ZnO) nanoparticles were used to produce spin-coated thin films on fluorine-doped tin oxide (FTO) coated glass slides. The UV/Vis absorbance (denoted as A and defined by $0.434\alpha d$, where d is the sample thickness) spectrum in Fig. 28.25 shows two distinct regions: (i) a sharp absorption edge due to interband transition in the incident photon energy $h\nu$ range between 3.15–3.25 eV and (ii) an absorption tail at low photon energies in the range 2.20–2.32 eV representing the localized states tailing into the band gap. The Tauc plot of $(Ah\nu)^2$ against

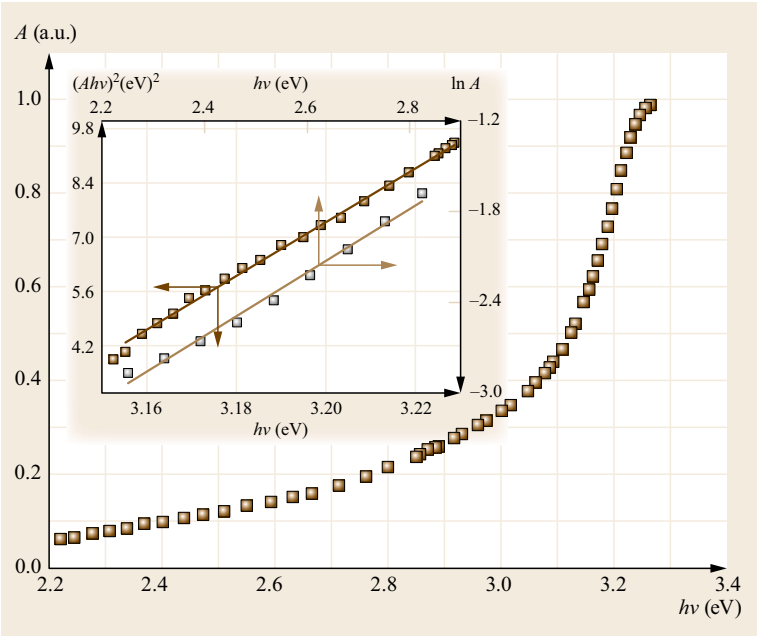

Fig. 28.25 UV-visible transmission spectra of as-deposited ZnO films on silica slides. Tauc and Urbach plots are included in the *inset*. *A* is the measured absorbance, and is plotted along the *y*-axis in arbitrary units

the incident energy $h\nu$ in the inset is linear, indicating the transition is direct for the sample. The intercept on the ordinate extrapolated to $h\nu = 0$ produced values of 3.15 eV for the direct optical band gap of the films. The linear plot of A against $h\nu$ between 2.20 and 2.32 eV in the second inset on a logarithmic linear scale represents the presence of the Urbach law in the following form

$$\alpha(h\nu) \propto \exp\left(\frac{h\nu - E_{\mathrm{CE}}}{E_{\mathrm{U}}}\right). \qquad (28.71)$$

The converging energy E_{CE} is taken to be higher than the optical band gap energy E_{g}. The Urbach energy E_{U}, which is related to the width of band tails of localized states extending into the gap, was found to be 0.53 meV from the inverse of the slope of the linear fit.

28.3.3 Electrical Properties

Chapter 2 in this Handbook provides an introduction to the electrical properties of materials and includes a section on the resistivity of thin films.

The electrical properties of thin films are one of their most important physical features, and differ from those of the corresponding bulk material for various reasons. Electrical properties cover a particularly wide field, and in this section only two important examples are covered. The first of these is the lateral conductivity (or corresponding resistivity) of thin metallic films. In metals we are usually concerned only with one type of charge carrier, electrons, and thus variations in conductivity σ due to the presence of both carrier types (such as compensation effects) are not considered. The main cause of deviations from the bulk material conductivity values is curtailment of the bulk electron mean free path λ_0 by the dimensions of the film. Clearly, if the film thickness $d < \lambda_0$, many instances of electron scattering occur at the film surfaces, thus reducing the effective electron mean free path and decreasing the conductivity. Modern theories also take into account electron scattering by individual grain boundaries as well as by the film surfaces. The second example of electrical properties in thin films is that of high-field conduction in insulators and semiconductors. Electric fields in thin films may approach the dielectric breakdown strength, and under these conditions the usual ohmic behaviour is not followed, but a range of different limiting conduction processes may take place. Conduction in semiconductors at somewhat lower electric fields is not discussed here, but is covered in detail elsewhere in the literature [28.1, 15, 18, 166]. Semiconductor conductivity is a broad subject, underlying the operation of many different electronic devices. We might note that the conductivity of semiconductors in their surface regions (and therefore also in semiconductor thin films) differs from that of the bulk material owing to depletion or accumulation regions at the surfaces, and that the application of a surface electric field forms the basis of several semiconductor devices, such as metal–oxide–semiconductor (MOS) transistors. Furthermore, the mobility of carriers in semiconductors frequently follows similar variations to those of the

conductivity in metallic films, for essentially the same regions, in that the surface and/or grain boundary scattering significantly influence the mobility and thus the conductivity.

Electrical Conductivity in Metallic Films

Chapter 2 included a basic introduction to the electrical resistivity of metallic thin films. In this chapter, we consider electrical conduction in thin films in more detail, and provide further useful references to both metallic and semiconducting thin films. The electrical conductivity in bulk metals σ_0 is given generally by an expression of the form

$$\sigma_0 = \frac{ne^2\lambda_0}{mv}\,, \tag{28.72}$$

where n is the concentration of free electrons, e is the electronic charge, λ_0 the bulk electron mean free path, m the electron effective mass and v the electron Fermi velocity. This expression results from the free-electron gas theory of metals, derived from the work of Drude, Lorentz and Sommerfield. The main feature of this result is that the electrical conductivity is proportional to the mean free path, and that if the mean free path is curtailed by any means, then the conductivity will be reduced, all other considerations remaining unaltered. A further consideration is the well-known result termed Matthiessen's rule,

$$\rho_0 = \rho_\mathrm{d} + \rho_\mathrm{ph}(T)\,, \tag{28.73}$$

where the bulk resistivity $\rho_0\,(=1/\sigma_0)$ is given by the sum of contributions from static defects and impurities ρ_d and from phonons $\rho_\mathrm{ph}(T)$. The latter contribution effectively isolates the main temperature-dependent effect from other scattering mechanisms, unless they too are temperature-dependent. Temperature-dependent phonon interactions increase with increasing temperature, giving rise to the positive temperature coefficient of resistivity (TCR) in metals. At very low temperatures $\rho_\mathrm{ph}(T) \to 0$, and only the residual resistivity ρ_d remains. For the case of a thin metal film, scattering at the surfaces also comes into play, and Matthiesen's rule is modified by the addition of an extra surface-scattering resistivity term ρ_s to give

$$\rho_\mathrm{f} = \rho_\mathrm{d} + \rho_\mathrm{ph}(T) + \rho_\mathrm{s} \tag{28.74}$$

for the thin-film resistivity ρ_f. For very thick films $\rho_\mathrm{s} \approx 0$, since the mean free path is not then limited by the surfaces, and the film resistivity is effectively the same as the bulk value. When ρ_s is significant for thinner films, $\rho_\mathrm{f} > \rho_0$, and the film conductivity $\sigma_\mathrm{f} < \sigma_0$. The above discussions follow naturally from the treatise in Chap. 2.

Over a century ago, *Thomson* [28.167] was the first to suggest that observed decreases in the conductivity of thin films as compared to the bulk values are the result of the limitation of the electron mean free path by the specimen size. He made the following assumption in obtaining an expression for the film conductivity: the bulk mean free path in the metal is a constant λ_0, greater than the film thickness d, and that when electrons collide with the internal film surfaces the scattering is independent of the angle at which they strike, i. e., the scattering is diffuse. Collisions occurring in the film were split into two regions, in the first the mean free path is determined by the surfaces (top and bottom) and in the second the mean free path is not limited by scattering at the surfaces. In terms of the parameter

$$k = \frac{d}{\lambda_0}\,, \tag{28.75}$$

the ratio of the film thickness to the bulk mean free path, the ratio of the film to bulk conductivity was determined as

$$\frac{\sigma_\mathrm{f}}{\sigma_0} = \frac{\rho_0}{\rho_\mathrm{f}} = \frac{k}{2}\left[\ln\left(\frac{1}{k}\right) + \frac{3}{2}\right]. \tag{28.76}$$

Fuchs [28.168] pointed out that this derivation neglected mean free paths starting at the film surfaces, and also the statistical distribution of the mean free paths about λ_0 in the bulk metal. A corrected version of Thomson's model for very thin films, i. e., $d \ll \lambda_0$ $(k \ll 1)$, where effectively all the mean free paths start from one of the surfaces, yields an alternative result [28.169]

$$\frac{\sigma_\mathrm{f}}{\sigma_0} = \frac{\rho_0}{\rho_\mathrm{f}} = k\left[\ln\left(\frac{1}{k}\right) + 1\right]. \tag{28.77}$$

Although both expressions predict a decrease in conductivity below the bulk value for films, neither gives a sensible prediction for very thick films, i. e., $d \gg \lambda_0$ $(k \gg 1)$.

A more useful general model to account for variations of conductivity with film thickness was introduced by *Fuchs* [28.168], who formulated the problem in terms of the Boltzmann transport equation, which describes the way in which the electron energy changes due to applied fields and collisions. Readers are referred to the original paper, or to one of the reviews mentioned at the end of this section, for details of the mathematical

arguments. The final result of this model is

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} = 1 + \frac{3}{4}\left(k - \frac{k^3}{12}\right) B(k) - \frac{3}{8k}\left(1 - e^{-k}\right) - \left(\frac{5}{8} + \frac{k}{16} + \frac{k^2}{16}\right) e^{-k}, \tag{28.78}$$

where $B(k)$ is a representative of the set of exponential integral functions, given by

$$B(x) = -\mathrm{Ei}(-x) = \int_x^\infty \frac{e^{-y}}{y}\mathrm{d}y\,. \tag{28.79}$$

Figure 28.26 shows the dependence of ρ_f/ρ_0 $(= \sigma_0/\sigma_f)$ on k over the range 0.1–10 for the curve labelled $p = 0$ (diffuse scattering). Here it is clear that the resistivity drops to the bulk value for thick films. Various approximations for (28.78) are frequently quoted to aid computation in specific thickness ranges. For thick films ($k \gg 1$)

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx 1 - \frac{3}{8k}\,. \tag{28.80}$$

This clearly shows that as $k \to \infty$, $\sigma_f \to \sigma_0$. For thinner films ($k \ll 1$), *Campbell* [28.170] quotes

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx \frac{3k}{4}\left[\ln\left(\frac{1}{k}\right) + 0.4228\right] \tag{28.81}$$

and for *very* thin films *Sondheimer* [28.171] gives

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx \frac{3k}{4}\left[\ln\left(\frac{1}{k}\right)\right]. \tag{28.82}$$

Equations (28.76), (28.77), (28.81) and (28.82) give some confidence in the general approach, since they are all of comparable form, with the right-hand sides each consisting of a constant $\times\, k \times$ [ln(1/k) + another constant].

Fuchs also considered the case where the electron scattering at the surfaces was not totally randomised, and that a constant proportion of electrons p are scattered specularly. p is termed the *specularity parameter*, where $p = 0$ for the case of totally diffuse scattering and $p = 1$ for totally specular scattering. Clearly in the latter case the film surfaces do not affect the conductivity, and σ_f reduces to the bulk value. Figure 28.26 also shows the variation of ρ_f/ρ_0 for $p = 0.5$ (intermediate between diffuse and specular scattering) and $p = 1$ (totally specular scattering). Again for the case of some specular scattering there are limiting expressions for thick films ($k \gg 1$) and thin films ($k \ll 1$), given respectively by

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx 1 - \frac{3(1-p)}{8k} \tag{28.83}$$

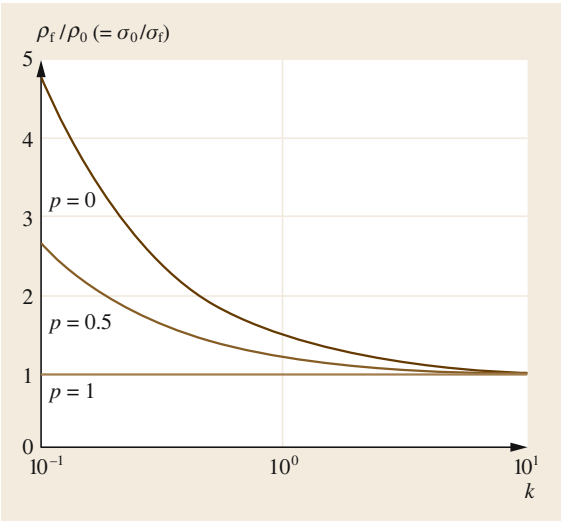

Fig. 28.26 Dependence of the ratio of film to bulk resistivity ρ_f/ρ_0 on the ratio of film thickness to bulk mean free path $k = d/\lambda_0$ predicted by the model of *Fuchs* [28.168]; p is the specularity parameter, with $p = 0$ representing totally diffuse scattering and $p = 1$ representing totally specular scattering, where for the latter $\rho_f/\rho_0 = 1$. The *curve* labelled $p = 0.5$ is intermediate between these two values

and

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx \frac{3k}{4}(1+2p)\left[\ln\left(\frac{1}{k}\right) + 0.4228\right], \tag{28.84}$$

where p is small in (28.84). For totally diffuse scattering, where $p = 0$, these two expressions reduce to the previous results of (28.80) and (28.81). An alternative expression for thin films is also given by *Sondheimer* [28.171],

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx \frac{3k}{4}\left(\frac{1+p}{1-p}\right)\ln\left(\frac{1}{k}\right). \tag{28.85}$$

This reduces to (28.82) for $p = 0$, and for small k and p is consistent with (28.84).

Both *Lucas* [28.172] and *Juretschke* [28.173, 174] have extended the specularity analysis by assuming a different specularity parameter for each side of the film, i. e., p and q. This is of course quite reasonable, in that the specularity parameter of the lower (substrate) surface is likely to be heavily influenced by the substrate surface. The thick- ($k \gg 1$) and thin-film ($k \ll 1$) approximations in this case are then

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx 1 - \frac{3}{8k}\left[1 - \left(\frac{p+q}{2}\right)\right] \tag{28.86}$$

and

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx \frac{3k}{4}\frac{(1+p)(1+q)}{(1-pq)} \ln\left(\frac{1}{k}\right), \qquad (28.87)$$

respectively. For identical surfaces with $p = q$, these expressions reduce to (28.83) and (28.85) respectively. Tabulated values of ρ_f/ρ_0 are given by *Chopra* [28.18] as functions of k for various combinations of p and q. The whole topic of the size-dependent electrical conductivity in thin metallic films and wires is thoroughly reviewed by *Larson* [28.175], but omitting the important work on grain-boundary scattering of *Mayadas* and *Shatzkes* [28.176]. This is, however, covered in a more recent book reviewing size effects in thin films generally [28.177], which also includes useful tabulated conductivity data.

A recent clear example in which surface scattering controls the effective resistivity of a thin film is shown in Fig. 28.27 where the authors have examined the resistivity of single crystal layers of Cu(100) grown epitaxially on insulating crystals TiN(001) and MgO(001) at substrate temperatures of 25 and 80 °C [28.178]. The measurements were made at two temperatures, 298 K (in situ in vacuum) and 77 K in liquid nitrogen; as expected at 77 K the resistivity is much lower. The solid

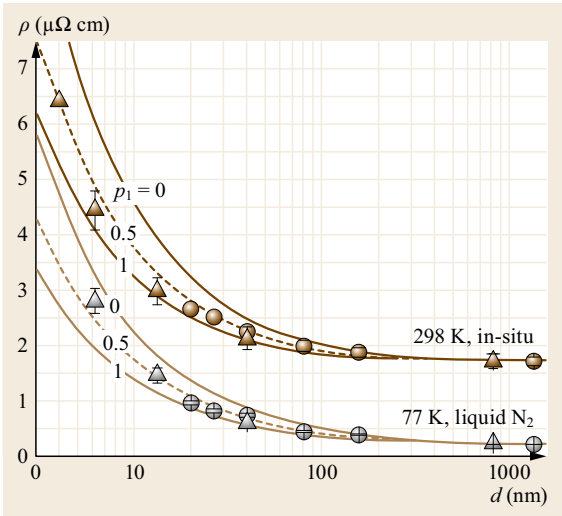

Fig. 28.27 The resistivity ρ measured at 298 K (in situ in vacuum) and 77 K versus layer thickness d of epitaxial Cu(001) layers grown on 2.5 nm TiN(001)/MgO(001) at a substrate temperature of 25 °C and MgO(001) at 80 °C. The *lines* represent the theoretical calculations based on the Fuchs–Sondheimer model at 298 and 77 K for $p_2 = 0$ and $p_1 = 0$, 0.5, and 1, as labeled; p_1 and p_2 are the upper surface and Cu–substrate interface secularity parameters. The *circles* are Cu on TiN and *triangles* are Cu on MgO. (Data extracted from [28.178])

curves are a theoretical prediction based on the Fuchs–Sondheimer formalism. The top and bottom surfaces of the film are assigned p_1 and p_2 for the specularity parameter with $p_2 = 0$ (Cu surface on the substrate) and $p_1 = 0$, 0.5, and 1. It is clear that within experimental error, it is possible to describe the resistivity within the Fuch–Sondheimer model. The distinct advantage of using an epitaxial thin film layer is that there are no grain boundaries within the film that would introduce an additional scattering process and thereby increase the resistivity.

As mentioned above, an important development in size-effect models came about with the inclusion of grain-boundary scattering [28.176]. In a bulk sample, the individual grains are normally considerably larger than the bulk mean free path λ_0, and do not therefore affect the conductivity. However, in thin films, the grain sizes and orientations depend on the preparation method and conditions. Typical grain sizes are of the same order as λ_0 and therefore scattering at their boundaries will influence the conductivity. Mathematically, the model takes account of the fact that grains tend to grow in a columnar structure, with the axes normal to the film plane. Single grains usually extend between both film surfaces, and thus their upper and lower boundaries do not affect the conductivity. Mayadas and Shatzkes argue that only grain boundaries normal to the film plane influence the conductivity. The grain boundaries are represented by δ-function potentials, and are used in the model in the solution of the Boltzmann transport equation, subject to suitable boundary conditions. The model is developed in terms of a dimensionless parameter α, given by

$$\alpha = \frac{\lambda_0}{D}\frac{R}{1-R}, \qquad (28.88)$$

where, as before λ_0 is the bulk mean free path, D is the mean grain dimension, and R is the grain-boundary electron reflection coefficient. The ratio of the grain-boundary conductivity σ_g (and the corresponding resistivity ρ_g) to the bulk values are then given by

$$\frac{\sigma_g}{\sigma_0} = \frac{\rho_0}{\rho_g} = 3\left[\frac{1}{3} - \frac{1}{2}\alpha + \alpha^2 - \alpha^3 \ln\left(1 + \frac{1}{\alpha}\right)\right]. \qquad (28.89)$$

This is easy to evaluate, and the dependence of ρ_g/ρ_0 $(= \sigma_0/\sigma_g)$ on α is shown in Fig. 28.28. For small values of α (i. e., large grain size D, small bulk mean free path λ_0, or small reflection coefficient R) the grain boundaries do not affect the overall conductivity, which remains at the bulk value. However, for large α the

grain-boundary resistivity increases (conductivity decreases). For very large ($\alpha \gg 1$) and very small ($\alpha \ll 1$) values of α, (28.89) has the limiting approximations

$$\frac{\sigma_0}{\sigma_g} = \frac{\rho_g}{\rho_0} \approx \frac{4}{3}\alpha \qquad (28.90)$$

and

$$\frac{\sigma_0}{\sigma_g} = \frac{\rho_g}{\rho_0} \approx 1 + \frac{3}{2}\alpha\,, \qquad (28.91)$$

respectively. Note that following the original work [28.176] the latter two expressions are quoted as the ratio ρ_g/ρ_0 $(= \sigma_0/\sigma_g)$, i. e., the reciprocal of the ratio in (28.89).

Mayadas and *Shatzkes* [28.176] also considered the case of grain-boundary scattering in conjunction with scattering at the film surfaces, and followed the *Fuchs* [28.168] formulation to arrive at an expression for the overall film resistivity ρ_f. Unfortunately, the resulting expression could not be evaluated analytically, requiring numerical solution. Detailed comparisons between the basic Fuchs model with $p = 0$ and $p = 0.5$, and their model using the same values of p and including grain-boundary scattering with $\alpha = 1$, led these workers to interpret their results as showing an enhancement of the intrinsic resistivity ρ_g in polycrystalline samples in which grain size is constant and independent of film thickness. However, discrepancies between the Fuchs and Mayadas–Shatzkes models become most apparent for very large α (very small grain size, D). For this situation the deviation corresponds to the additional resistivity arising from grain boundaries rather than from surface scattering [28.179, 180]. Useful tabulated data of resistivity ratios in samples with both grain-boundary and surface scattering are given elsewhere in the literature [28.177, 181].

The above description of thin film resistivity neglects the roughness of the film surfaces, which can increase the resistivity further. The surfaces are simply assigned a specularity parameter p depending on the nature of scattering at the surface. *Namba* [28.182] considered the resistivity of thin films with surface roughness and derived an expression for the resistivity in terms of the film thickness and the ratio of the roughness h to the mean free path length λ_0 in the bulk. The film was assumed to have a certain mean thickness d and a sinusoidal variation of the top surface that follows $h\sin(kx)$, so that the total thickness was modulated as $d + h\sin(kx)$ where x is the distance parallel to the current flow and k is the spatial frequency of the sinusoidal variation or $2\pi/\Lambda$ where Λ is the periodicity of roughness, i. e., a roughness wavelength. (Roughness variations are implicitly assumed to be on the mesoscopic scale.) Grain boundary scattering was neglected. Figure 28.29 shows the results of his calculations for the normalized resistivity ρ/ρ_0 in terms of the film normalized thickness d/λ_0 for different values of h/λ_0. The case for $h/\lambda_0 = 0$ reduces to the Fuchs–Sondheimer formalism, as expected, and the description is often referred to as the Fuchs–Namba model. There have been several discussions on the effect of surface roughness on measured resistivity, and potential improvements to Namba's approach, see for example, the discussions by

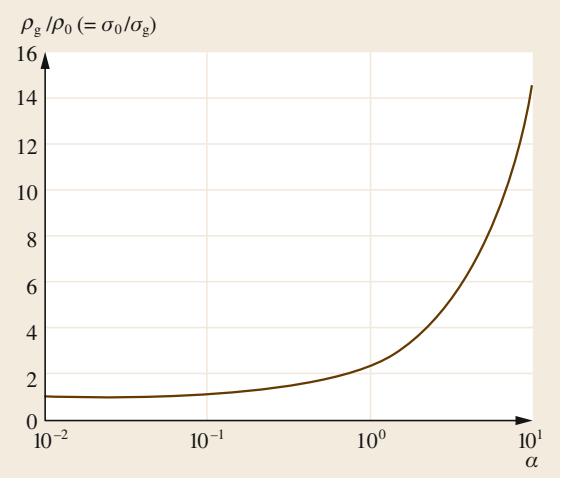

Fig. 28.28 Dependence of the ratio of grain-boundary to bulk resistivity ρ_g/ρ_0 on the parameter α from the model of *Mayadas* and *Shatzkes* [28.176]. The data are calculated from (28.89)

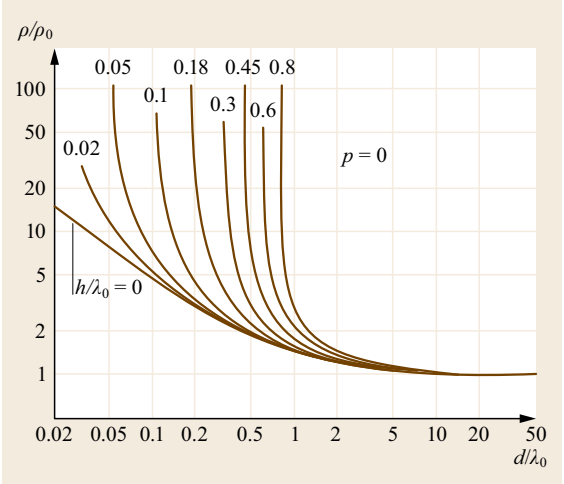

Fig. 28.29 Normalized resistivity (ρ/ρ_0) versus normalized film thickness d/λ_0 for various values of normalized surface roughness h/λ_0. (Data from [28.182])

Trivedi and *Ashcroft* [28.183] and *Jacob* et al. [28.184]. There are several examples in the literature in which good agreements have been reported between the thickness dependence of the thin film resistivity and the Fuchs–Namba model as in references [28.185, 186].

Finally, we briefly discuss the thickness variations of the temperature coefficient of resistivity. This is a measure of the response of the resistivity to changes in temperature, and is usually denoted by the symbol α. To avoid confusion with the Mayadas–Shatzkes parameter, here we denote it by α_T. The temperature coefficient of resistivity is given for the bulk (α_{T0}) and for thin films (α_{Tf}) by

$$\alpha_{T0} = \frac{1}{\rho_0}\frac{d\rho_0}{dT}; \quad \alpha_{Tf} = \frac{1}{\rho_f}\frac{d\rho_f}{dT} \tag{28.92}$$

where ρ_0 and ρ_f are the bulk and thin-film resistivities, as given in (28.73) and (28.74). From the above relationships, and Matthiesen's rule, it is possible to derive expressions for α_{Tf}/α_{T0} in a similar manner as ρ_f/ρ_0. Referring to (28.74), ρ_d is essentially temperature-independent, while the temperature dependence of ρ_s depends on the film thickness. For thicker films ($k \gg 1$), ρ_s is also temperature-independent, and thus

$$\frac{d\rho_f}{dT} = \frac{d\rho_{ph}}{dT} \tag{28.93}$$

Similarly, from (28.73) for the bulk material

$$\frac{d\rho_0}{dT} = \frac{d\rho_{ph}}{dT} \tag{28.94}$$

and therefore both the differentials in (28.92) are equal, and we obtain

$$\alpha_{T0}\rho_0 = \alpha_{Tf}\rho_f \,. \tag{28.95}$$

This useful result implies that

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} = \frac{\alpha_{Tf}}{\alpha_{T0}} \tag{28.96}$$

and that for the case of thicker films the ratio of the film-to-bulk temperature coefficient of resistivity is equal to the ratio of film-to-bulk conductivity. For the case of thinner films ($k \ll 1$), the situation is complicated by the fact that ρ_s is also temperature-dependent, because the mean free path decreases with increasing temperature and becomes significant for small k. Various calculated data for α_{Tf} are given elsewhere in the literature [28.6, 18, 170, 175, 177], to which the reader is referred for a fuller discussion. Discussions concerning the applicability of the various models described above to several types of metallic film are also given in some of these references, and a wider coverage including additional contributions to the size effect models, which cannot be included in the present work, is given in the book by *Tellier* and *Tosser* [28.177].

High-Field Conduction in Insulating and Semiconducting Thin Films

Here electrical conductivity is considered for the case where a voltage is applied across an insulating or semiconducting thin film prepared in a sandwich configuration between metallic electrodes. This situation is in direct contrast to that described in the previous section, in that the intrinsic film conductivity is significantly lower, and the electric field applied can be extremely high, even when only low voltages are applied. The latter point is clearly illustrated by the fact that in a film of thickness 1 μm subjected to a voltage of only 10 V, the mean electric field established across the film is 10^7 V/m, approaching the dielectric breakdown strength of many materials. Several high-field conduction mechanisms that may in principle occur in thin dielectric films have been thoroughly reviewed in the literature [28.187]. These have also been observed in relatively wide-band-gap semiconducting films. These processes are discussed later in this section, together with the appropriate current density–voltage expressions which aid in their identification and analysis. First, however, it is useful to discuss the types of electrical contact which may be applied to dielectric films, since the dominant conduction process is frequently determined by the type of electrical contact and its interfacial properties.

Simmons [28.187] has demonstrated that the type of electrode used significantly influences the conduction processes which may be observed; the various conduction mechanisms were classified as either *bulk-limited* or *electrode-limited*. For the former the charge carriers are generated in the bulk of the material and the electrodes merely serve to apply a potential which generates a drift current. In the latter, at the interface between the electrode and the insulator or semiconductor, a potential barrier to the flow of charge is established, which limits the current. Contacts themselves are said to be either *ohmic* or *blocking*, with an intermediate *neutral* contact. Blocking contacts are conventionally known as Schottky barriers. In principle, the type of contact formed depends on the relative work functions of the insulator or semiconductor ψ_i and that of the metal contact ψ_m. Excellent energy-band diagrams of the various types of contact are given in the literature [28.187], and are reproduced elsewhere in descriptions of contacts to cadmium compound films [28.38] and to nanostructures [28.11]. In equilibrium the vacuum and the Fermi

levels are continuous across the interface, and with no applied voltage the Fermi level also must be flat, in order that no current flows. Away from the interface in the bulk of the material, the energy difference between the vacuum and Fermi levels will be equal to the work function ψ_i, and it can easily be seen that the potential barrier height at the interface φ_0 is given by

$$\varphi_0 = \psi_m - \chi \,, \tag{28.97}$$

where χ is the film electron affinity and ψ_m is the metal work function. However, it is the *type* of contact rather than its precise barrier height which determines the type of conductivity observed. We consider primarily electrons as the charge carriers, as it has been argued that for insulators conduction by holes may normally be ignored, owing to relatively low mobilities and to immobilisation by trapping effects. Similar arguments are also applicable in the case of wide-band-gap semiconductors, and thus for both insulators and some semiconductors n-type conductivity is usual. For p-type conductivity, the conditions concerning the relative values of the work functions are reversed [28.188].

Ohmic contacts occur for electron injection when $\psi_m < \psi_i$. Electrons are injected from the electrode into the insulator or semiconductor in order to comply with thermal equilibrium requirements. They are subsequently located within the insulator or semiconductor conduction band and penetrate a distance λ_0 below the interface, forming a region of negative space charge which is termed an *accumulation region*. Upwards band bending of the conduction band occurs in the accumulation region, beyond which the dielectric is shielded from the electrode. The accumulation region acts as a charge reservoir, and can supply electrons to the material as required by the bias conditions. It has been pointed out by *Simmons* [28.187] that the conductivity is limited by the rate at which electrons can flow into the bulk of the material, and is therefore bulk-limited. Conversely, blocking contacts or Schottky barriers occur when $\psi_m > \psi_i$. In this case the initial flow of charge is reversed, with electrons flowing from the insulator or semiconductor to the metal electrode. In contrast to the case for ohmic contacts, this results in a positive space-charge region near the interface in the insulator or semiconductor, which, owing to the absence of electrons, is termed a *depletion region*. An equal and opposite negative charge is induced on the electrode, and the interaction between the two charges establishes a local electric field near the interface. In this case the conduction band in the insulator or semiconductor bends downwards, and the free-electron concentration in the interfacial region is much lower than in the bulk of the film material. The rate of flow of electrons is thus limited by the rate at which they can flow over the interfacial barrier, and the conductivity is electrode-limited.

Although, in principle, the type of contact established depends on the relative values of ψ_m and ψ_i, in reality such considerations are usually inadequate in predicting the type of contact formed, because of the existence of *surface states*. These are due either to the effects of unsaturated bonds and impurities at the interface [28.189] or to the departure from periodicity in the structure at the interface. It is very difficult to accurately predict a priori the presence and concentration of surface states. If a significant concentration of surface states does exist, (28.97) is inapplicable and the type of contact and the conduction process are determined almost entirely by their presence.

In the remainder of this section the bulk-limited conduction processes are first considered, where the conductivity does not depend on the barrier height at the interface. Following this the electrode-limited processes are considered, where the barrier height becomes a significant feature in the current density–voltage (J–V) equations.

A particularly important conduction process in insulating and semiconducting thin films is that of space-charge-limited conductivity (SCLC) (the same acronym is also used for space charge limited current). For SCLC to occur there is a requirement that the injecting electrode is an ohmic contact. Thus there is a charge reservoir available in the accumulation region, and electrons do not need to be excited over a potential barrier. At low voltages the thermally generated carrier concentration exceeds the injected concentration, and the current density J is proportional to the applied voltage V, following Ohm's law,

$$J = n_0 e \mu \frac{V}{d} \,, \tag{28.98}$$

where n_0 is the thermally generated carrier concentration (electrons), e is the electronic charge, μ the mobility and d the film thickness. When the injected electron concentration exceeds that of the thermally generated concentration the SCLC current becomes dominant. SCLC current density–voltage relationships are derived by taking into account both the drift and diffusion currents, and solving Poisson's equation. This results in an expression for the electric field as a function of distance from the interface. Charge-carrier traps normally exist within the insulating or semiconducting film, and these are effective in mopping up or immobilising most of the injected electrons. For shallow traps located at a discrete energy E_t below the conduction band edge the SCLC current density is given

by [28.187]

$$J = \frac{9}{8}\varepsilon_r\varepsilon_0\theta\mu\frac{V^2}{d^3}\,, \tag{28.99}$$

where ε_r is the relative permittivity of the material, ε_0 the permittivity of free space and θ is the ratio of free to trapped charge. This expression predicts that $J \propto V^2$ and $J \propto d^{-3}$, and the search for these relationships is an important tool in identifying SCLC dominated by a discrete trap level. For perfect materials which do not contain traps, θ is replaced by unity in (28.99). The ratio of free to trapped charge is given by [28.190]

$$\theta = \frac{N_c}{N_{t(s)}}\exp\left(-\frac{E_t}{k_BT}\right), \tag{28.100}$$

where N_c is the effective density of states at the conduction band edge, $N_{t(s)}$ is the shallow trap concentration located at the discrete energy level, k_B is Boltzmann's constant and T is the absolute temperature. A transition between ohmic conductivity and SCLC takes place when the injected carrier concentration first exceeds the thermally generated carrier concentration. An expression for the transition voltage V_t at which this occurs is obtained by simultaneously solving (28.98) and (28.99) to yield

$$V_t = \frac{8en_0d^2}{9\theta\varepsilon_r\varepsilon_0}\,. \tag{28.101}$$

SCLC of this type, showing square-law J–V behaviour, has been observed in many types of thin films. In SbS_3 dielectric films, with bismuth oxide ohmic contacts, the current was at first ohmic, before a transition to SCLC [28.191]. Current density was also found to be proportional to $1/d^3$ at constant voltage, and the transition voltage V_t showed the characteristic linear variation with d^2. It has also been observed in CdS films [28.40, 192, 193], particularly with In injecting electrodes, and a discrete-trap concentration of $2.5\times10^{20}\,m^{-3}$ was deduced [28.40]. In CdTe, a square-law SCLC behaviour was recorded in electro-deposited Ni-CdTe-Au structures [28.194]. The work also showed a systematic increase in current density with temperature over the range 273–338 K, together with the expected $J \propto 1/d^3$ behaviour. *Dharmadhikari* [28.195] observed similar behaviour in evaporated CdTe films in the lower voltage range, although power-law behaviour became apparent at higher voltages. CdSe films have also been reported as showing square-law SCLC [28.196, 197]. In organic films, the phthalocyanines are well know for exhibiting SCLC behaviour [28.120]. Square-law behaviour with discrete trap levels has been seen in several of these materials, with typical activation energies of 0.77 eV [28.198] and 0.62 eV [28.199] in copper phthalocyanine, 0.42 eV in lead phthalocyanine [28.200], 0.58 eV in nickel phthalocyanine [28.201] and 0.45 and 0.69 eV in cobalt phthalocyanine [28.202]. These values appear to vary according to the central metal atomic species in the molecule, and also with the oxygen content. In general these materials are p-type, having a trap concentration for discrete levels in the range 5×10^{16}–$7.1\times10^{25}\,m^{-3}$.

For amorphous and polycrystalline materials, where a single shallow trap level is unlikely to be present, several poorly defined trap levels can lead to an overall exponential distribution of traps $N(E)$ [28.190] given by

$$N(E) = N_0\exp\left(-\frac{E}{k_BT_t}\right), \tag{28.102}$$

where $N(E)$ is the trap concentration per unit energy range at an energy E below the conduction band edge, N_0 is the value of $N(E)$ at the conduction band edge and $T_t > T$ is a temperature parameter which characterises the distribution. Furthermore, it can be shown that the total concentration of traps comprising the distribution $N_{t(e)}$ is [28.203]

$$N_{t(e)} = N_0k_BT_t\,. \tag{28.103}$$

Lampert [28.204] obtained an expression for the current density by assuming an exponential trap distribution as described by (28.102) to yield

$$J = e\mu N_c\left(\frac{\varepsilon_r\varepsilon_0}{eN_0k_BT_t}\right)^l\frac{V^{l+1}}{d^{2l+1}}\,. \tag{28.104}$$

This expression predicts a power-law dependence of J on V, with the exponent $n = l+1$, where l represents the ratio T_t/T. J is also expected to be proportional to $d^{-(2l+1)}$. Similarly to the case for a single shallow trap level, there is also a transition voltage between ohmic conduction and SCLC dominated by an exponential trap distribution. The transition voltage in this case is given by [28.205]

$$V_t = \left(\frac{n_0}{N_c}\right)^{1/l}\frac{eN_0k_BT_td^2}{\varepsilon_r\varepsilon_0}\,. \tag{28.105}$$

Many instances of power-law SCLC are also reported in the literature. *Zuleeg* [28.192] observed a cubic power-law dependence at higher voltages in his CdS films, which suggested that an exponential trap distribution was present. *Dharmadhikari* [28.195] appears to have been the first to observe a power-law J–V dependence in CdTe films at higher voltage levels, in addition to the square-law dependence at lower voltages. Very

high exponents were recorded, although at the time these was not analysed using the exponential trap distribution expressions given above. This connection was made in a later series of measurements [28.206], where the intermediate square-law behaviour was absent. This J–V dependence is shown in Fig. 28.30 [28.206] for three different film thicknesses, and is typical of many results on various different materials showing an exponential trap distribution. Similar exponential trap distributions have also been identified in some CdSe films [28.207–209], notwithstanding the earlier results which indicated discrete trap levels [28.196, 197]. The differences between these two classes of results appear to depend on the different deposition conditions and processing used. Exponential trap distributions are extremely prevalent in phthalocyanine films, and were originally investigated by *Sussman* [28.210] for copper phthalocyanine films with ohmic Au electrodes. The material was shown to be p-type, and exhibited exponent values n in the J–V characteristics in the range 2.6–4.0. The predicted thickness dependence for this type of conductivity was also observed. Many other phthalocyanine films have subsequently shown this type of conductivity, and data on these are tabulated and compared in the literature [28.120]. Total trap concentrations for the exponential distributions are in the range 6×10^{20}–$9.3\times10^{26}\,\mathrm{m}^{-3}$.

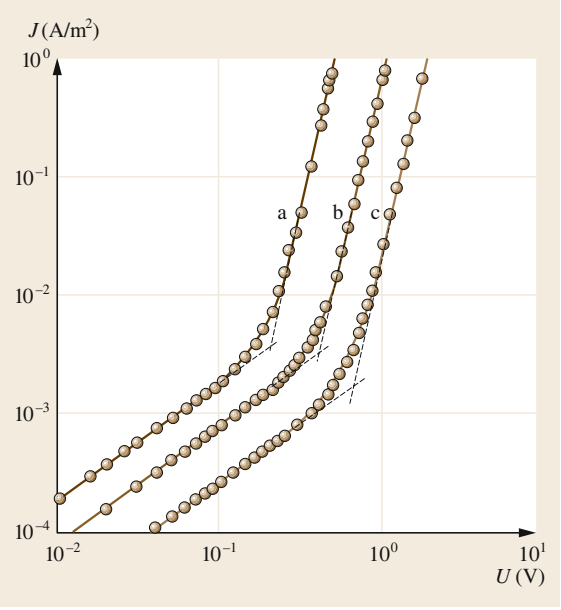

Fig. 28.30 Room-temperature current density–voltage characteristics for evaporated Al-CdTe-Al sandwich structures of thickness 0.31 μm (*a*), 0.45 μm (*b*) and 0.56 μm (*c*), showing ohmic conduction and SCLC. U is the applied voltage. (Data extracted from [28.206])

Using the above Eqs. (28.102)–(28.104) as a starting point, it was shown by the present author [28.211] that for SCLC dominated by an exponential trap distribution, measurements of J as a function of temperature at constant applied voltage in the SCLC region are sufficient to determine both the mobility and the trap concentration. If the data are plotted in the form $\log_{10} J$ against $1/T$ the curves should be linear, and when extrapolated to negative values of $1/T$, should all intersect at a common point irrespective of the applied voltage. The coordinates of this point are given by

$$\log_{10} J = \log_{10}\left(\frac{e^2\mu d N_c N_{t(e)}}{\varepsilon_r\varepsilon_0}\right); \quad \frac{1}{T} = -\frac{1}{T_t}\,. \tag{28.106}$$

Other useful results enabling data to be extracted from these plots are that for the gradient, given by

$$\frac{\mathrm{d}(\log_{10} J)}{\mathrm{d}(1/T)} = T_t \log_{10}\left(\frac{\varepsilon_r\varepsilon_0 V}{e d^2 N_{t(e)}}\right) \tag{28.107}$$

and for the intercept $\log_{10} J_0$ on the $\log_{10} J$ axis, which is

$$\log_{10} J_0 = \log_{10}\left(\frac{e\mu N_c V}{d}\right) \tag{28.108}$$

This set of equations has been used to determine mobility and trap concentration in several different materials showing this form of SCLC, including copper phthalocyanine, where these quantities were measured as functions of the ratio of evaporation background pressure to deposition rate [28.212]. In another example the method was used to determine these quantities in semiconducting CdTe films [28.213].

We might mention that *Rose* [28.190] also explored the possibility of a uniform trap distribution, in addition to discrete energy levels and the exponential distribution. In this case $J \propto V\exp(tV)$, where t is a temperature-dependent constant, but this is observed far less frequently than the square-law and power-law behaviour described above. An example is in the case of electrodeposited p-type CdTe films [28.214], where Rose's expression was followed and the trap concentration per unit energy range was $10^{21}\,\mathrm{eV}^{-1}\,\mathrm{m}^{-3}$. It was also observed in early work on copper phthalocyanine films with ohmic Au electrodes [28.215]. The discussion above for all types of SCLC considers carrier injection of a single type only. Double injection, when one electrode is ohmic for electrons and the other ohmic for holes, is covered in detail in the text by *Lampert* and *Mark* [28.216] on current injection in solids, and is also discussed by *Lamb* [28.189].

The assignment of the observed I–V characteristics to SCLC usually involves testing the current and voltage data for different film thicknesses. The examination of (28.104) and (28.111) shows that in both cases J/d is a function of V/d^2 i. e., in (28.104) $J/d \propto (V/d^2)^2$ and in (28.111) $J/d \propto (V/d^2)^{l+1}$. This observation is generally true for SCLCs that are due to one type of carrier; either electrons or holes are injected into the film and contribute to the observed current. The *scaling law* generalizes this observation in the form,

$$\frac{J}{d} = f\left(\frac{V}{d^2}\right), \tag{28.109}$$

where f represents the SCLC function for the particular film. The scaling law provides a means of testing for SCLCs, provided that the film thickness can be varied without altering any other properties. Figure 28.31 shows an application of the scaling law to Bi_2O_3 thin films in which I/d has been plotted against (V/d^2) on a log–log plot. The electrode area is the same (A in $J = I/A$) but the samples have different thicknesses with d in the range 75–680 nm (almost an order of magnitude). The scaling law is at least obeyed approximately for the wide range of thicknesses and over the entire range of currents; and the observed I–V characteristics on different films can all be interpreted in terms of a single SCLC mechanism similar to (28.111). Note that the function f in (28.109) depends on the exact nature of transport involved through the space charge, with (28.104) and (28.111) being two special examples in which the transport is shallow trap controlled or the deep trap is exponential in energy distribution as in (28.108). If both electrons and holes are injected, the analysis becomes more complicated and the reader is referred to [28.216].

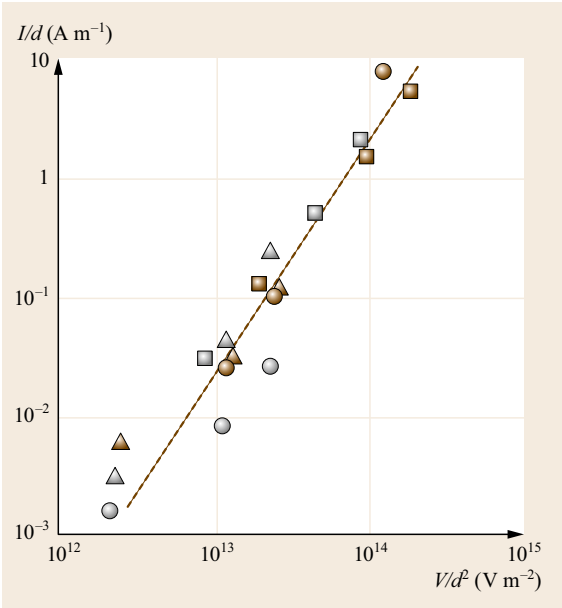

Fig. 28.31 Plot of I/d versus V/d^2 for BiO films with d in the range 75 to 680 nm. All samples have the same sample electrode area. *Each symbol* corresponds to a different thickness of film. A single *line* through all points suggests SCLC. The counter electrodes were Zn and Au. (Data extracted from [28.217, Fig. 4])

The second bulk-limited conduction process to be discussed is the Poole–Frenkel effect, which is essentially the field-assisted lowering of the Coulombic potential barrier φ between electrons located at impurity sites and the edge of the conduction band. Electrons in such centres are unable to contribute to the conductivity until they overcome the potential barrier φ and are promoted into the conduction band. For an applied electric field F the potential is reduced by an amount eFx where e is the electronic charge and x is the distance from the centre. For high electric fields the lowering of the potential can be significant. Such a variation is illustrated in the literature, usually for the case of a donor level located an energy E_d below the bottom of the conduction band [28.187]. The potential energy of the electron in the Coulombic field is $-e^2/(4\pi\varepsilon_r\varepsilon_0 x)$, and there is also another contribution to the potential energy, $-eFx$, resulting from the applied field F. The combined effect of both these contributions to the potential energy is that there is a maximum in the potential energy for emission at a distance x_m from the centre. The effective potential barrier for Poole–Frenkel emission is then lowered by an amount $\Delta\varphi_{PF}$, which depends on the electric field according to the relationship

$$\Delta\varphi_{PF} = \beta_{PF} F^{1/2}\,, \tag{28.110}$$

where

$$\beta_{PF} = \left(\frac{e^3}{\pi\varepsilon_r\varepsilon_0}\right)^{1/2} \tag{28.111}$$

is referred to as the Poole–Frenkel field-lowering coefficient. The conductivity, and consequently the current density, depend exponentially on the potential barrier for excitation of electrons into the conduction band, and since this is lowered by $\Delta\varphi_{PF} = \beta_{PF}F^{1/2}$ the current density is increased by an exponential factor. The current density is given by

$$J = J_0 \exp\left(\frac{\beta_{PF}F^{1/2}}{k_B T}\right), \tag{28.112}$$

where $J_0 = \sigma_0 F$ is the low-field current density. Although J_0 in this expression depends linearly on F,

it is frequently ignored in comparison with the exponential term, which increases far more rapidly with F. Equation (28.112) is usually applicable for thin-film insulators and semiconductors in the presence of traps. If, rarely, traps are absent and the low-field conductivity σ_0 shows an intrinsic dependence proportional to the factor $\exp(-E_g/(2k_BT))$, where E_g is the energy gap, then a factor of 2 appears in the denominator of the exponential term in (28.112) [28.187]. Since $F = V/d$, the above expression can be written

$$J = J_0 \exp\left(\frac{\beta_{PF} V^{1/2}}{k_B T d^{1/2}}\right). \qquad (28.113)$$

Therefore a plot of $\log J$ against $V^{1/2}$ should show a linear relationship in the case of Poole–Frenkel conductivity, from which a value of the field-lowering coefficient can be deduced and compared with the theoretical value of (28.111). If it is necessary for the variation of the pre-exponential factor to also be taken into account, then a linear plot of $\log(J/V)$ against $V^{1/2}$ should be obtained.

Modifications to (28.112) have been proposed to account for the somewhat different current density dependence in the presence of various combinations of donors and traps. *Simmons* [28.187] mentioned the case where the material contains donor levels below the Fermi level as well as shallow neutral traps, in which the coefficient of $F^{1/2}/(k_BT)$ is one half of the theoretical value given by (28.111). For the case of a nonuniform electric field, having a maximum value of $\alpha^2 F$, where F is the mean field, the following expression has been proposed [28.218]

$$J = \frac{2J_0 k_B T}{\alpha\beta_{PF} F^{1/2}} \exp\left(\frac{\alpha\beta_{PF} F^{1/2}}{k_B T}\right). \qquad (28.114)$$

Although this expression was originally proposed for the case of CdTe films, it has also been adopted for the interpretation of results in other materials.

The Poole–Frenkel effect has been observed in many types of thin film, including insulating oxides, semiconductors and organic materials. The main indicator of Poole–Frenkel conductivity is a linear dependence of $\log J$ on $V^{-1/2}$, although it is also seen in the case of the Schottky effect, as will be discussed later. Care must be taken in distinguishing between the two processes. In SiO films, good agreement with (28.113) was obtained [28.219], but the value of β derived exceeded the theoretical Poole–Frenkel value. This type of discrepancy had previously been discussed in the literature [28.220], and it was later proved that in this model the J–V characteristics were symmetric over five orders of magnitude of applied voltage, irrespective of electrode material, which ruled out the Schottky mechanism [28.221]. In another important insulator, silicon nitride, *Sze* [28.222] observed Poole–Frenkel behaviour in metal–insulator–semiconductor (MIS) diodes fabricated on a degenerate Si substrate, over a range of nearly four decades in current. It was found that the current density versus electric field characteristics were independent of film thickness, sample area, electrode materials and polarity, suggesting that the conductivity was bulk-limited rather than electrode-limited, and therefore eliminating the Schottky effect. Poole–Frenkel conductivity has also been observed in several semiconducting cadmium compounds, such as RF-sputtered CdS films [28.223, 224] and more widely in CdTe films [28.218, 225, 226]. In Al-CdTe-Al samples, Poole–Frenkel-type conductivity was consistently observed over the temperature range 0–108 °C. These results are typical of Poole–Frenkel behaviour, and are illustrated in Fig. 28.32 [28.226]. However, the value of the experimental field-lowering coefficient increased from 4.95×10^{-5} eV m$^{1/2}$ V$^{-1/2}$ at 0 °C to 7.7×10^{-5} eV m$^{1/2}$ V$^{-1/2}$ at 108 °C, and was about twice the theoretical β_{PF} for CdTe. The Schottky effect was eliminated, as the results did not appear to depend on the electrode workfunction when the Al electrodes were

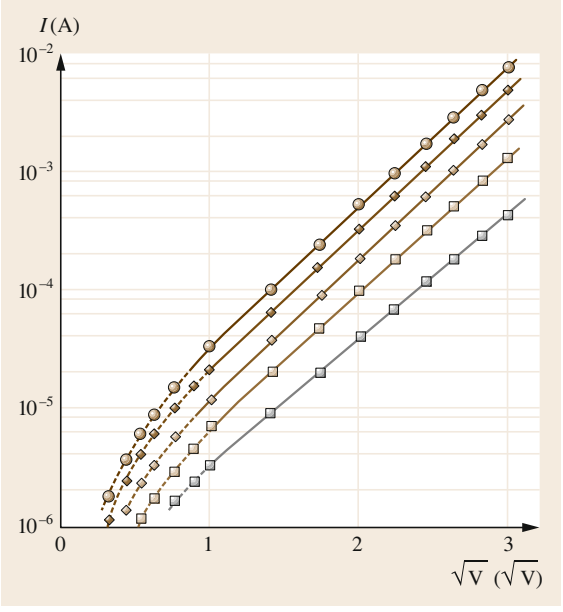

Fig. 28.32 Linear dependence of the logarithm of current on the square root of the applied voltage in an evaporated Al-CdTe-Al sandwich structure of thickness 722.5 nm at 0 °C (*bottom curve*), 30 °C, 55 °C, 80 °C and 108 °C (*top curve*). The behaviour was identified with a form of the Poole–Frenkel effect. (Data extracted from [28.226])

replaced with either In or Ag. These workers adopted the suggestion of *Jonscher* and *Ansari* [28.221] that electrons can hop between sites as the result of thermal activation; on this assumption good agreement was found with the predicted β_{PF}, with an activation energy between hopping sites of 0.15 eV. Very similar results to these were also observed subsequently [28.218], and again the measured value of β exceeded the theoretical Poole–Frenkel value. This coefficient was also calculated from the gradients of the $\ln J$–$V^{1/2}$ characteristics as a function of temperature, and consistent values were obtained. It was suggested that the similarity between the results of this work and the earlier work [28.226] was related to individual centres experiencing varying electric fields, i. e., the electric field was nonuniform. Equation (28.114) was proposed to account for this effect, and has been successful in accounting for the enhanced coefficients sometimes obtained. Poole–Frenkel conductivity was also identified in p-type CdTe, which also shows a change in conductivity type from SCLC to Poole–Frenkel conductivity [28.227]. This conduction mechanism has also been observed in other cadmium compounds, namely CdSe [28.209] and Cd_3As_2 [28.228]. In phthalocyanine films several instances of this effect have been reported. In oxygen-doped copper phthalocyanine films with a Au and an Al electrode, slightly enhanced values of β were obtained and attributed to a nonuniform electric field, whereas in annealed films the field appeared to be uniform [28.229]. Agreement with the basic model was also found for samples with a Au and a Pb electrode [28.198]. Lead phthalocyanine films with Au and Al electrodes exhibited two different values of β [28.200] consistent with Poole–Frenkel conductivity at higher fields and the Schottky effect at lower fields. However other workers had not considered that Poole–Frenkel conductivity was apparent in the same system [28.230], preferring an interpretation based on two different Schottky barrier widths. Both Schottky and Poole–Frenkel behaviour were observed in oxygen-containing lead phthalocyanine films with two Au electrodes [28.231].

Hopping is a third bulk-limited conduction process which is observed in thin films. This type of conductivity is observed particularly in noncrystalline materials, and is thoroughly discussed in various texts concerned with this topic [28.130, 232]. In this type of material the lack of long-range order results in a phenomenon known as localisation, where the energy levels do not merge into a continuum, particularly in the band-tail regions at the edge of the energy bands. Electrons are transported through the material in a series of jumps or *hops* from one localised energy level to another. The hopping process can occur between the localised energy levels even when only small amounts of thermal energy are available, because the localised levels are normally very closely spaced in energy. For this reason, the process can take place at very low temperatures when other processes are energetically impossible. *Mott* and *Davis* [28.130] argued that the conductivity σ exhibits different behaviour in different temperature regions. At higher temperatures thermal excitation of carriers to the band edges is possible and extended-state or free-band conductivity can take place, while at lower temperatures, where less thermal energy is available, hopping may occur. Different varieties of hopping may take place, and these are distinguished by the length of the hop. Nearest-neighbour hopping is self-explanatory, while in variable-range hopping the hops are on average further than to the nearest neighbour, but the energy difference between the states involved is lower. In the case of variable-range hopping the conductivity has been shown to follow a relationship of the form [28.232]

$$\sigma = \sigma_0 \exp\left(-\frac{A}{T}\right)^{1/4} \qquad (28.115)$$

where σ_0 and A are constants. This relationship is known as the Mott $T^{1/4}$ law, since a plot of log σ against $T^{-1/4}$ shows a linear characteristic with negative slope.

Hopping conduction has been observed in many materials, and is extensively reviewed in the literature [28.130, 232, 233]. The $T^{-1/4}$ law is observed in amorphous Ge [28.234], with the results of *Walley* and *Jonscher* [28.235] also showing this behaviour [28.130]. There is also an example of its appearance in amorphous carbon films [28.236]. AC hopping effects have been observed in several cadmium chalcogenides, and this work is reviewed elsewhere [28.38]. DC hopping was identified in CdTe films with Al electrodes [28.237] following earlier work on AC conductivity [28.195]. The results suggested a hopping process at temperatures below about 175 K, with a hopping centre concentration of about $9\times10^{12}\,\mathrm{m}^{-3}$ and a hopping mobility of $2.16\times10^{-5}\,\mathrm{m}^2/(\mathrm{V\,s})$, the latter considerably lower than the free-band mobility applicable at higher temperatures. The extent of the electron wavefunction was estimated to be 0.69 nm, corresponding to the lattice parameter in CdTe, and supporting the existence of a nearest-neighbour hopping process. Hopping at lower fields was also identified in CdSe films [28.238] and associated with an impurity conduction process proposed previously [28.239]. Variable-range hopping following the $T^{-1/4}$ law has been observed in iron phthalocyanine and in triclinic lead phthalocyanine films [28.240, 241], although the temperature range was restricted. In the work on iron

phthalocyanine the law was followed over the range 140–220 K, with particularly good agreement in the range 156–175 K. In the lead phthalocyanine films similar very good linear behaviour was observed in the temperature range of approximately 220–260 K. Hopping at low temperatures has also been indicated from AC measurements in various phthalocyanine systems [28.242–245].

The first electrode-limited conduction process to be considered is that of tunnelling, which is a quantum-mechanical effect, in which the electron wavefunction is attenuated only moderately by a *thin* barrier, resulting in there being a finite probability of its existence on the opposite side of the barrier. Tunnelling directly from the Fermi level of one electrode to the conduction band of the other is normally possible only for very thin films of thickness less than about 10 nm when subjected to a high electric field. *Simmons* [28.246] investigated the effects of tunnelling between similar electrodes separated by a thin insulating film of thickness s, where the barrier presented by the film was of arbitrary shape. The Wentzel–Kramers–Brillouin (WKB) approximation was used to predict the probability of an electron penetrating the barrier. Different approximations for the current density were found, depending on the relative values of the applied voltage V and φ_0/e, where φ_0 is the barrier height at the electrode interface and e is the electronic charge. These approximations are too unwieldy to be included here, however for the case of $V > \varphi_0/e$ it is only necessary for electrons tunnelling from the Fermi level of one electrode to penetrate a distance $\Delta s < s$ to reach unoccupied levels in the second electrode. This worker also suggested [28.247] that for $V > \varphi_0/e$ a modified *Fowler–Nordheim* [28.248] expression may be applicable for tunnelling through an interfacial region. In this case, the electric field at the barrier is sufficiently high to reduce the barrier width, measured at the Fermi level, to about 5 nm. Under these circumstances the current density is related to the voltage and barrier thickness according to the expression

$$J = \frac{e^3 V^2}{8\pi h \varphi_0 d_t^2} \exp\left(-\frac{8\pi (2m)^{1/2} \varphi_0^{3/2} d_t}{3ehV}\right), \quad (28.116)$$

where h is Planck's constant, φ_0 and d_t are the barrier height and effective thickness, respectively, of the tunnelling barrier and m is the free electron mass. The tunnelling current is largely controlled by the barrier height φ_0, which appears both in the pre-exponential and in the exponential terms. Fowler–Nordheim tunnelling is indicated by a linear dependence of $\log J/V^2$ on $1/V$. A further interesting point for tunnelling in general is that there is very little temperature dependence in the current density, a feature allowing it to be distinguished from other temperature-dependent mechanisms, such as the Schottky effect. There is in fact a very slight quadratic dependence on temperature [28.187], but this is normally negligible within the limitations of experimental measurement.

Early measurements on tunnelling were made by *Fisher* and *Giaever* [28.249] on Al_2O_3 produced by oxidation of Al. There was good agreement with an early tunnelling model [28.250], providing the electron effective mass in the insulator was about $1/9$ of the free electron mass. Very thin films of Al_2O_3 and BeO showed ohmic and faster-than-exponential dependencies of J on V at lower and higher voltages respectively [28.251]. These results were correlated with direct metal-to-metal electrode tunnelling at low voltages, and from the Al electrode to the insulator conduction band at higher voltages. The model of *Simmons* [28.187] was tested by measurements on thermally grown Al_2O_3 films on Al, which used several different types of evaporated counter electrodes [28.252]. An extended tunnelling model [28.253], which is applicable to samples with dissimilar electrodes, was followed over nine decades of current. Measurements on thermally grown SiO_2 films, of thickness 65–500 nm with Al or Au electrodes, showed strong evidence of Fowler–Nordheim tunnelling [28.254]. Since these films were relatively thick, high voltages could be applied, which reduced the Fermi level barrier thickness to that suitable for tunnelling. A linear dependence of $\log J/V^2$ on $1/V$ was obtained, but the measured currents were somewhat lower than those predicted by the theory, probably as the result of trapping effects. Effective masses of $0.48m$ for Ag, $0.39m$ for Al and $0.42m$ for Si were estimated, where m is the free electron mass. Since these early tunnelling measurements, the mechanism has been observed in many different insulating films.

Tunnelling is semiconductors forms the basis of the operation of the tunnel diode. However, in this case a doubly degenerate p-n junction is used, and tunnelling occurs across the depletion region. The operation of this device is described in a standard text on semiconductor devices [28.255]. In sandwich samples of nondegenerate materials, tunnelling has been observed in CdTe [28.225]. In this case there was a linear dependence of the logarithm of the drift mobility on reciprocal electric field for fields in excess of 1.2×10^6 V/m, which is consistent with (28.116). Tunnelling has also been observed in sandwich structures consisting of a copper phthalocyanine film with In electrodes [28.256]. A modified Fowler–Nordheim expression for tunnelling through an interfacial barrier, when the electric field is sufficient to reduce the barrier width to about 5 nm, has been proposed [28.247], and was applied in this case to the In/Cu phthalocyanine

interfacial region. Depending on the sample structure, barrier heights of 0.27 and 0.36 eV were derived. Current densities were somewhat lower than predicted by theory, but were accounted for by the fact that tunnelling areas are often considerably lower than the geometric area [28.18] and that in the presence of traps and space charge the current density is also reduced [28.257].

The second electrode-limited conduction process to be considered may occur when the insulating or semiconducting film is too thick for tunnelling to take place and the concentration of allowed states in the forbidden gap is too low for the hopping process to occur. It is known as the Schottky effect, and is the field-assisted lowering of a potential barrier at the injecting electrode. It is similar in origin to the Poole–Frenkel effect, the latter effect having previously been termed the bulk analogue of the Schottky effect [28.258]. The potential barrier at the injecting electrode interface is reduced by an amount $\Delta\varphi_S$ which is given by

$$\Delta\varphi_S = \beta_S F^{1/2} , \tag{28.117}$$

where

$$\beta_S = \left(\frac{e^3}{4\pi\varepsilon_r\varepsilon_0}\right)^{1/2} \tag{28.118}$$

is the Schottky field-lowering coefficient. The barrier lowering process is similar to that for the Poole–Frenkel effect, and is also illustrated in various literature reviews [28.187–189]. Differences between the standard Poole–Frenkel and Schottky coefficients given by (28.111) and (28.118) are related to the dissimilar symmetry of the potential barriers in the two cases. Clearly the two field-lowering coefficients are related, with $\beta_{PF} = 2\beta_S$. The fundamental thermionic emission equation of Richardson

$$J = AT^2 \exp\left(-\frac{\varphi}{k_B T}\right) \tag{28.119}$$

gives the current density flowing by a process of electron emission over a potential barrier of height φ at a temperature T. In this expression, the constant $A = 1.2\times10^6\,\mathrm{A/m^2}$, and is known as the Richardson constant. The current density depends only on the potential barrier height and the temperature, and does not require an applied voltage to flow, the electrons acquiring thermal energy only. For the case of Schottky emission, if φ_0, given by (28.97), is the zero-voltage barrier height then the reduced barrier height φ is given by $(\varphi_0 - \Delta\varphi_S)$, so that (28.119) becomes

$$J = AT^2 \exp\left(-\frac{\varphi_0}{k_B T}\right) \exp\left(\frac{\beta_S F^{1/2}}{k_B T}\right) \tag{28.120}$$

or

$$J = AT^2 \exp\left(-\frac{\varphi_0}{k_B T}\right) \exp\left(\frac{\beta_S V^{1/2}}{k_B T d^{1/2}}\right) . \tag{28.121}$$

Thus, the Schottky effect should show a linear dependence of $\log J$ on $V^{1/2}$, as for the Poole–Frenkel effect described by (28.113). In principle the two effects can be distinguished by the measured value of the field-lowering coefficient, which should be twice as high for the Poole–Frenkel effect as for the Schottky effect.

The Schottky effect has been reported in many inorganic materials, both insulators and semiconductors. *Emtage* and *Tantraporn* [28.259] observed the effect in both Al_2O_3 and GeO_2 sandwich structures having Al electrodes, while *Pollack* [28.260] made similar observations in Al_2O_3 films with Pb electrodes. In this case, not only the constant voltage J–V characteristics were as predicted by (28.121), but the gradients of $\log J$–$V^{1/2}$ curves increased linearly with reciprocal temperature for temperatures above 235 K, as also predicted by this expression. Below this temperature the variation with temperature was very small, and therefore tunnelling was identified in this region. The dependence of the Schottky effect on the species of electrode was determined in Ta-Ta_2O_5-Au samples prepared by electron beam evaporation and plasma oxidation [28.261]. In this system the Schottky effect was observed when the Ta electrode was biassed negatively and tunnelling when it was biassed positively. Similar results were obtained in CdS films [28.192] using In (ohmic) and Au (blocking) contacts. For electron injection from the Au electrode Schottky-type behaviour was observed, with a Schottky barrier height of 0.88 eV obtained from differential capacitance measurements, close to the value expected for Au contacts to CdS single crystals. Field-lowering behaviour has also been observed in Cd_3As_2 films with a bottom Ag electrode and a top electrode of Ag, Al or Au [28.228]. Although the Schottky barrier height is unlikely to be consistent with the simple model of (28.97) owing to the very narrow band gap and the presence of surface states, the experimental value of β was consistent with the value of β_S predicted by (28.118) for a relative permittivity value of 12.

The Schottky effect has also been observed in several organic thin-film materials. Examples are given here only for the phthalocyanines, which are invariably p-type semiconductors. The Schottky effect occurs for hole injection at the blocking contact. Both metal-free [28.262] and copper phthalocyanine films [28.263] having Al electrodes have shown this effect. Behaviour consistent with the Schottky effect has also been observed in planar copper phthalocyanine films with Al electrodes [28.264], with a depletion region width

of thickness 96 nm. In sandwich structures having a copper phthalocyanine film and a positively biased Al electrode, values of β several times higher than the theoretical $\beta_S = 2\times10^{-5}\,\mathrm{eV\,m^{1/2}\,V^{-1/2}}$ were obtained [28.229]. However, if the theoretical value of β_S were assumed and also that most of the voltage was dropped over a depletion region of thickness d_S as suggested previously [28.264], values of $d_S = 120\,\mathrm{nm}$ and $\varphi_0 = 0.88\,\mathrm{eV}$ were derived. This type of assumption has also been subsequently applied in the case of hole injection from a Pb electrode into copper phthalocyanine films [28.198] and for hole injection in triclinic lead phthalocyanine films from an Al electrode [28.200, 230]. In both cases the Schottky barrier width was 50 nm with a barrier height of either 1.11 or 1.0 eV.

In this section the main high-field conduction processes that might be observed in insulating and semiconducting films have been reviewed, and illustrative examples quoted from the literature. It should be emphasised that identification of a particular mechanism is nontrivial, particularly in distinguishing between the Poole–Frenkel and Schottky effects which have very similar J–V dependencies. Furthermore J–V data obtained over a specified voltage range may also show a good correlation with both SCLC and the Poole–Frenkel effect. It is essential to measure temperature dependencies and also to determine the effects of electrode species on the conductivity, making a full consideration of the type of contacts (ohmic or blocking). As devices and structures become ever smaller with the advance of nanotechnology, some of these conduction processes will inevitably become important in nanoelectronic devices. A discussion concerning this aspect is given elsewhere in the literature [28.11].

28.4 Concluding Remarks

In this chapter, an overview of the deposition methods, structures and major properties of thin films has been given. In this section these are briefly summarised and some possible future developments outlined.

Films may be prepared by many different methods. However, these may usually be classified into chemical or physical methods. In the physical methods the film is deposited from a vapour, maintained at a pressure considerably below that of the atmosphere. Vacuum evaporation is the first of these, where the material is transformed into the vapour phase by heating at reduced pressure. Various types of process have been developed to ensure stoichiometry of the deposited material, such as reactive evaporation and co-evaporation. Taken to its limit of sophistication, the method may be operated under UHV conditions using several sources, each of which may be independently controlled. In this case epitaxial films may be deposited, and the method is known as molecular-beam epitaxy (MBE). The second widely used physical method is that of sputtering, which involves the removal of particles (atoms, molecules or larger fragments) from the surface of a target. This is normally achieved using a gas discharge, which delivers high-energy ions to the target surface. Sputtering has several advantages over evaporation, including deposition of stoichiometric materials, better adhesion to the substrate and the capability of depositing most materials. There are several varieties of sputtering, including DC (diode) sputtering, reactive sputtering and RF sputtering, the latter enabling the deposition of insulators as well as conducting materials. Reactive and co-sputtering give greater flexibility, and higher deposition rates are possible using magnetron sputtering. Various chemical methods may also be utilised for the deposition of films from materials having specific chemical properties. Electrodeposition and electroplating involve passing a high electric current through a solution containing the material, while chemical vapour deposition (CVD) entails the use of various chemical reactions to generate a vapour. The latter method is frequently used in the deposition of electronic materials, and substantial work has been performed in developing processes for several of these. Again there are several different subdivisions of this method, operating at different pressures and with different types of precursor materials. A third chemical method that has found favour in recent years is Langmuir–Blodgett deposition, where molecular layers are applied individually using a dipping process. It has the advantage that high vacuum and elevated temperatures are not required, and film thicknesses are easily derived from the number of layers deposited. It is, however, limited to certain defined materials, and does not have the flexibility of the other methods.

In common with bulk materials, the crystal structure and morphology of thin films may be investigated using diffraction methods and various microscopic techniques (electron microscopy, scanning tunnelling microscopy, etc.). Diffraction methods allow the type of crystal structure to be determined by measurement of the unit cell dimensions in the case of epitaxial and polycrystalline films. Frequently a material may exist in two or more crystalline modifications, and generally these may be distinguished by comparison of diffraction data

from the film with tabulated standard data. The type of crystalline modification that is deposited can depend sensitively on the deposition conditions such as the substrate temperature and deposition rate, and this dependence may be established by systematically depositing films under a wide combination of conditions. Many films have a preferred crystalline orientation, and this too may sometimes be correlated with deposition conditions and the substrate morphology. In polycrystalline films, the crystallites are generally preferentially oriented and show a fibre texture. Estimates of the mean microcrystallite size may be obtained from the width of the diffraction peaks using the Scherrer method. The morphological characteristics of thin films commonly have a columnar grain structure when physical deposition methods are used, and the orientation of the grains may sometimes be related to the incident direction of the depositing atoms or molecules. Larger-scale features of the morphology may often be accounted for in terms of a zone model, where the observed features are identified with the ratio of the substrate temperature to the melting temperature of the film material. Examples of some of these effects in different thin-film materials have been given, and although these are representative of behaviour shown in many thin-film systems, it is clear that both crystal structure and morphology require determination in any specific process used to deposit a particular film material. These features are likely to be particularly important in influencing the optical and electrical properties.

The optical and electrical properties of thin films are those most relevant to this Handbook, and examples of some of the basic properties have been considered as a foundation for some of the more advanced applications described in other chapters. The interference properties of light are fundamental to most of the phenomena observed. In principle the properties of light propagating through media are described by Maxwell's equations, which allow a full analysis for both nonabsorbing and absorbing films for various states of polarisation and optical frequencies. The Fresnel coefficients for reflection and transmission of light at the boundaries between different optical media allow expressions for the energy reflectance and transmittance to be derived. Some examples of these have been given, together with an introduction to matrix methods which may be used to calculate the electric and magnetic field vectors for optical designs of considerable complexity, involving both nonabsorbing and absorbing films. The operation of optical filters, other optical components and fibre-optic waveguides may be predicted by advanced application of these methods. Examples of the basic electrical properties of thin films, which are directly related to the film thickness, are lateral electrical conductivity and high-field conduction processes. Lateral electrical conduction in thin films is a very important feature, which is determined primarily by electron scattering within the film. For metallic films, conductivity–film thickness relationships have been derived in terms of a parameter k, the ratio of the film thickness to the bulk electron mean free path. One would intuitively expect the conductivity to decrease (or the resistivity to increase) with decreasing k, since this implies a curtailment of the mean free path. This problem was first tackled over a century ago by Thomson, and more realistic expressions have been obtained subsequently by solving the Boltzmann transport equation. Unfortunately, the derived general expressions are somewhat complex, but a wide variety of approximations have been obtained for various ranges of k, and the conductivity is predicted to reduce to that of the bulk material for thick films. Further refinements in the analysis were made by introducing a specularity parameter, p, which takes into account the proportion of electrons which are specularly scattered at the surfaces. Better agreement with experimental results is generally obtained if the value of p is intermediate between that for totally diffuse scattering ($p = 0$) and totally specular scattering ($p = 1$). Another development of the theory includes assigning different specularity parameters to the two film surfaces, since scattering at the substrate surface is clearly different from scattering at the top surface. In general the various expressions derived from this type of model are consistent with each other, in that those derived from the more complex assumptions normally reduce to those obtained using simpler assumptions if suitable limits are chosen. Scattering by internal grain boundaries has also been investigated by solving the Boltzmann transport equation, and allows contributions to the conductivity resulting from internal features, as well as the surfaces, to be included in the analysis. The ratio of the thin-film to bulk temperature coefficient of resistivity has been shown to be equal to the ratio of thin-film to bulk conductivity for the case of thicker films, although no such convenient relationship applies for thinner films owing to the dependence of the bulk mean free path on temperature, which is particularly significant for very thin films. Considerations of these types of effect need to be fully assessed when designing interconnects to integrated circuits operating in particular temperature ranges. In insulating or semiconducting thin films, very high electric fields may be applied across the thickness of the film. Under these circumstances a variety of different conduction processes may occur, none of which are observed at lower fields. Crucial to the type of conduction process which develops is the type of contact at the interface. Ohmic contacts allow currents to pass unimpeded by the contact, and

the conduction process is bulk-limited, while blocking contacts effectively limit the conductivity, which is then electrode-limited. Bulk-limited conduction processes include SCLC, Poole–Frenkel conductivity and hopping. Varies types of SCLC have been observed, depending on the type of trap distribution present, if any, and may be distinguished by their characteristic voltage and temperature dependencies. Poole–Frenkel conductivity results from field-dependent lowering of the potential barrier for emission of electrons into the conduction band. Again, various varieties of this process have been observed depending on the appearance of donors and/or traps, and also for the case of nonuniform fields. Hopping is observed particularly in noncrystalline solids, where electrons hop from one localised energy level to another. It is characterised by low mobility, but requires little thermal energy, and is therefore often observed at low temperatures. Different types of hopping are characterised by the mean distance of the electron hopping process, and show different characteristic behaviours. Electrode-limited conduction processes include tunnelling and the Schottky effect. Tunnelling is a quantum-mechanical effect, where for a thin barrier the electron wavefunction has a finite probability of existence on the opposite side of the barrier. Tunnelling may be either directly from one electrode to the other, or may be from the Fermi level of the injecting electrode into the conduction band of the insulator or semiconductor. The type of tunnelling depends on the relative values of the applied voltage and the barrier height at the interface. The tunnelling current is almost independent of temperature, a feature which allows it to be identified relatively easily. For structures where the barrier is too thick for tunnelling to occur, the Schottky effect may take place instead. This is the field-assisted lowering of a potential barrier at the interface, and has several similarities with the bulk Poole–Frenkel effect. Similar J–V characteristics are predicted for both, but may usually be distinguished from the value of a measured field-lowering coefficient, or from considerations of the current level drawn with varying electrode species.

In conclusion, it should be noted that in this chapter only the main established deposition methods and some of the structural, optical and electrical properties of thin films have been reviewed. Although it is hoped that the references included herein are sufficient to allow the reader to explore the subject in some considerable depth, it is clear that these can only provide a snapshot of knowledge at the present time. During the past half century, there have been tremendous developments in all areas of thin-film knowledge, although the basic principles and properties stressed in this chapter underpin most of them. The main physical methods of deposition have been known for a century or so, but improvements have been contingent on advances in vacuum technology, gas-handling capabilities and theoretical work concerning atomic interactions in solids. MBE deposition systems of considerable complexity and sophistication now exist, enabling the deposition of a considerable range of materials in a variety of structures and designs, although only some of the most important processes have been developed to the level where they are employed in automated manufacture. Control of many factors are vital in successful deposition processes, and progress in this area has gone hand in hand with the development of computerised monitoring and data-handling systems. Progress in the manipulation of individual atoms and molecules has been made by the adoption of techniques originally developed for very high-resolution surface imaging, such as scanning tunnelling and atomic force microscopy. Chemical methods of film deposition have developed into many dedicated CVD systems, exploiting reactions which are specific to a particular material or class of materials. Additionally many types of films may be deposited using the Langmuir–Blodgett technique, although this relies on the ingenuity of chemists to develop suitable substituted organic compounds. Further development of many of these deposition methods will undoubtedly progress in future years, particularly as the power of computer systems increases. The most significant advances are likely to be in the area of nanotechnology, where MBE systems, equipped with facilities to build nanostructures atom by atom, are currently under development. The structure and morphology adopted by thin films are likely to have a significant influence on all their properties; this is not restricted to just the optical and electrical properties described in this chapter. Diffraction methods are becoming more precise, and can now be used for the investigation of real-time changes when synchrotron radiation is used. Scanning tunnelling and atomic force microscopic techniques have enabled the acquisition of surface images with resolution of atomic dimensions, and the increased use and development of these and associated techniques will be necessary for future investigation of nanostructures. Optical properties described in this chapter will no doubt be exploited in more complex and sophisticated filter and mirror designs, as well as their employment in fibre-optic cables and applications in photonics. Recent developments in the area of negative-refractive-index materials will no doubt also be exploited in due course. The electrical properties of thin films under both low- and high-field conditions are reasonably well understood, and it is anticipated that applications are likely to be made in the area of nanoelectronics. Some possible applications have been

proposed elsewhere [28.11]. The provision of electrical contacts will remain of particular importance, although it may not be possible to consider the contact region separately from the remaining nanostructure. The efficient injection of charge into nanostructures using tunnelling and Schottky barrier (blocking) contacts may be achieved, and high current densities may be obtained with trap-free SCLC contacts. It is nevertheless clear, however, that in all areas of future development in thin-film technology, the control of deposition processes and materials processing aspects are of paramount importance. This is likely to remain a considerable challenge in the future.

Acknowledgments. We thank Jan Mistrik for his help in checking the section on opical properties.

29. Thick Films

Neil White

Thick film technology is an example of one of the earliest forms of microelectronics-enabling technologies and it has its origins in the 1950s. At that time it offered an alternative approach to printed circuit board technology and the ability to produce miniature, integrated, robust circuits. It has largely lived in the shadow of silicon technology since the 1960s. The films are deposited by screen printing (stenciling), a graphic reproduction technique that can be dated back to the great Chinese dynasties of around a thousand years ago. Indeed, there is evidence that even early Palaeolithic cave paintings from circa 15 000 BC may have been created using primitive stenciling techniques. With the advent of surface-mounted electronic devices in the 1980s, thick film technology again became popular because it allowed the fabrication of circuits without through-hole components.

This chapter will review the main stages of the thick film fabrication process and discuss some of the commonly used materials and substrates. It will highlight the way in which the technology can be used to manufacture hybrid microelectronic circuits. The latter stages of the chapter will demonstrate how the technology has evolved over the past twenty years or so to become an important method in the production of solid state sensors.

References 720

The term *thick film* is often misinterpreted, and so it is worth noting from the outset that it has little to do with the actual thickness of the film itself. The preferred definition encompasses the fabrication process, namely screen printing, used to deposit the films. The typical range of thicknesses for thick film layers is $0.1-100\,\mu m$. Screen printing is one of the oldest forms of graphic art reproduction and involves the deposition of an ink (or paste) onto a base material (or substrate) through the use of a finely-woven screen with an etched pattern of the desired geometry. The process is commonly used for the production of graphics and text onto items such as T-shirts, mugs, pencils, textiles and so on, and is very similar to that used for microelectronic thick films. The degree of sophistication for the latter is, however, significantly greater, resulting in high-quality, reproducible films for use in a variety of electronic systems.

The technology used to manufacture thick film hybrid microelectronic circuits was introduced in the 1950s. Such circuits typically comprised semiconductor devices, monolithic integrated circuits, discrete passive components and the thick films themselves [29.1, 2]. In the early days of the technology, the thick films

were mainly resistors, conductors or dielectric layers. Evidence of thick film circuits can still be found in many of today's commercial devices such as televisions, calculators and telephones. The use of thick film technology was overshadowed in the 1960s by the impact of silicon technology. It found popularity again in the 1980s as a result of the advent of surface-mounted devices, which can be attached to circuit boards using screen-printed solder layers. Nowadays, thick films are not only used in hybrid circuits but also in advanced solid state sensors and actuators, as we shall see later. In broad terms, thick films can be classified as either *cermets* (ceramic/metallics), requiring high-temperature processing, or *polymer* thick films, which are cured at significantly lower temperatures. Polymer thick films will be covered in more detail in Sect. 29.3.4.

29.1 Thick Film Processing

Thick film technology is sometimes referred to as an *additive* technology in that the layers are built up in sequence without the need to remove (or subtract) parts of the film by techniques such as etching. Compare this with, say, a standard printed circuit board (PCB), where the conductive tracks are formed by selectively etching away the undesired areas (gaps) from a continuous copper layer. In the early days of the technology, the ability to fabricate together components made with different enabling technologies to produce a *hybrid* circuit was seen as a way of opening up a whole new field of electronics. This is still one of the most endearing features of the technology today.

29.1.1 Screen Printing

This is the distinguishing feature of thick film technology and is the method of depositing the desired films. The fundamental aspects of the process, traditionally recognized as an art, have been modernized and updated to provide a scientific tool for microelectronic technology. Figure 29.1 illustrates the main aspects of the screen printing process [29.3].

The screen fabric is permanently attached to the screen frame, which is firmly held within the screen printing machine. The distance between the screen and the substrate is typically around 0.5 mm, although the precise gap size is dependent on the overall screen dimensions. The substrate is held in place in the holder by either a vacuum or a mechanical clamp. The position of the screen can be finely adjusted to ensure good registration between consecutive layers. The paste is applied to the upper surface of the screen and the flexible *squeegee* is pulled across the screen over the ink, which is forced through the open areas of the screen mesh. At a point immediately behind the squeegee, the screen peels away from the substrate and, due to the surface tension between the ink and the substrate, leaves a deposit of the paste in the desired pattern on the substrate.

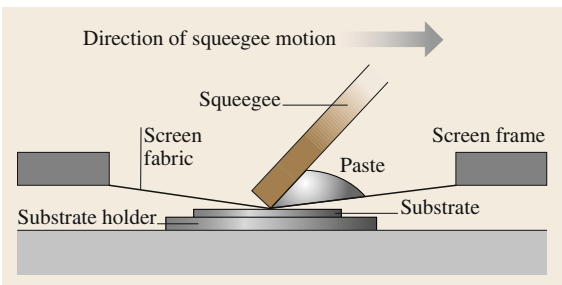

Fig. 29.1 The basic screen printing process

The squeegee is a flexible blade whose function is to transfer the ink through the screen and onto the substrate. It is usually made from materials such as polyurethane or neoprene. The squeegee pressure is adjustable and facilitates accurate and repeatable print thicknesses. The pastes generally exhibit pseudoplastic behavior in that the viscosity varies with the applied shear force. This is a necessary property because the ink must have minimum viscosity to ensure good transfer though the screen, but it also must become more viscous after printing to provide a good definition of the film.

The function of the screen is to define the pattern of the printed film and also to control the amount of paste being deposited. The screens used in graphic artwork are generally made of silk and the process is often termed silk screen printing. For microelectronic circuits, however, the screens tend to be made from polyester, nylon or stainless steel. The resolution of the printed line widths is largely determined by the mesh count (in lines per inch or centimeter) and the mesh filament diameter. Nylon has very good elastic properties but relatively poor resilience. Stainless steel screens produce excellent line definition and durability and are particularly well suited to flat substrates. Polyester screens have the highest resilience and offer a long lifetime and low squeegee wear. Figure 29.2 shows a plain weave pattern on a typical thick film screen. An ultraviolet (UV)-sensitive emulsion covers the underside of the screen. The desired

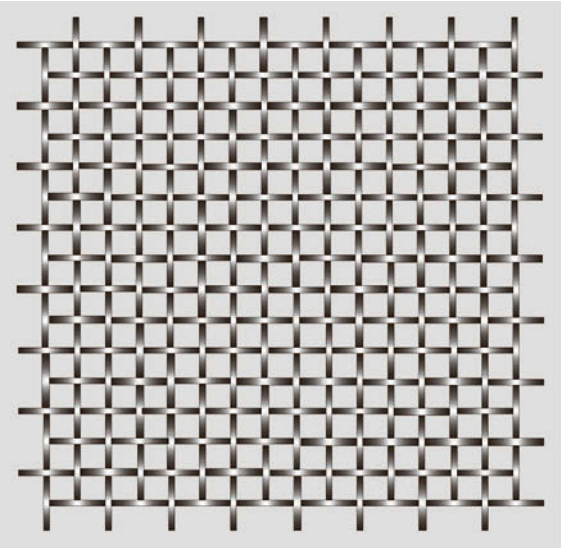

Fig. 29.2 A plain weave screen mesh

pattern is formed onto screen emulsion using a photographic process. The screen printing process can be used to deposit both cermet and polymer thick films; the processing steps that follow are, however, different.

29.1.2 The Drying and Firing Process

The final form of a cermet thick film is a fired, composite layer that is firmly attached to the substrate. Essentially, there are three main stages in the production process: screen printing, drying and firing. At each of these stages, the film is in a slightly different state. Commercial thick film pastes are purchased from the manufacturer in plastic jars and are similar to standard printing inks in many respects. The three main components in a thick film paste are:

- The active material
- A glass frit
- An organic vehicle.

The active material is a finely ground powder with a typical particle size of a few microns. A conductor paste, for example, will contain a precious metal or metal alloy. The glass frit serves as a binder that holds the active particles together and also bonds the film to the substrate. The organic vehicle is necessary to give the paste the correct viscosity for screen printing. It usually contains a resin dissolved in a solvent together with a surfactant that ensures good dispersion of the solid particles.

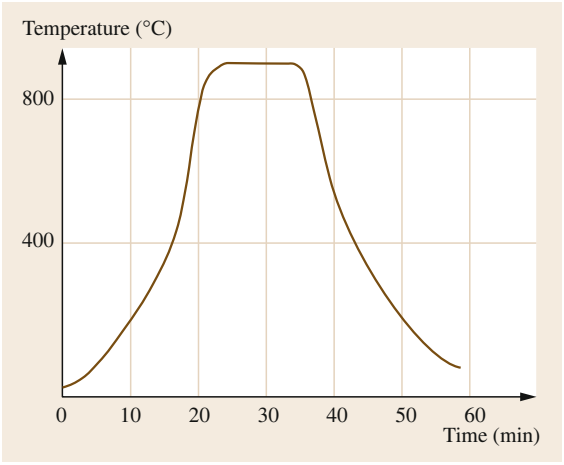

Fig. 29.3 A typical thick film firing profile with a peak temperature of 850 °C

After screen printing, it is usual to allow the film to stand in air for a few minutes to let the paste level off. The film is then dried in an infrared belt drier or a conventional box oven at temperatures up to 150 °C. The purpose of drying is to remove the organic solvents so that the film and substrate can be handled during further processing steps. After drying, the films then proceed to the firing stage. In some circumstances, however, they may be overprinted with another thick film layer if the nature of the film allows this.

The high-temperature firing cycle performs three main functions: the remaining organic carrier is removed from the film, the electrical properties are developed, and the film is bonded to the substrate. In order to achieve these, it is necessary to subject the films to temperatures of up to 1000 °C in a moving belt furnace. Inside the furnace there are several heating zones, which can be independently controlled to a profile specified by the paste manufacturer. Figure 29.3 shows a typical firing profile that is used with commercial thick film resistor pastes. The substrates enter the furnace on a metal chain mesh belt at ambient temperature and slowly (at a rate of a few centimeters per minute) travel through the heating zones, which have their temperatures set to form the desired profile. The substrates remain at the peak temperature for about ten minutes and the electrical properties of the film are formed during this phase. Most thick film materials are fired in a clean, filtered air atmosphere, as this produces high-quality films with repeatable characteristics. Occasionally, however, it is necessary to provide an inert atmosphere such as nitrogen, so that materials such as copper can be processed.

29.2 Substrates

The main functions of the substrate are to provide mechanical support and electrical insulation for the thick films and hybrid circuits. Some of the main considerations for selecting substrates are listed below:

- Dielectric constant: This determines the capacitance associated with different elements fabricated onto the substrate. The dielectric strength will also determine the breakdown properties of the substrate.
- Thermal conductivity: Substrates with a high thermal conductivity can be used in applications where the circuit generates significant amounts of heat.
- Thermal coefficient of expansion (TCE): In general terms, the TCE of the substrate should be closely matched to the thick film materials and other components mounted on it. In some cases this cannot be assured, and in this case the consequences (in terms of thermal strains) must be fully considered.

The main substrate materials used in thick film technology are the ceramic materials alumina (Al_2O_3), beryllia (BeO) and aluminium nitride (AlN). Enamelled or insulated stainless steel substrates are sometimes used in some applications. Silicon has also been used in specialist transducer applications. Alumina, however, is the most common substrate material and it possesses desirable physical and chemical properties in addition to providing an economical solution. Alumina of 96% purity is used in the vast majority of worldwide commercial circuits. The remaining 4% weight fraction of the content is made up of magnesia and silica, which improve the densification and electrical properties. Beryllia has a high thermal conductivity and is used in applications where rapid heat removal is required. It is, however, a very toxic material and is therefore only used in limited application areas. Aluminium nitride is, essentially, an alternative for beryllia, with a high thermal conductivity and also improved mechanical properties such as higher flexural strength. Insulated stainless steel substrates are sometimes used in applications where a high thermal dissipation and mechanical ruggedness are required. They are particularly well suited to mechanical sensor applications.

29.2.1 Alumina

Alumina substrates are manufactured by blending alumina powder, with an average particle size of around 1 μm, together with small amounts of silica, magnesia and calcia. These are either ball- or roll-milled for about 10 h with lubricants, binders and solvents that ensure thorough mixing. Most thick film substrates are less than one millimeter thick, and the preferred method of fabrication is sheet casting. A slurry is allowed to flow out onto a smooth belt, and it passes under a metal doctor blade which controls the resultant thickness. The material is then dried in air to remove the solvent and, at this stage, it is sometimes referred to as the *green state* because of its color. The substrates are then fired in a kiln for at least 12 h. A peak temperature of around 1500 °C ensures that the materials are properly sintered. During firing, the substrates can shrink by up to 20%, and this needs to be taken into consideration for the formation of the final substrate. The surface finish can be improved by coating the surface with a thin, glassy layer (glazing), which is done as an additional step at a lower temperature.

29.2.2 Stainless Steel

Stainless steel is a strong, elastic material with a relatively high thermal conductivity. Being a good electrical conductor, the steel must be coated with an insulating layer before it can be used as a substrate for thick film circuits. Porcelain enamelled steel substrates are made by coating a stainless steel plate with a glassy layer between 100 and 200 μm in thickness. The steel is enamelled either by dipping, electrostatic spraying or electrophoretic deposition of a low-alkali glass and subsequent firing at several hundred degrees Celsius. Some commercial paste manufacturers produce an insulating dielectric thick film ink that can be screen printed directly onto various types of stainless steel. The substrates are fired at a temperature of around 900 °C. The paste contains a devitrifying glass that does not recrystallize on further firings and therefore provides compatibility with other standard thick film materials. Insulated stainless steel substrates also offer the advantages of having a built-in ground plane (the steel itself) and excellent electromagnetic and electrostatic shielding properties. It is also possible to machine the substrate, using conventional workshop facilities, prior to the circuit fabrication.

29.2.3 Polymer Substrates

In some applications it is desirable to fabricate a circuit onto a flexible substrate; evidence of these can be found in mobile telephones, calculators and notebook computers. Cermet thick film materials are not compatible with flexible substrates and hence special polymer thick film materials are used (Sect. 29.3.4). Polymer substrate materials are mainly based on polyesters, polycarbonates and polyimide plastics. The maximum processing temperature is usually limited to around 200 °C.

29.3 Thick Film Materials

29.3.1 Conductors

Thick film conductors are the most widely used material in thick film hybrid circuits. Their main function is to provide interconnection between the components in the circuit. For a multilayered circuit, the conductor tracks are separated by dielectric layers and connection between each layer is achieved with metallized vias. Conductors are also used to form attachment pads for surface-mounted components such as integrated circuits or discrete passive components (resistors, capacitors and inductors). They can also be used as bond pads for naked dice, which may be attached directly to the thick film circuit. Another function of conductors is to provide the terminations for thick film resistors. With such a diverse range of applications, it is no surprise that a wide range of conductor materials is available.

The characteristics of thick film conductors are dependent upon the composition of the functional phase of the paste. Typically, these comprise finely divided particles of precious metals such as silver, gold, platinum or palladium. Base metals such as aluminium, copper, nickel, chromium, tungsten or molybdenum are also used. The particle size, distribution and shape also have an effect on the electrical and physical properties of the fired film.

The resistance of a conductor film is given by

$$R = \frac{\rho l}{wt} ,$$

where ρ is the bulk resistivity (Ω cm), l and w are the length and width of the conductor respectively, and t is the fired thickness of the film. The term *sheet resistivity* is often used for thick films and is defined as the bulk resistivity at a given thickness (ρ/t), expressed in ohms per square ($\Omega/\square$). This is convenient because the resistance of the track can then be calculated by simply multiplying the sheet resistivity by the aspect ratio (l/w) of the film. Table 29.1 summarizes some of the most common metals and metal alloys used in thick film conductors together with their sheet resistivities.

Table 29.1 Most of the common metals and metal alloys used in thick film conductors and their sheet resistivities

Metallurgy	Sheet resistivity (m$\Omega/\square$)
Silver (Ag)	1–3
Gold (Au)	3–5
Copper (Cu)	2–3
Silver/palladium (Ag/Pd)	10–50
Gold/palladium (Au/Pd)	10–80
Gold/platinum (Au/Pt)	50–100

Silver Conductors

Silver pastes were one of the earliest thick film conductors to be developed. They possess good bond strength and high conductivity. There are, however, several disadvantages to using pure silver which prevent it being widely used in many applications. These include:

- Poor leach resistance to solder
- Oxidation in air over time
- Susceptible to electromigration in the presence of moisture, elevated temperature and bias voltage.

Silver/Palladium Conductors

The alloy of silver and palladium is the most common type of thick film conductor and is the alloy most widely used in the hybrid circuit industry. It can be used for interconnecting tracks, attachment pads and resistor terminations, but is generally not recommended for wiring bonding pads. Silver/palladium conductors overcome many of the problems associated with pure silver, and low-migration formulations are available from several commercial suppliers.

Gold Conductors

Gold pastes have a high conductivity and are mainly used in applications where high reliability is required. Gold is a particularly good material for wire bonding pads, although it has relatively poor solderability. Gold is a precious material and hence very expensive; it is therefore not used for general purpose applications and is limited to those areas that can justify the higher costs.

Copper Conductors

Copper thick films have to be processed in an inert atmosphere; nitrogen is typically used in this case. Copper is widely used as the conductor material for printed circuit boards owing to its good electrical conductivity and solderability. These features are also applicable to thick film copper conductors, which also offer ability to handle larger currents than most other thick film conductors.

Platinum Conductors

Not too surprisingly, perhaps, these are the most expensive of all the commercial thick film conductor materials. Platinum films have a very high resistance to solder leaching and exhibit similar electrical properties to those of the bulk material: a linear, well-defined temperature coefficient of resistance (TCR). Platinum films are therefore used in specialist applications such as heaters, temperature sensors and screen-printed chemical sensors.

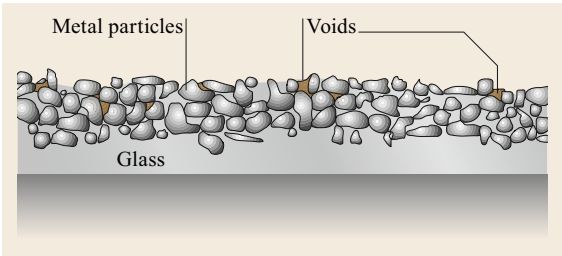

Fig. 29.4 Idealized cross-sectional view of a cermet thick film conductor

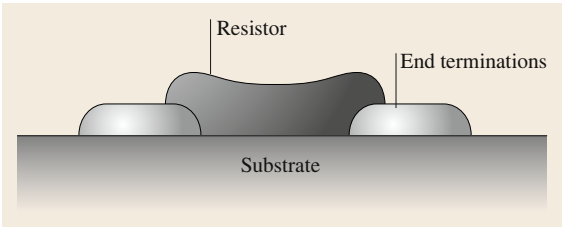

Fig. 29.5 An idealized cross-section of a thick film resistor

Gold Alloy Conductors (Au/Pd, Au/Pt)

These have good bond strength, good solder leach resistance and are relatively easy to solder. The conductivity of the gold alloys tends to be inferior to that of the other type of thick film conductor, but they can be used with both ultrasonic (aluminium) and thermosonic (gold) wire bonds.

Once the conductor has been fired, a composite structure is formed. Figure 29.4 shows a simplified view of the cross-section of a fired thick film conductor on a substrate. Many of the metallic particles have joined together to make a continuous chain. The glass is mainly evident at the interface between the bulk of the film and the substrate. The presence of voids (gaps), both within the film and on its surface, can also be noted.

29.3.2 Resistors

Resistor inks consist of a mixture of the three main phases listed earlier. The relative proportions of the active material to glass frit can have a dramatic effect on the electrical properties of the fired film. The earliest resistors were made from materials such as carbon, silver and iron oxide and were found to suffer from poor long-term stability, unpredictability of fired resistivity, and unacceptably high temperature coefficients. Modern thick film resistor systems are mainly based on ruthenium dioxide (RuO_2) and have much-improved characteristics. This material has a high conductivity

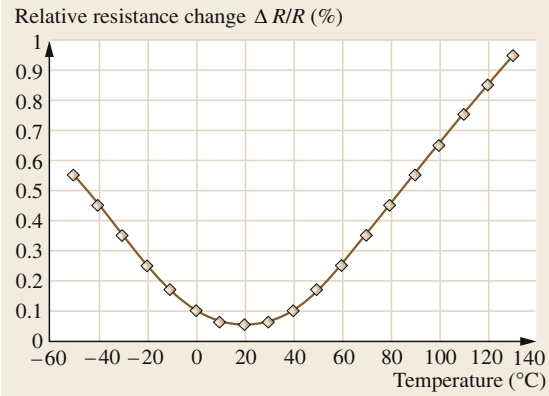

Fig. 29.6 A plot of relative resistance change against temperature for a thick film resistor

and is extremely stable at high temperatures. Within the resistive paste, the conductive phase comprises submicron particles, and these are mixed with larger glass particles (several microns in diameter). Various additives are added to the formulation to improve the stability and electrical properties of the fired film. The nature of these additives is proprietary knowledge of the paste manufacturer.

Figure 29.5 shows an idealized cross-section of a thick film resistor fabricated onto a substrate. The end terminations are first printed and fired and then the resistor is formed in the same manner, allowing for a slight overlap on the terminations so that small misalignments during the printing of the resistor can be accounted for. The actual surface profile of a real resistor would show a nonuniform thickness across its length.

Commercial thick film resistor pastes are available in a range of sheet resistivities from $1-10^9\,\Omega/\square$, and the value of the fired resistor is determined by the selected sheet resistivity and the ratio of the length to the width, as previously described for conductors. For example, a $10\,k\Omega$ resistor could be made by printing a square ($l = w$) of $10\,k\Omega/\square$ resistor paste. Similarly, a $5\,k\Omega$ resistor requires an aspect ratio of $1:2$ ($l:w$) if printed with the same paste. Note that the absolute value of a thick film resistor is not limited to a preferred value, as is the case for discrete resistors.

Figure 29.6 shows the temperature dependence of resistance for a typical thick film resistor. The shape of the plot is unusual because there is a point at which the resistance is a minimum (T_{min}). In general terms, the sensitivity of a resistor to temperature is denoted by the temperature coefficient of resistance (TCR). Mathemat-

ically, this can be expressed by

$$\mathrm{TCR} = \frac{\Delta R/R}{\Delta T} ,$$

where $\Delta R/R$ is the relative change in resistance and ΔT is a small change in temperature. Metals generally exhibit an increase in resistance with increasing temperature, so the TCR is positive. A thick film resistor appears to have both a positive and negative TCR at different regions of the resistance versus temperature curve [29.4]. The point of minimum resistance occurs around room temperature, which means that the resistance is stable under normal operating conditions. It is common practice to refer to the *hot* and *cold* TCR for the regions above and below T_{min}, respectively.

The long-term stability of thick film resistors in air at room temperature is excellent, with a typical change of less than 0.2% over 10^5 h (about 100 years!). At elevated temperatures the stability is still impressive, with most resistance values changing by only 0.5% over 1000 h at 150 °C. The tolerance of fired resistors is around ±20% due to a variety of reasons, including variations in resistor thickness, the tolerance on the quoted sheet resistivity and the effects of the firing process. If accurate values of resistance are required, it is therefore necessary to trim the resistor. This is achieved by removing areas of the resistor with either an air-abrasive jet or a laser. Resistor values can only be increased by trimming, so the printed value is always designed to be less than that of the post-trimmed value.

29.3.3 Dielectrics

Dielectric pastes have four main uses in thick film hybrid circuit applications:

- Cross-over insulators for multilayer circuits
- Thick film capacitor dielectrics
- Passivation layers
- Insulation layers for stainless steel substrates.

Cross-over dielectrics comprise a ceramic material such as alumina, together with the usual glass frit and organic vehicle. These films are required to have a low dielectric constant in order to minimize capacitive coupling between the conducting tracks. They must also have a good insulation resistance and a smooth, pinhole-free surface finish.

There is an occasional requirement to fabricate thick film capacitors, although the wide availability of surface-mounted capacitors has largely precluded their need. It is also difficult to ensure that post-fired values of thick film capacitors closely match those for which they were designed. An expensive trimming process is needed to ensure that the correct valves are obtained.

Overglazes are mainly used to protect resistors from overspray during trimming and also the circuit from environmental attack during operation. The passivation layer is usually the last one to be processed and it is therefore fired at a reduced temperature in order to minimize any adverse refiring effects on other layers. Overglaze materials are therefore almost exclusively made from low-temperature glasses that fire at temperatures of 450–500 °C.

The use of insulated stainless steel substrates was mentioned earlier. The dielectric materials used for this purpose must provide a high insulation resistance (in excess of $10^{12}\,\Omega$) and also possess a high breakdown voltage (greater than 2 kV/mm). There is an inherent mismatch between the thermal coefficient of expansion of the metal substrate and that of the insulation layer, which limits the type of steels that can be used for this purpose.

29.3.4 Polymer Thick Films

The processing temperatures for polymer thick films are significantly less than those needed for cermet materials. Rather than being *fired*, polymer materials are cured at temperatures below 200 °C. One advantage of polymer thick films over cermets is a reduction in processing and material costs. As with cermet pastes, the formulation of polymer thick films comprises the active material, a polymer matrix and various solvents. The polymer matrix acts as *glue* for the active component. Three types of polymer organic composition are used in polymer thick films:

- Thermoplastic
- Thermosetting
- Ultraviolet (UV)-curable.

With thermoplastics, the required viscosity for screen printing is achieved via solvents. The polymer material is typically acrylic, polyester, urethane or vinyl. After printing, the paste is hardened by drying in a belt or box oven. These types of film have relatively poor resistance to environmental conditions and are not resistant to elevated temperatures and solvents. Thermosetting pastes have polymers that are partially cured and are typically epoxy, silicone or phenolic resin. After printing, the polymer is fully cured, providing a strong and stable matrix. Solvents are still needed to provide the correct rheology for printing. The UV curable pastes are generally used for dielectric inks and can be cured at room temperature under an ultraviolet light source.

For conductors, the most commonly used active phases are silver, copper and nickel. Owing to their poor stability at high temperatures, polymer thick film

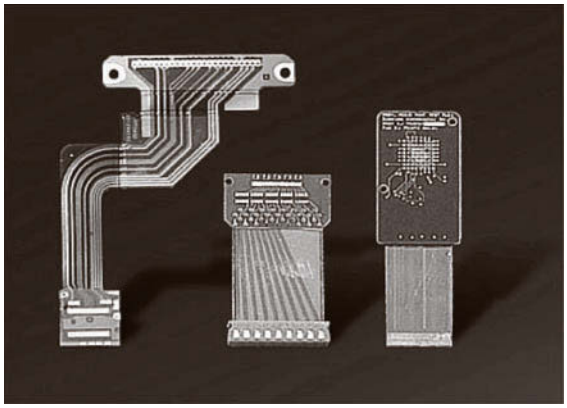

Fig. 29.7 A selection of flexible circuits. (Courtesy of Flex Interconnect Technologies, Milpitas, USA)

conductors cannot be soldered and alternative forms of attachment must be adopted. Carbon is typically used as the active material in polymer thick film resistors. The performance of these resistors is inferior to that of their cermet counterparts and they are therefore seldom used in critical applications. The dielectric pastes are similar in nature to conductors and resistors except that the conducting phase is omitted from the formulation. Some manufacturers add minerals to improve the electrical and mechanical properties of the dielectric films. Polymer thick films are a popular choice of material for disposable biosensors such as those used in the home testing of levels of glucose in human blood samples.

The process for fabricating polymer thick films is similar to that used with cermet materials. Once they have been screen printed, the layers are left to stand in air for a few minutes to ensure that the surface is level and contains no residual mesh patterns. The curing process is achieved in a box oven or an infrared belt dryer at temperatures in the range 150–200 °C. For a thermoset polymer, the higher the temperature and longer the curing time, the greater the cross-linking of the polymer chains in the matrix. This can lead to improved film stability and increased shrinkage.

An early and successful application of polymer thick film technology was the fabrication of membrane switches for keyboards. Today, examples of polymer thick film circuits can be found in many consumer products, such as mobile phones, portable computers, personal digital assistants and calculators. Figure 29.7 shows some typical flexible polymer circuits.

29.4 Components and Assembly

29.4.1 Passive Components

Passive electronic components are those that do not require an external energy source to function. Examples are resistors, capacitors and inductors. As we have seen earlier, thick film technology allows the fabrication of high-quality, stable resistors. It is also possible to add resistors to a thick film circuit in the form of an additional chip component. Such devices are available as surface-mounted devices, which do not require holes to be drilled into the circuit board. Interestingly, chip resistors are often manufactured as multiple parts using thick film techniques on ceramic substrates. These are then diced and the terminations are added. An example of a typical chip component is shown in Fig. 29.8. Resistor values can range 1 Ω to 10 MΩ, with typical tolerances of between ±1 to ±20%.

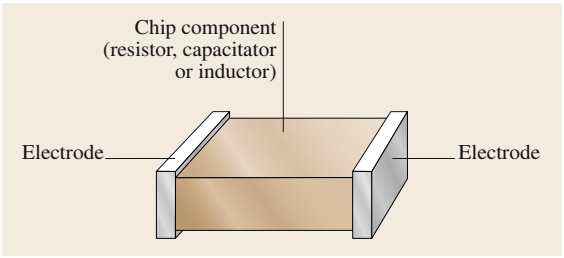

Fig. 29.8 A typical surface-mounted chip component

Planar screen-printed capacitors are rarely used in thick film hybrid circuits owing to their poor stability and high production costs. They typically comprise at least three layers (two electrodes and one dielectric layer), and trimming is often required to achieve the target value of capacitance. Chip capacitors offer improved performance at a lower cost. Capacitances in the range 1 pF to 100 μF are readily available in a range of sizes from the 0201 series (0.6 mm × 0.3 mm × 0.3 mm) to the 2220 series (5.7 mm × 5.0 mm × 3.2 mm). Chip inductors are also available (typical range: 0.1–1000 μH) in a variety of package sizes. There is also a wide choice of variable passive components such as potentiometers and variable capacitors/inductors that are currently available from many major component suppliers.

29.4.2 Active Components

Active components are those that require an external energy source to function. Examples are transistors, diodes and semiconductor integrated circuits (ICs). A wide variety of semiconductor components are avail-

able to the thick film circuit designer. Transistors and diodes, being relatively small devices, are obtained in a small plastic package with three terminals. This is known as a SOT-23 package and is shown in Fig. 29.9a. Many standard integrated circuits that are available in dual-in-line (DIL) packages for through-hole printed circuit boards are also available in small outline (SO) packages for hybrid circuits. An example of a small outline device is shown in Fig. 29.9b, and these usually have between 8 and 40 pins. For devices with higher pin counts such as microprocessor, gate arrays and so on, it is usual to place the leads on all four sides of the package, as with the flatpack device shown in Fig. 29.9c. Occasionally, ICs may be obtained in the form of a naked die, without any packaging. In such cases, it is necessary to glue the chip to the board and to bond very fine wires from the chip to the board. Care has to be taken to ensure that the naked device is suitably encapsulated for use afterwards.

Other forms of IC include flip chips, which are essentially naked chips with raised connection contacts (bumps) made of solder, gold or aluminium. These are mounted by turning over the chip (flipping) and bonding directly to the substrate. Beam lead chips also examples of naked dice with either gold or aluminium leads protruding from the edge. The leads (beams) are an integral part of the chip metallization process. Such devices are usually passivated with a layer of silicon nitride during processing. Tab automated bonding (TAB) refers to a technique by which the naked chip is attached to metallized fingers on a continuous strip of film. Large quantities of devices can be produced on a single roll and the leads of the devices are welded onto the boards before the carrier film is removed. In this manner, it is possible to achieve good yields on high-density circuit populations.

29.4.3 Trimming

The tolerance on the printed value of thick film components such as resistors is around ±20% of the desired value. Many applications require a much tighter tolerance, and so the components need to be trimmed. The two most popular techniques used are trimming by laser or by an air-abrasive jet. Both of these are capable of producing resistors with a tolerance of ±0.1%. Laser trimming, however, is more amenable to large-scale component adjustment.

Air-abrasive trimming uses a pressurized jet of air containing a fine abrasive powder to remove a small area of the fired thick film. The diameter of the jet nozzle is around 0.5 to 1 mm. Alumina particles of average diameter 25 μm are often used as the abrasive medium. The substrate containing the component to be trimmed is held underneath the nozzle at a distance of around 0.6 mm and electrical probes are attached to the device. During trimming, the particles in the jet stream remove material from the component. The debris is removed from the substrate by a vacuum exhaust system. In the case of resistor trimming, the value can only increase because the material is being removed. Resistor values cannot be reduced by the trimming process. For this reason, resistors requiring trimming are designed to be between 25 and 30% lower than the post-trimmed value.

Laser trimming has the advantage of offering a fully automated, high-speed way of adjusting component values. The thick film is vaporized with high-energy laser beam pulses. The laser is typically a Q-switched neodymium-doped YAG (yttrium aluminium garnet) type. A single pulse removes a hole of material and a line is achieved by overlapping consecutive pulses.

Resistors are the most common component requiring trimming. Sometimes conductor tracks need to be adjusted in special circumstances. For example, a platinum conductor being used as a classic Pt 100 resistance thermometer must have a resistance of 100 Ω at 0 °C. In rare circumstances, thick film capacitors can be trimmed by removing an area of one of the plates, although the post-trimmed stability is poor.

Figure 29.10 shows some examples of different types of cut that can be used to trim resistors. The straight cut is the fastest way to trim, but it does not provide a reliable way of achieving a high accuracy. The L-cut overcomes this problem; the resistor is first trimmed straight and then the cut runs parallel to its length, providing a finer adjustment of the value. Both the serpentine and double cut require additional cuts perpendicular to an initial straight cut. The top hat structure is used in situations where a large change in resistance is needed.

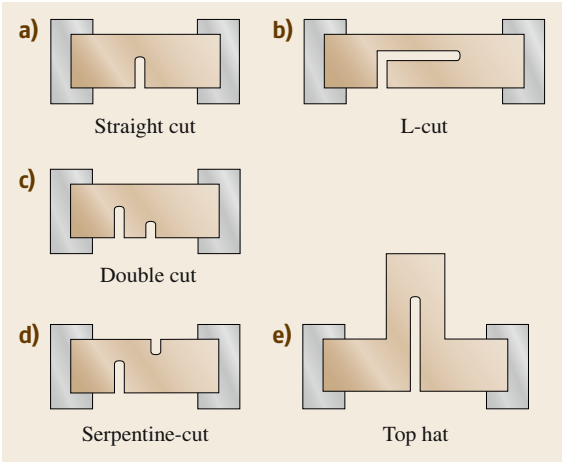

Fig. 29.10a–e Examples of trim cuts for resistors **(a)** Straight cut **(b)** L-cut **(c)** Double cut **(d)** Serpentine cut **(e)** Top hat

29.4.4 Wire Bonding

When a naked integrated circuit is needed as part of a hybrid circuit, connection must be made directly to the bond pads on the die. The chip can be attached to the substrate using an epoxy or by a gold/silicon eutectic bond. Once the chip is firmly held in position, wire bonding can commence. Three main methods are:

- Thermocompression
- Ultrasonic
- Thermosonic.

Thermocompression bonding relies on a combination of heat and pressure. The wire is usually made of gold with a diameter of around 25 μm. Gold or palladium/gold pads are deposited onto the hybrid substrate prior to bonding. The wire is fed through a ceramic capillary and a ball is formed at the end of the wire by a flame or spark discharge. A temperature of 350 °C is required for the bond and is achieved by heating either the substrate or the capillary. An epoxy chip bond cannot be used with this technique as it will soften during the bonding process. The first part of the bond is made on the aluminium bond pad on the chip; the capillary is lowered onto the pad and a force is applied to form a ball shape on the pad. The wire feeds out of the capillary and is then positioned over the desired pad on the substrate. As the capillary is lowered, a combination of heat and pressure forms the bond and the wire is then broken so that the process can be repeated for further bonds.

Ultrasonic bonding uses either a gold or aluminium wire and does not require external heat. The ultrasonic energy is supplied from a 40 kHz transducer. The combination of pressure and ultrasonic vibration causes the materials to bond together at the interface of the wire and the bond pad. This is generally a faster technique than the thermocompression method.

The final category, thermosonic bonding, is a combination of the other techniques. The substrate is heated to around 150 °C and the bond is made using the ultrasonic vibrations. This method is amenable to multilevel and multidirectional bonding and is therefore the preferred method, allowing bonding of up to 100 wires per minute.

29.4.5 Soldering of Surface-Mounted Components

Several techniques exist for the attachment of surface-mounted components to a thick film hybrid circuit. Surface-mounted components are generally much smaller than their through-hole counterparts. Of course, soldering by hand is also possible, although this is a tricky task requiring good operator skill and is often impractical because of the relatively long length of time needed.

Solder dipping requires the components to be placed on the board, either by hand or by a special pick-and-place machine. The components are fixed in position on the substrate by adding a small dot of glue and elevating the temperature to between 120 and 180 °C, which is sufficient to cure the adhesive. The board can then be dipped into a bath of molten solder at a temperature of 200 °C and then withdrawn at a sufficient rate to ensure that an adequate solder coating is obtained.

Wave soldering also requires the components to be fixed in position prior to the soldering process. Wave soldering machines were originally used for soldering through-hole components onto printed circuit boards, but they can also be used effectively with surface-mounted devices. The substrates are placed on a moving belt component side-down and initially pass through a flux bath before entering a solder bath. A wave of molten solder then flows over the substrate and creates a good joint at the desired location. This process can expose the components to a great thermal shock and it is therefore common to have a preheating phase which minimizes such effects. With both of these techniques, it is also necessary to ensure that a solder resist layer is applied to the substrate to cover all the areas that are not required to be soldered. With very densely populated circuits, there can also be a masking effect where some areas are not sufficiently coated with solder.

Reflow soldering is the preferred method of attaching surface-mounted devices. A solder cream is deposited onto the component pads either by screen

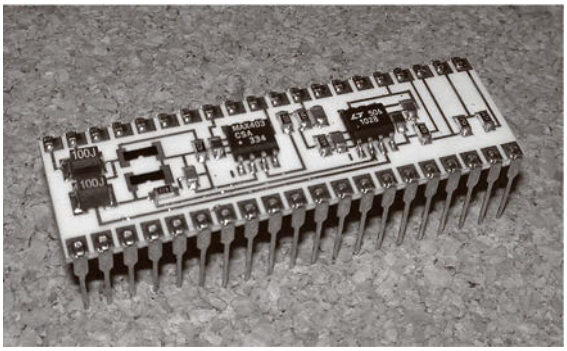

Fig. 29.11 A thick film hybrid circuit

printing or by a solder dispenser. The flux within the cream is sufficiently tacky to hold the component in place so that handling of the substrate is possible. After all of the components have been positioned on the circuit, the solder cream is dried and then reflowed. This process takes place by belt reflow, vapor phase or infrared belt system. A typical belt reflow system comprises a thermally conducting belt upon which the substrates are placed. The belt then travels through a number of heating stages, which causes the solder cream to melt (reflow). Vapor-phase soldering requires the substrates to be lowered into a vessel containing a boiling, inert fluorocarbon. The vapor condenses onto the substrate and raises the temperature uniformly to that of the liquid below. Infrared belt reflow systems are similar to those used for drying thick film materials. The substrate is placed on a wire-mesh belt, which travels through several infrared radiator zones.

29.4.6 Packaging and Testing

Thick film hybrid circuits are very versatile and offer advantages over other forms of enabling technologies. Owing to this flexibility, the circuits have a wide range of shapes and sizes and hence there is no *standard* package type. Selection of a particular form of packaging must therefore involve the consideration of issues such as:

- Protection of the circuit from harsh environmental conditions
- Protection from mechanical damage
- Avoidance of water ingress
- Electrical or mechanical connections to other parts of the system
- Thermal mismatches of different materials.

A simple way of protecting the circuit is to screen print an overglaze layer over the substrate, covering all areas of the substrate except those where components are to be added. A lead frame can then be added to the substrate to allow external connections to be made. An example of a thick film hybrid circuit (without overglaze) is depicted in Fig. 29.11. The two resistors on the left of the circuit have been trimmed and the straight cuts are visible.

Conformal coatings are often used to protect the circuit from environmental attack. These are applied in the form of either a powder or fluid. In the former case, the substrate is heated and immersed into the powder. The temperature is then increased so that the coating dries. For fluids, the substrate is dipped into the coating material and subsequently dried at a temperature of around 70 °C. Typically, the thickness of a conformal coating is between 300 and 1200 μm.

For circuits requiring operation in harsh environments, a special hermetic packaging is needed. The package can be made from ceramics, metals, ceramic/metal or glass/ceramic compositions. The hermetic seal is made by brazing, welding or glass sealing techniques. This form of packaging is often very expensive and is therefore only used in special application areas.

The final stage of the process is to test the circuit to see that its performance matches the design specification. Electrical testing can be difficult if the circuit has been coated or hermetically sealed, as physical access to components may be restricted. It is therefore usual to ensure that key test points are brought out to an external pin on the package. Environmental testing over a range of temperature and humidity may also be required in some circumstances. High-reliability circuits are often subject to a so-called burn-in phase, which involves holding the circuits at an elevated temperature for a given time to simulate the ageing process.

29.5 Sensors

Advances in the field of sensor development are greatly affected by the technologies that are used for their fabrication. The use of thick film processes as an enabling technology for modern-day sensors continues to expand. As we have already seen, the ability to produce miniaturized circuits is clearly one area in which thick film technology excels. The hybrid electronic circuitry can be integrated into the sensor housing to produce the

basis of a smart (or intelligent) sensor [29.5]. Thick film technology also offers the advantage that it can provide a supporting structure onto which other materials can be deposited, possibly using other enabling technologies [29.6].

A major contribution of the technology to sensor development, however, results from the fact that the thick film itself can act as a primary sensing element. As an example, the thick film strain gauge, described below, is merely a conventional thick film resistor that is configured in such a way as to exploit one of its physical characteristics. Commercial thick film platinum conductors can be trimmed and used as calibrated temperature sensors. Most standard pastes, however, have not been specifically developed for sensor applications and do not necessarily have optimum sensing properties. The formulation of special-purpose thick film sensor pastes is the subject of intensive research activity [29.7].

For the purpose of this text, a *sensor* is considered as being a device that translates a signal from one of the common sensing domains (mechanical, thermal, optical, chemical or magnetic) into an electrical signal. An *actuator* is a device that converts an electrical signal into one of the other domains (mainly mechanical).

29.5.1 Mechanical

In broad terms, thick film mechanical sensors are mainly based on piezoresistive, piezoelectric or capacitive techniques. Materials that exhibit a change in bulk resistivity when subjected to deformation by an external force are termed *piezoresistive*. A more common term is the strain gauge, denoting the fact that such devices produce a change in resistance when strained. The effect can be observed in standard cermet thick film resistors [29.6, 8]. The sensitivity of a strain gauge is called the gauge factor (GF) and is defined as

$$\mathrm{GF} = \frac{\Delta R/R}{\varepsilon} ,$$

where $\Delta R/R$ is the relative change in resistance and ε is the applied strain (dimensionless). The gauge factors of metal foil strain gauges and thick film resistors are around 2 and 10 respectively. The former have typical resistance values of either 120 or 350 Ω. As we have already seen, however, it is possible to produce thick film resistors with a wide range of resistance values, and this allows greater flexibility in strain gauge design. It is usual to place the strain gauges in a Wheatstone bridge configuration in order to produce a linear output analog voltage change that is proportional to the mechanical measurand. A wide range of thick film piezoresistive sensors exist, including accelerometers, pressure sensors and load cells.

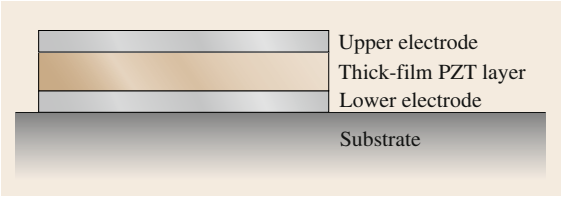

Fig. 29.12 Cross-section of a thick film piezoelectric sample

Piezoelectric materials exhibit the property of producing an electric charge when subjected to an applied mechanical force. They also deform in response to an externally applied electric field. This is an unusual effect, as the material can act as both a sensor and actuator. Certain crystals such as quartz and Rochelle salt are naturally occurring piezoelectrics, whilst others, like the ceramic materials barium titanate, lead zirconate titanate (PZT) and the polymer material polyvinylidene fluoride (PVDF), are *ferroelectric*. Ferroelectric materials are those that exhibit spontaneous polarization upon the application of an applied electric field. This means that ferroelectrics must be poled (polarized) prior to use in order to obtain piezoelectric behavior.

Thick film piezoelectrics have been made by mixing together PZT powder, a glass binder and an organic carrier [29.9]. A conducting layer is first screen printed, dried and fired onto a substrate and then several layers of the PZT film are deposited onto this lower electrode. The piezoelectric layer can be processed in a similar manner to conventional thick films. An upper electrode layer is then deposited onto the PZT in order to make a sandwich structure similar to that shown in Fig. 29.12. This is essentially a planar capacitor and the as-fired film must undergo a poling process by applying a direct current (DC) electric field of around 4 MV/m and elevating the temperature to about 120 °C.

Thick film piezoelectrics have been used in a variety of sensor and actuator applications, including accelerometers, pressure sensors [29.10], micromachined pumps [29.11], surface acoustic wave (SAW) [29.12] and resonant sensors [29.13].

The capacitance C of a parallel plate capacitor is given by

$$C = \frac{\varepsilon_0 \varepsilon_\mathrm{r} A}{d} ,$$

where ε_0 is the permittivity of free space, ε_r is the relative permittivity of the material between the electrodes, A is the area of overlap, and d is the separation of the electrodes. A mechanical sensor exhibiting a change in capacitance can be made by varying A, d or by dis-

placing the dielectric (changing ε_r). The most popular configuration is to vary d in accordance with the desired measurand. This results in a nonlinear relationship between displacement and capacitance. If the variable plate is positioned between two fixed outer electrodes, then a differential structure with a linear response can be obtained. This is a common arrangement in many types of pressure sensor.

29.5.2 Thermal

Devices that exhibit a change in resistance in accordance with variations in temperature are termed *thermoresistive*. For metals, such devices have a linear response to temperature and are known as resistance thermometers. Thermally sensitive semiconductors, typically having a nonlinear response, are termed *thermistors*. Thick film platinum conductor layers can be used as resistance thermometers and exhibit a linear TCR of around 3800 ppm/°C (ppm: parts per million), slightly lower than that of bulk platinum, which is around 4000 ppm/°C. Platinum resistance thermometers (PRTs) are often trimmed so that they have a resistance (R_0) of 100 Ω at 0 °C. Such sensors are sometimes referred to as Pt 100s and are often made of wound platinum wire. Thick film Pt 100s, fabricated onto alumina substrates, are available commercially and are considerably cheaper than the bulk versions. The following expression applies to a PRT over the linear part of the temperature characteristic (−200 to +500 °C)

$$R = R_0(1 + \alpha T) ,$$

where R is the resistance at a temperature T and α is the TCR (ppm/°C).

Thermistors are usually available in the form of discs, rods or beads comprising a sintered composite of a ceramic and a metallic oxide (typically manganese, copper or iron). Thermistor pastes are commercially available and screen-printed sensors are fabricated in a similar manner to conventional thick film resistors. The electrodes are first printed and fired onto an alumina substrate. The thermistor is then deposited across the electrodes and can be trimmed to a specific value if desired. Most thermistors have a negative temperature coefficient (NTC) of resistance; in other words their resistance decreases as the temperature increases. The resistance versus temperature relationship is of the form

$$R = R_0 \exp\left[\beta\left(\frac{1}{T} - \frac{1}{T_0}\right)\right] ,$$

where R_0 is the resistance at a reference temperature T_0 (usually 25 °C).

Positive temperature coefficient (PTC) thermistors are also available, although they are generally not as stable or repeatable as NTCs and are therefore used as simple thermal detectors rather than calibrated devices.

Another type of temperature sensor can be made by joining together two dissimilar metals (or semiconductors). If a temperature difference exists between the joined and open ends, then an open-circuit voltage can be measured between the open ends. This is known as the Seebeck effect and is the basis of a *thermocouple*. A thick film version can be made by overlapping different conductor materials on a substrate, although the thermal sensitivity is much less than traditional wire-based devices.

29.5.3 Optical

Screen-printed photosensors are probably one of the earliest examples of thick film sensors, and their use dates back to the mid 1950s. Materials that exhibit a change in electrical conductivity due to absorbed electromagnetic radiation are known as *photoconductors*. Cadmium sulfide (CdS) is an example of such a material and is notable because of its highly sensitive response in the visible range (450–700 nm). The resistances of such devices can drop from several tens of MΩ in the dark to a few tens of ohms in bright sunlight.

Thick film photoconductor pastes are not widely available commercially, but have been the subject of some research activity [29.14]. Such pastes, based on cadmium sulfide and selenide, are prepared by sintering powdered CdS or CdSe with a small amount of cadmium chloride (which acts as a flux) at a temperature of around 600 °C. This is then ground into a powder and mixed with an organic carrier to make a screen-printable paste. This can then be printed over metal electrodes and fired at a temperature of around 600 °C in air.

29.5.4 Chemical

Thick film materials have been used in a variety of chemical sensor applications for the measurement of gas and liquid composition, acidity and humidity [29.15]. The two main techniques are impedance-based sensors and electrochemical sensors. With the former method, the measurand causes a variation in resistance or capacitance, whilst the latter relies on the sensed quantity changing an electrochemical potential or current.

Impedance-based gas sensor pastes usually comprise a semiconducting metal oxide powder, inorganic

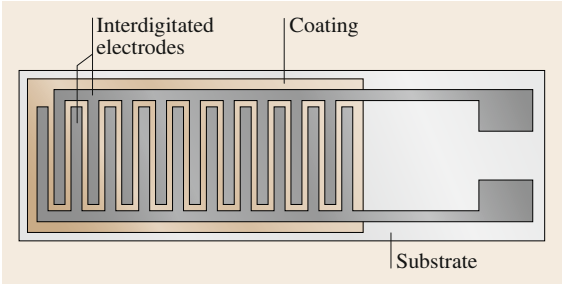

Fig. 29.13 A thick film humidity sensor

additives and organic binders [29.16]. The paste is printed over metal electrodes and a back-heated resistor on an alumina substrate. The heating element is necessary to promote the reaction between the gas being measured and the sensing layer. Figure 29.13 shows an example of a thick film sensor, without a heating element, that can be used to measure humidity. The interlocking *finger* electrodes are often referred to as interdigitated electrodes and are screen printed and fired onto an alumina substrate. A porous dielectric layer is then screen printed onto the electrodes. As the humidity increases, moisture will penetrate the surface of the dielectric layer causing a change in dielectric constant within the sensitive layer. This results in a change in capacitance between the electrodes.

Electrochemical techniques can be used to realise pH sensors. These are often used in biomedical, fermentation, process control and environmental applications. These devices often make use of a solid electrolyte which generates an electrochemical potential between two electrodes in response to the measurand.

Perhaps the most common example of a thick film chemical sensor is the disposable, polymer-based glucose sensor used in many home testing kits for diabetic patients. This illustrates how thick film sensors can offer robust, compact and cost-effective solutions to many modern-day requirements.

29.5.5 Magnetic

Some screen-printable conductors, particularly those containing nickel, exhibit a change in resistivity in response to an applied magnetic field. Such devices are referred to as *magnetoresistive* sensors. Air-fireable nickel-based conductors have been shown to exhibit a nonlinear change in resistance for a linear increase in applied magnetic field [29.17]. A peak change in resistance of around 1% can occur at an applied field of 0.1 T. Researchers have made linear and rotary displacement sensors based on thick film nickel pastes, although it should be noted that such devices are also thermoresistive and therefore the magnetic measurements need to be taken in a temperature-controlled environment.

29.5.6 Actuators

We have previously defined an actuator as a device that converts a signal from the electrical domain into one of the other signal domains. It was noted earlier that piezoelectric materials produce a mechanical stress in response to an electrical charge. Such materials can therefore be used as actuators. Thick film piezoelectric layers have been screen printed onto thin silicon diaphragms in order to form the basis of a micropump [29.11].

Photovoltaic devices convert incident optical radiation into electric current and are often termed *solar cells*. They are used to power devices such as calculators, clocks, pumps and lighting. In general terms, the output power level is proportional to the physical size of the photovoltaic cell. The device is essentially a heterojunction between n-type and p-type semiconductors. Thick film solar cells have been made comprising CdS (n-type) and CdTe (p-type) as the junction materials [29.18]. Such thick film actuators have been shown to have relatively low conversion efficiencies (between 1 and 10%).

30. III–V Ternary and Quaternary Compounds

Sadao Adachi

III–V ternary and quaternary alloy systems are potentially of great importance for many high-speed electronic and optoelectronic devices, because they provide a natural means of tuning the magnitude of forbidden gaps so as to optimize and widen the applications of such semiconductor devices. Literature on the fundamental properties of these material systems is growing rapidly. Even though the basic semiconductor alloy concepts are understood at this time, some practical and device parameters in these material systems have been hampered by a lack of definite knowledge of many material parameters and properties.

This chapter attempts to summarize, in graphical and tabular forms, most of the important theoretical and experimental data on the III–V ternary and quaternary alloy parameters and properties. They can be classified into six groups:

1. Structural parameters
2. Mechanical, elastic, and lattice vibronic properties
3. Thermal properties
4. Energy band parameters
5. Optical properties
6. Carrier transport properties.

The III–V ternary and quaternary alloys considered here are those of Group III (Al, Ga, In) and V (N, P, As, Sb) atoms. The model used in some cases is based on an interpolation scheme and, therefore, requires that data on the material parameters for the related binaries (AlN, AlP, GaN, GaP, etc.) are known. These data have been taken mainly from the Landolt-Börnstein collection, Vol. III/41, and from the *Handbook on Physical Properties of Semiconductors Volume 2: III–V Compound Semiconductors*, published by Springer in 2004. The material parameters and properties derived here are used with wide success to obtain the general properties of these alloy semiconductors.

30.1 Introduction to III–V Ternary and Quaternary Compounds

III–V semiconducting compound alloys are widely used as materials for optoelectronic devices such as light-emitting diodes, laser diodes and photodetectors, as well as for electronic transport devices such as field effect transistors, high electron mobility transistors and heterojunction bipolar transistors. In a ternary alloy, the bandgap energy E_g and the lattice parameter a are generally both functions of a single composition parameter, so they cannot be selected independently. In quaternary alloys, on the other hand, the two composition parameters allow E_g and a to be selected independently, within the constraints of a given alloy-substrate system. Even though the basic semiconductor alloy concepts are understood at this time, the determination of some practical device parameters has been hampered by a lack of definite knowledge of many material parameters. This chapter provides data on the fundamental material properties of III–V ternary and quaternary alloys. The model used here is based on an interpolation scheme and thus requires that values of the material parameters for the related endpoint binaries are known. We therefore begin with the constituent binaries and gradually move on to alloys. The phenomenon of spontaneous ordering in semiconductor alloys, which can be categorized as a self-organized process, is observed to occur spontaneously during the epitaxial growth of certain alloys, and results in modifications to their structural, electronic and optical properties. This topic is omitted from the coverage [30.1].

30.2 Interpolation Scheme

The electronic energy band parameters of III–V compound alloys and their dependence on alloy composition are very important device parameters, and so they have received considerable attention in the past. Investigations of many device parameters have, however, been hampered by a lack of definite knowledge of various material parameters. This necessitates the use of some kind of interpolation scheme. Although the interpolation scheme is still open to experimental verification, it can provide more useful and reliable material parameters over the entire range of alloy composition [30.2].

If one uses the linear interpolation scheme, the ternary parameter T can be derived from the binary parameters (B) by

$$T_{A_xB_{1-x}C} = xB_{AC} + (1-x)B_{BC} \equiv a + bx \qquad (30.1)$$

for an alloy of the form $A_xB_{1-x}C$, where $a \equiv B_{BC}$ and $b \equiv B_{AC} - B_{BC}$. Some material parameters, however, deviate significantly from the linear relation (30.1), and exhibit an approximately quadratic dependence on the mole fraction x. The ternary material parameter in such a case can be very efficiently approximated by the relationship

$$\begin{aligned} T_{A_xB_{1-x}C} &= xB_{AC} + (1-x)B_{BC} + C_{A-B}x(1-x) \\ &\equiv a + bx + cx^2 \,, \end{aligned} \qquad (30.2)$$

where $a \equiv B_{BC}$ and $b \equiv B_{AC} - B_{BC} + C_{A-B}$, and $c \equiv -C_{A-B}$. The parameter c is called the bowing or nonlinear parameter.

The quaternary material $A_xB_{1-x}C_yD_{1-y}$ is thought to be constructed from four binaries: AC, AD, BC, and BD. If one uses the linear interpolation scheme, the quaternary parameter Q can be derived from the Bs by

$$\begin{aligned} Q(x,y) = {} & xyB_{AC} + x(1-y)B_{AD} + (1-x)yB_{BC} \\ & + (1-x)(1-y)B_{BD} \,. \end{aligned} \qquad (30.3)$$

If one of the four binary parameters (e.g., B_{AD}) is lacking, Q can be estimated from

$$Q(x,y) = xB_{AC} + (y-x)B_{BC} + (1-y)B_{BD} \,. \qquad (30.4)$$

The quaternary material $A_xB_yC_{1-x-y}D$ is thought to be constructed from three binaries: AD, BD, and CD. The corresponding linear interpolation is given by

$$Q(x,y) = xB_{AD} + yB_{BD} + (1-x-y)B_{CD} \,. \qquad (30.5)$$

If the material parameter can be given by a specific expression owing to some physical basis, it is natural to consider that the interpolation scheme may also obey this expression. The static dielectric constant ε_s is just the case that follows the Clausius–Mosotti relation. Then, the interpolation expression for the $A_xB_{1-x}C_yD_{1-y}$ quaternary, for example, has the

form

$$\frac{\varepsilon_s(x,y)-1}{\varepsilon_s(x,y)-2} = xy\frac{\varepsilon_s(\mathrm{AC})-1}{\varepsilon_s(\mathrm{AC})-2} + x(1-y)\frac{\varepsilon_s(\mathrm{AD})-1}{\varepsilon_s(\mathrm{AD})-2} + (1-x)y\frac{\varepsilon_s(\mathrm{BC})-1}{\varepsilon_s(\mathrm{BC})-2} + (1-x)(1-y)\frac{\varepsilon_s(\mathrm{BD})-1}{\varepsilon_s(\mathrm{BD})-2} . \quad (30.6)$$

When bowing from the anion sublattice disorder is independent of the disorder in the cation sublattice, the interpolation scheme is written by incorporating these cation and anion bowing parameters into the linear interpolation scheme as

$$Q(x,y) = xyB_{\mathrm{AC}} + x(1-y)B_{\mathrm{AD}} + (1-x)yB_{\mathrm{BC}} + (1-x)(1-y)B_{\mathrm{BD}} + C_{\mathrm{A-B}}x(1-x) + C_{\mathrm{C-D}}y(1-y) \quad (30.7)$$

for the $A_xB_{1-x}C_yD_{1-y}$ quaternary, or

$$Q(x,y) = xB_{\mathrm{AD}} + yB_{\mathrm{BD}} + (1-x-y)B_{\mathrm{CD}} + C_{\mathrm{A-B-C}}xy(1-x-y) \quad (30.8)$$

for the $A_xB_yC_{1-x-y}D$ quaternary.

If relationships for the ternary parameters Ts are available, the quaternary parameter Q can be expressed either as$(A_xB_{1-x}C_yD_{1-y})$

$$Q(x,y) = \frac{x(1-x)[yT_{\mathrm{ABC}}(x)+(1-y)T_{\mathrm{ABD}}(x)]}{x(1-x)+y(1-y)} + \frac{y(1-y)[xT_{\mathrm{ACD}}(y)+(1-x)T_{\mathrm{BCD}}(y)]}{x(1-x)+y(1-y)} , \quad (30.9)$$

or $(A_xB_yC_{1-x-y}D)$

$$Q(x,y) = \frac{xyT_{\mathrm{ABD}}(u)+y(1-x-y)T_{\mathrm{BCD}}(v)}{xy+y(1-x-y)+x(1-x-y)} + \frac{x(1-x-y)T_{\mathrm{ACD}}(w)}{xy+y(1-x-y)+x(1-x-y)} \quad (30.10)$$

with

$$u = \frac{1}{2}(1-x-y) ,$$
$$v = \frac{1}{2}(2-x-2y) ,$$
$$w = \frac{1}{2}(2-2x-y) . \quad (30.11)$$

30.3 Structural Parameters

30.3.1 Lattice Parameters and Lattice-Matching Conditions Between III–V Quaternaries and Binary Substrates

The lattice parameter a (c) is known to obey Vegard's law well, i. e., to vary linearly with composition. Thus, the lattice parameter for a III–V ternary can be simply obtained from (30.1) using the binary data listed in Table 30.1 [30.3, 4]. Introducing the lattice parameters in Table 30.1 into (30.3) [(30.5)], one can also obtain the lattice-matching conditions for $A_{1-x}B_xC_yD_{1-y}$ ($A_xB_yC_{1-x-y}D$) quaternaries on various III–V binary substrates (GaAs, GaSb, InP and InAs). These results are summarized in Tables 30.2, 30.3, 30.4 and 30.5.

30.3.2 Molecular and Crystal Densities

The molecular density d_{M} can be obtained via

$$d_{\mathrm{M}} = \frac{4}{a^3} \quad (30.12)$$

for zinc blende-type materials, and

$$d_{\mathrm{M}} = \frac{4}{a_{\mathrm{eff}}^3} \quad (30.13)$$

for wurtzite-type materials, where a_{eff} is an effective cubic lattice parameter defined by

$$a_{\mathrm{eff}} = \left(\sqrt{3}a^2c\right)^{1/3} . \quad (30.14)$$

The x-ray crystal density g can be simply written, using d_M, as

$$g = \frac{Md_M}{N_A} , \tag{30.15}$$

where M is the molecular weight and $N_A = 6.022 \times 10^{23}\,\mathrm{mol}^{-1}$ is the Avogadro constant. We list g for some III–V binaries in Table 30.1. Alloy values of d_M and g can be accurately obtained using Vegard's law, i. e., (30.1), (30.3), and (30.5).

30.4 Mechanical, Elastic and Lattice Vibronic Properties

30.4.1 Microhardness

The hardness test has been used for a long time as a simple means of characterizing the mechanical behavior of solids. The Knoop hardness H_P for $Ga_xIn_{1-x}P_yAs_{1-y}$ lattice-matched to InP has been reported [30.5], and is found to increase gradually from 520 kg/mm^2 for $y = 0$ ($Ga_{0.47}In_{0.53}As$) to 380 kg/mm^2 for $y = 1.0$ (InP). It has also been reported that the microhardness in $Al_xGa_{1-x}N$ thin film slightly decreases with increasing AlN composition x [30.6].

30.4.2 Elastic Constants and Related Moduli

Although the elastic properties of the III–V binaries have been studied extensively, little is known about their alloys. Recent studies, however, suggested that the elastic properties of the alloys can be obtained, to a good approximation, by averaging the binary endpoint values [30.7, 8]. We have, therefore, listed in Tables 30.6 and 30.7 the elastic stiffness (C_{ij}) and compliance constants (S_{ij}) for some III–V binaries with zinc blende and wurtzite structures, respectively. Table 30.8 also summarizes the functional expressions for the bulk modulus B_u, Young's modulus Y, and Poisson's ratio P. Note that Y and P are not isotropic, even in the cubic zinc blende lattice.

30.4.3 Long-Wavelength Phonons

The atoms of a crystal can be visualized as being joined by harmonic springs, and the crystal dynamics can be analyzed in terms of a linear combination of $3N$ normal modes of vibration (N is the number of different types of atoms; different in terms of mass or ordering in space). In alloys, the nature of the lattice optical spectrum depends on the difference between the quantities representing the lattice vibronic properties of the components. If these quantities are similar, then the optical response of an alloy is similar to the response of a crystal with the quantities averaged over the composition (one-mode behavior). In one-mode systems, such as most I–VII alloys, a single set of long-wavelength optical modes appears, as schematically shown in Fig. 30.1. When the parameters differ strongly, the response of a system is more complex; the spectrum contains a number of bands, each of which corresponds to one of the components, and it has an intensity governed by its content in the alloy (*multimode* behavior). For example, a two-mode system exhibits

Table 30.9 Behavior of the long-wavelength optical modes in III–V ternary and quaternary alloys

Behavior	Alloy
One mode	AlGaN (LO; cubic), AlGaN (except for E_1(TO); wurtzite), GaInN, AlAsSb
Two mode	AlGaN (TO; cubic), AlGaN (E_1(TO); wurtzite), AlInN, AlGaP, AlGaAs, AlGaSb, AlInP, AlInAs, AlInSb, GaInP, GaInAs, GaNP, GaNAs, GaPAs, GaPSb, GaAsSb, InPAs, InPSb
One–two mode	GaInSb, InAsSb
Two–three mode	AlGaInP/GaAs
Three mode	AlGaAsSb, GaInAsSb, AlGaInAs/InP, InPAsSb
Three–four mode	AlGaPAs
Four mode	GaInPSb, GaInPAs/GaAs, GaInPAs/InP

two distinct sets of optical modes with frequencies characteristic of each end member and strengths that are roughly proportional to the respective concentrations.

As seen in Table 30.9, the long-wavelength optical phonons in III–V ternaries exhibit either one-mode or two-mode behavior, or more rigorously, three different types of mode behavior: one-mode, two-mode, and one–two-mode behaviors. The one–two-mode system exhibits a single mode over only a part of the composition range, with two modes observed over the remaining range of compositions.

In a quaternary alloy of the $A_xB_{1-x}C_yD_{1-y}$ type, there are four kinds of unit cells: AC, AD, BC, and BD. On the other hand, in the $A_xB_yC_{1-x-y}D$ type there are three kinds of unit cells: AD, BD, and CD. We can, thus, expect four-mode or three-mode behavior of the long-wavelength optical modes in such quaternary alloys ([30.9]; Table 30.9). However, the $Ga_xIn_{1-x}As_ySb_{1-y}$ quaternary showed three-mode behavior with GaAs, InSb and mixed InAs/GaAs characteristics [30.10]. The $Ga_xIn_{1-x}As_ySb_{1-y}$ quaternary was also reported to show two-mode or three-mode behavior, depending on the alloy composition [30.11].

The long-wavelength optical phonon behavior in the $Al_xGa_{1-x}As$ ternary has been studied both theoretically and experimentally. These studies suggest that the optical phonons in $Al_xGa_{1-x}As$ exhibit the two-mode behavior over the whole composition range. Thus, the $Al_xGa_{1-x}As$ system has two couples of the transverse optical (TO) and longitudinal optical (LO) modes; one is the GaAs-like mode and the other is the AlAs-like mode. Each phonon frequency can be expressed as [30.12]:

- TO (GaAs): $268-14x\ \mathrm{cm}^{-1}$
- LO (GaAs): $292-38x\ \mathrm{cm}^{-1}$
- TO (AlAs): $358+4x\ \mathrm{cm}^{-1}$
- LO (AlAs): $358+71x-26x^2\ \mathrm{cm}^{-1}$.

It is observed that only the AlAs-like LO mode shows a weak nonlinearity with respect to the alloy composition x.

30.5 Thermal Properties

30.5.1 Specific Heat and Debye Temperature

Since alloying has no significant effect on elastic properties, it appears that using the linear interpolation scheme for alloys can provide generally acceptable specific heat values (C). In fact, it has been reported that the C values for InP_xAs_{1-x} [30.13] and $Al_xGa_{1-x}As$ [30.14] vary fairly linearly with alloy composition x. It has also been shown [30.12] that the Debye temperature θ_D for alloys shows very weak nonlinearity with composition. From these facts, one can suppose that the linear interpolation scheme may provide generally acceptable C and θ_D values for III–V semiconductor alloys. We have, therefore, listed in Table 30.10 the III–V binary endpoint values for C and θ_D at $T = 300\,\mathrm{K}$. Using these values, the linearly interpolated C value for $Al_xGa_{1-x}As$ can be obtained from $C(x) = 0.424x + 0.327(1-x) = 0.327 + 0.097x$ (J/(g K)).

Table 30.10 Specific heat C and Debye temperature θ_D for some III–V binaries at 300 K

Binary	C (J/(g K))	θ_D (K)	α_{th} ($10^{-6}K^{-1}$)

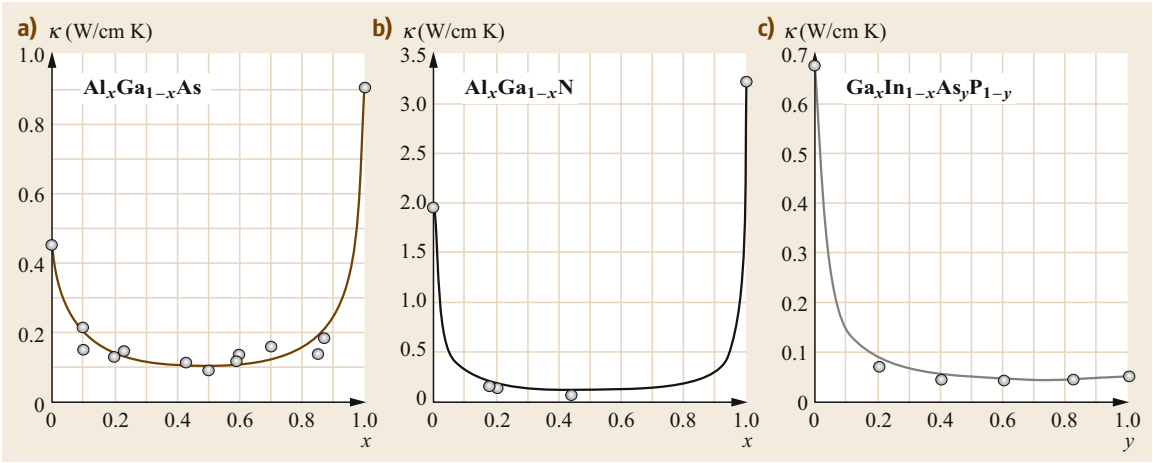

Fig. 30.3a–c Thermal conductivity κ as a function of $x(y)$ for **(a)** $Al_xGa_{1-x}As$, **(b)** $Al_xGa_{1-x}N$, and **(c)** $Ga_xIn_{1-x}As_yP_{1-y}$ lattice-matched to InP at $T = 300\,K$. The experimental data (*solid circles*) are gathered from various sources. The *solid lines* represent the results calculated from (30.2) and (30.6) using the binary endpoint values and nonlinear parameters in Table 30.11

30.5.2 Thermal Expansion Coefficient

The linear thermal expansion coefficient α_{th} is usually measured by measuring the temperature dependence of the lattice parameter. The composition dependence of α_{th} has been measured for many semiconductor alloys, including $Ga_xIn_{1-x}P$ [30.15] and GaP_xAs_{1-x} [30.16]. These studies indicate that the α_{th} value varies almost linearly with composition. This suggests that the thermal expansion coefficient can be accurately estimated using linear interpolation. In fact, we plot in Fig. 30.2 the 300 K value of α_{th} as a function of x for the $Al_xGa_{1-x}As$ ternary. By using the least-squares fit procedure, we obtain the linear relationship between α_{th} and x as $\alpha_{th}(x) = 6.01-1.74x\ (10^{-6}\,K^{-1})$. This expression is almost the same as that obtained using the linear interpolation expression

$$\alpha_{th}(x) = 4.28x + 6.03(1-x)$$
$$= 6.03-1.75(10^{-6}\,K^{-1})\,.$$

The binary endpoint values of α_{th} are listed in Table 30.10.

30.5.3 Thermal Conductivity

The lattice thermal conductivity κ, or the thermal resistivity $W = 1/\kappa$, results mainly from interactions between phonons and from the scattering of phonons by crystalline imperfections. It is important to point out that when large numbers of foreign atoms are added to the host lattice, as in alloying, the thermal conductivity may decrease significantly. Experimental data on various alloy semiconductors, in fact, exhibit strong nonlinearity with respect to the alloy composition. Such a composition dependence can be successfully explained by using the quadratic expression of (30.2) or (30.6) [30.17].

In Fig. 30.3 we compare the results calculated from (30.2) [(30.7)] to the experimental data for $Al_xGa_{1-x}As$, $Al_xGa_{1-x}N$ and $Ga_xIn_{1-x}As_yP_{1-y}$/InP alloys. The binary W values used in these calculations are taken from Table 30.11. The corresponding nonlinear parameters C_{A-B} are also listed in Table 30.11. The agreement between the calculated and experimen-

Table 30.11 Thermal resistivity values W for some III–V binaries at 300 K. Several cation and anion bowing parameters used for the calculation of alloy values are also listed in the last column

Binary	W (cm K/W)	C_{A-B} (cm K/W)
AlN	0.31[a]	
AlP	1.11	$C_{Al-Ga} = 32$
AlAs	1.10	$C_{Al-In} = 15$
AlSb	1.75	$C_{Ga-In} = 72$
α-GaN	0.51[a]	$C_{N-P} = 36$
GaP	1.30	$C_{N-As} = 12$
GaAs	2.22	$C_{N-Sb} = 10$
GaSb	2.78	$C_{P-As} = 25$
InN	2.22[b]	$C_{P-Sb} = 16$
InP	1.47	$C_{As-Sb} = 91$
InAs	3.33	
InSb	5.41–6.06	

[a] Heat flow parallel to the basal plane, [b] ceramics

tal data is excellent. By applying the present model, it is possible to estimate the κ (or W) values of experimentally unknown III–V alloy systems, such as $GaAs_xSb_{1-x}$ and $Al_xGa_yIn_{1-x-y}As$.

30.6 Energy Band Parameters

30.6.1 Bandgap Energy

Lowest Direct and Lowest Indirect Band Gaps

The bandgap energies of III–V ternaries usually deviate from the simple linear relation of (30.1) and have an approximately quadratic dependence on the alloy composition x. Table 30.12 summarizes the lowest direct gap energy E_0 and the lowest indirect gap energies E_g^X and E_g^L for some III–V binaries of interest here. The corresponding nonlinear parameters C_{A-B} are listed in Table 30.13 [30.18]. Note that the E_g^X and E_g^L transitions correspond to those from the highest valence band at the Γ point to the lowest conduction band near X ($\Gamma_8 \rightarrow X_6$) or near L ($\Gamma_8 \rightarrow L_6$), respectively. The E_0 transitions take place at the Γ point ($\Gamma_8 \rightarrow \Gamma_6$).

Figure 30.4 plots the values of E_0 and E_g^X as a function of alloy composition x for the $Ga_xIn_{1-x}P$ ternary at $T = 300$ K. The solid lines are obtained by introducing the numerical values from Tables 30.12 and 30.13 into (30.2). These curves provide the direct–indirect crossover composition at $x \approx 0.7$. Figure 30.5 also shows the variation in composition of E_0 in the $Ga_xIn_{1-x}As$, $InAs_xSb_{1-x}$ and $Ga_xIn_{1-x}Sb$ ternaries. It is understood from Table 30.13 that the bowing parameters for the bandgap energies of III–V ternaries are negative or very small, implying a downward bowing or a linear interpolation to within experimental uncertainty (Figs. 30.4 and 30.5). It should be noted that nitrogen incorporation into (In,Ga)(P,As) results in a giant bandgap bowing of the host lattice for increasing nitrogen concentration [30.19]. We also summarize in Table 30.14 the expressions for the E_0 gap energy of some III–V quaternaries as a function of alloy composition.

summarize in Table 30.15 the higher-lying bandgap energies E_1 and E_2 for some III–V binaries. The corresponding bowing parameters for these gaps are listed in Table 30.16.

30.6.2 Carrier Effective Mass

Electron Effective Mass

Since the carrier effective mass is strongly connected with the carrier mobility, it is known to be one of the most important device parameters. Effective masses can be measured by a variety of techniques, such as the Shubnikov-de Haas effect, magnetophonon resonance, cyclotron resonance, and interband magneto-optical effects. We list in Table 30.17 the electron effective mass (m_e^Γ) at the Γ-conduction band and the density of states (m_e^α) and conductivity masses (m_c^α) at the X-conduction and L-conduction bands of some III–V binaries. We also list in Table 30.18 the bowing parameters used when calculating the electron effective mass m_e^Γ for some III–V ternaries from (30.2). Note that the density of states mass m_e^α for electrons in the conduction band minima $\alpha = \Gamma$, X, and L can be obtained from

$$m_e^\alpha = N^{2/3} m_{t\alpha}^{2/3} m_{l\alpha}^{1/3} , \qquad (30.16)$$

where N is the number of equivalent α minima ($N = 1$ for the Γ minimum, $N = 3$ for the X minima, and $N = 4$ for the L minima). The two masses m_l and m_t in (30.16) are called the longitudinal and transverse masses, respectively. The density of states effective mass m_e^α is used to calculate the density of states. The conductivity effective mass m_c^α, which can be used for calculating the conductivity (mobility), is also given by

$$m_c^\alpha = \frac{3 m_{t\alpha} m_{l\alpha}}{m_{t\alpha} + 2 m_{l\alpha}} . \qquad (30.17)$$

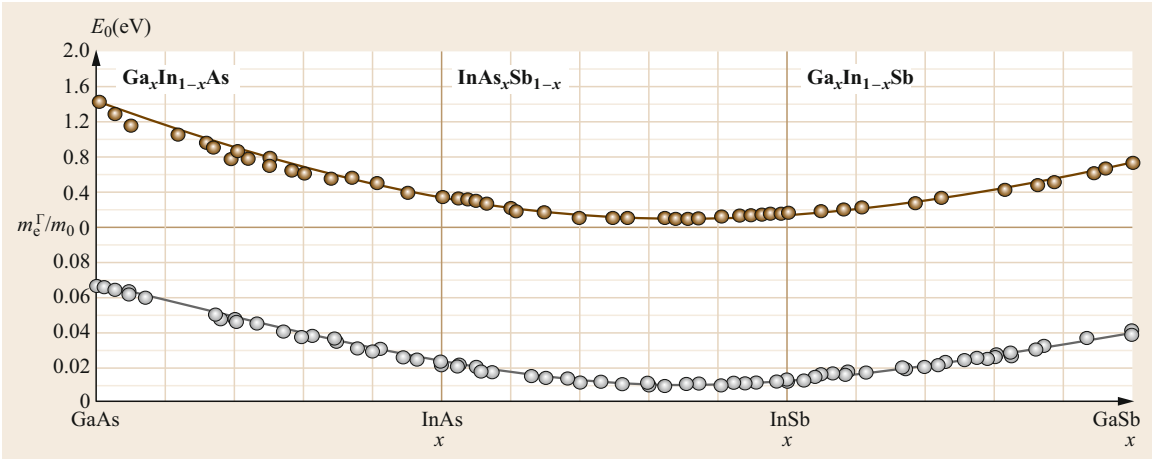

Fig. 30.5 Variation of the lowest direct gap energy E_0 ($T = 300\,K$) and electron effective mass m_e^Γ at the Γ-conduction bands of $Ga_xIn_{1-x}As$, $InAs_xSb_{1-x}$ and $Ga_xIn_{1-x}Sb$ ternaries. The experimental data are gathered from various sources. The *solid lines* are calculated from (30.2) using the binary endpoint values and bowing parameters in Tables 30.12 and 30.13 (E_0) and those in Tables 30.17 and 30.18 (m_e^Γ)

Since $m_{l\Gamma} = m_{l\Gamma}$ at the $\alpha = \Gamma$ minimum of cubic semiconductors, we have the relation $m_e^\Gamma = m_c^\Gamma$. In the case of wurtzite semiconductors, we have the relation $m_e^\Gamma \neq m_c^\Gamma$, but the difference is very small.

The composition dependence of the electron effective mass m_e^Γ at the Γ-conduction bands of $Ga_xIn_{1-x}As$, $InAs_xSb_{1-x}$ and $Ga_xIn_{1-x}Sb$ ternaries is plotted in Fig. 30.5. The solid lines are calculated from (30.2) using the binary endpoint values and bowing parameters in Tables 30.17 and 30.18. For conventional semiconductors, the values of the effective mass are known to decrease with decreasing bandgap energy (Fig. 30.5). This is in agreement with a trend predicted by the $\boldsymbol{k}\cdot\boldsymbol{p}$ theory [30.2]. In III–V-N alloys, the electron effective mass has been predicted to increase with increasing nitrogen composition in the low composition range [30.19]. This behavior is rather unusual, and in fact is opposite to what is seen in conventional semiconductors. However, a more recent study suggested that the effective electron mass in GaN_xAs_{1-x} decreases from $0.084m_0$ to $0.029m_0$ as x increases from 0 to 0.004 [30.20]. We also summarize in Table 30.19 the composition dependence of m_e^Γ, determined for $Ga_xIn_{1-x}P_yAs_{1-y}$ and $Al_xGa_yIn_{1-x-y}As$ quaternaries lattice-matched to InP.

Hole Effective Mass

The effective mass can only be clearly defined for an isotropic parabolic band. In the case of III–V materials, the valence bands are warped from spherical symmetry some distance away from the Brillouin zone center (Γ). Depending on the measurement or calculation technique employed, different values of hole masses are then possible experimentally or theoretically. Thus, it is always important to choose the correct definition of the effective hole mass which appropriate to the physical phenomenon considered.

We list in Table 30.20 the density of states heavy hole (m_{HH}^*), the averaged light hole (m_{LH}^*), and spin orbit splitoff effective hole masses (m_{SO}) in some cubic III–V semiconductors. These masses are, respectively, defined using Luttinger's valence band parameters γ_i by

$$m_{HH}^* = \frac{\left(1 + 0.05\gamma_h + 0.0164\gamma_h^2\right)^{2/3}}{\gamma_1 - \overline{\gamma}}\,, \tag{30.18}$$

$$m_{LH}^* = \frac{1}{\gamma_1 + \overline{\gamma}}\,, \tag{30.19}$$

$$m_{SO} = \frac{1}{\gamma_1} \tag{30.20}$$

Only a few experimental studies have been performed on the effective hole masses in III–V alloys, e.g., the $Ga_xIn_{1-x}P_yAs_{1-y}$ quaternary [30.2]. While some data imply a bowing parameter, the large uncertainties in existing determinations make it difficult to conclusively state that such experimental values are preferable to a linear interpolation. The binary endpoint data listed in Table 30.20 enable us to estimate alloy values using the linear interpolation scheme.

30.6.3 Deformation Potential

The deformation potentials of the electronic states at the Brillouin zone centers of semiconductors play an important role in many physical phenomena. For example, the splitting of the heavy hole and light hole bands at the Γ point of the strained substance can be explained by the shear deformation potentials, b and d. The lattice mobilities of holes are also strongly affected by these potentials. Several experimental data have been

reported on the deformation potential values for III–V alloys, $Al_xGa_{1-x}As$ [30.12], GaP_xAs_{1-x} [30.21] and $Al_xIn_{1-x}As$ [30.22]. Due to the large scatter in the experimental binary endpoint values, it is very difficult to establish any evolution of the deformation potentials with composition. We list in Table 30.21 the recommended values for the conduction band (a_c) and valence band deformation potentials (a_v, b, d) of some cubic III–V binaries. The deformation potentials for some wurtzite III–V semiconductors are also collected in Table 30.22. Until more precise data become available, we suggest employing the linear interpolation expressions in order to estimate the parameter values of these poorly explored properties.

30.7 Optical Properties

30.7.1 The Reststrahlen Region

It should be noted that in homopolar semiconductors like Si and Ge, the fundamental vibration has no dipole moment and is infrared inactive. In heteropolar semiconductors, such as GaAs and InP, the first-order dipole moment gives rise to a very strong absorption band associated with optical modes that have a $\boldsymbol{k}$ vector of essentially zero (i. e., long-wavelength optical phonons). This band is called the reststrahlen band. Below this band, the real part of the dielectric constant asymptotically approaches the static or low-frequency dielectric constant ε_s. The optical constant connecting the reststrahlen near-infrared spectral range is called the high-frequency or optical dielectric constant ε_∞. The value of ε_∞ is, therefore, measured for frequencies well above the long-wavelength LO phonon frequency but below the fundamental absorption edge.

The general properties of ε_s and ε_∞ for a specific family of compounds, namely III–V and II–VI compounds, suggest that the dielectric constants in alloy semiconductors could be deduced by using the linear interpolation method [30.26]. The simplest linear interpolation method is to use (30.1), (30.3) or (30.5). The linear interpolation scheme based on the Clausius–Mosotti relation can also be obtained from (30.6). In Fig. 30.6, we show the interpolated ε_∞ as a function of x for the $Al_xGa_{1-x}Sb$ ternary. The solid and dashed lines are, respectively, calculated from (30.1) and (30.6) (ternary). The experimental data are taken from *Lu-*

values for some wurtzite III–V binary semiconductors.

The optical spectra observed in the reststrahlen region of alloy semiconductors can be explained by the following multioscillator model [30.12]

$$\varepsilon(\omega) = \varepsilon_\infty + \sum_j \frac{S_j \omega_{\mathrm{TO}j}^2}{\omega_{\mathrm{TO}j}^2 - \omega^2 - \mathrm{i}\omega\gamma_j}\,, \qquad (30.22)$$

where $S_j = \varepsilon_\infty\,(\omega_{\mathrm{LO}j}^2 - \omega_{\mathrm{TO}j}^2)$ is the oscillator strength, $\omega_{\mathrm{TO}j}$ ($\omega_{\mathrm{LO}j}$) is the TO (LO) phonon frequency, and γ_j is the damping constant of the j-th lattice oscillator. We show in Fig. 30.7, as an example, the optical spectra in the reststrahlen region of the $Al_xGa_{1-x}As$ ternary. As expected from the two-mode behavior of the long-wavelength optical phonons, the $\varepsilon(\omega)$ spec-

tra of $Al_xGa_{1-x}As$ exhibit two main optical resonances: GaAs-like and AlAs-like.

30.7.2 The Interband Transition Region

The optical constants in the interband transition regions of semiconductors depend fundamentally on the electronic energy band structure of the semiconductors. The relation between the electronic energy band structure and $\varepsilon_2(E)$ is given by

$$\varepsilon_2(E) = \frac{4e^2\hbar^2}{\pi\mu^2E^2}\int \mathrm{d}\boldsymbol{k}\,|P_{\mathrm{cv}}(\boldsymbol{k})|^2\,\delta[E_{\mathrm{c}}(k)-E_{\mathrm{v}}(k)-E]\,, \tag{30.23}$$

where μ is the combined density of states mass, the Dirac δ function represents the spectral joint density of states between the valence-band $[E_{\mathrm{v}}(\boldsymbol{k})]$ and conduction-band states $[E_{\mathrm{c}}(\boldsymbol{k})]$, differing by the energy $E = \hbar\omega$ of the incident light, $P_{\mathrm{cv}}(\boldsymbol{k})$ is the momentum matrix element between the valence-band and conduction-band states, and the integration is performed over the first Brillouin zone. The Kramers–Kronig relations link $\varepsilon_2(E)$ and $\varepsilon_1(E)$ in a manner that means that $\varepsilon_1(E)$ can be calculated at each photon energy if $\varepsilon_2(E)$ is known explicitly over the entire photon energy range, and vice versa. The Kramers–Kronig relations are of fundamental importance in the analysis of optical spectra [30.9].

The refractive indices and absorption coefficients of semiconductors are the basis of many important applications of semiconductors, such as light-emitting diodes, laser diodes and photodetectors. The optical constants of III–V binaries and their ternary and quaternary alloys have been presented in tabular and graphical forms [30.27]. We plot in Fig. 30.8 the $\varepsilon(E)$ spectra for $Al_xGa_yIn_{1-x-y}P/GaAs$ taken from tabulation by *Adachi* ([30.27]; open and solid circles). The solid lines represent the theoretical fits of the model dielectric function (MDF) calculation [30.9]. The three major features of the spectra seen in Fig. 30.8 are the E_0, E_1 and E_2 structures at ≈ 2, ≈ 3.5 and ≈ 4.5 eV, respectively. It is found that the E_0 and E_1 structures move to higher energies with increasing x, while the E_2 structure does not do so to any perceptible degree. We can see that the MDF calculation enables us to calculate the optical spectra for optional compositions of alloy semiconductors with good accuracy.

30.8 Carrier Transport Properties

An accurate comparison between experimental mobility and theoretical calculation is of great importance for the determination of a variety of fundamental material parameters and carrier scattering mechanisms. There are various carrier scattering mechanisms in semiconductors, as schematically shown in Fig. 30.9. The effect of the individual scattering mechanisms on the total calculated carrier mobility can be visualized using Matthiessen's rule:

$$\frac{1}{\mu_{\mathrm{tot}}} = \sum_i \frac{1}{\mu_i}\,. \tag{30.24}$$

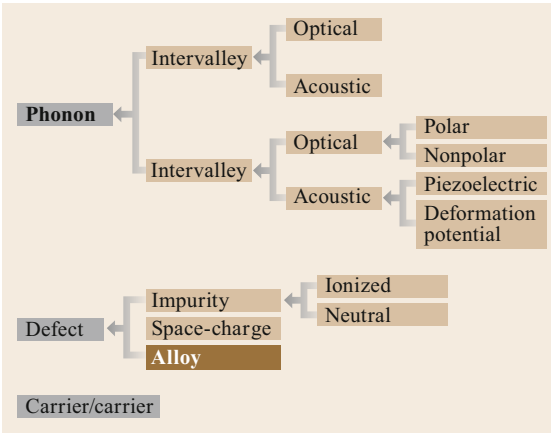

Fig. 30.9 Various possible carrier scattering mechanisms in semiconductor alloys

Table 30.25 Hall mobilities for electrons (μ_e) and holes (μ_h) obtained at 300 K for relatively pure samples of III–V binaries (in $cm^2/(V\,s)$)

Binary	μ_e	μ_h
AlN	125	14
AlP	80	450
AlAs	294	105
AlSb	200	420
α-GaN	1245	370
β-GaN	760	350
GaP	189	140
GaAs	9340	450
GaSb	12 040	1624
InN	3100	39
InP	6460	180
InAs	33 000	450
InSb	77 000	1100

The total carrier mobility μ_{tot} can then be obtained from the scattering-limited mobilities μ_i of each scattering mechanism. We note that in alloy semiconductors the charged carriers see potential fluctuations as a result of the composition disorder. This kind of scattering mechanism, so-called alloy scattering, is important in some III–V ternaries and quaternaries. The alloy scattering limited mobility in ternary alloys can be formulated as

$$\mu_{al} = \frac{\sqrt{2\pi}e\hbar^4 N_{al}\alpha}{3(m_c^*)^{5/2}(kT)^{1/2}x(1-x)(\Delta U)^2}\,, \qquad (30.25)$$

where N_{al} is the density of alloy sites, m_c^* is the electron or hole conductivity mass, x and $(1-x)$ are the mole fractions of the binary endpoint materials, and ΔU is the alloy scattering potential. The factor α is caused by the band degeneracy and is given by $\alpha = 1$ for electrons and by $\alpha = [(d^{5/2}+d^3)/(1+d^{3/2})^2]$ for holes with $d = m_{HH}/m_{LH}$, where m_{HH} and m_{LH} are the heavy hole and light hole band masses, respectively [30.12].

Let us simply express the total carrier mobility μ_{tot} in alloy $A_xB_{1-x}C$ as

$$\frac{1}{\mu_{tot}(x)} = \frac{1}{x\mu_{tot}(AC)+(1-x)\mu_{tot}(BC)} + \frac{1}{\mu_{al,0}/\frac{x}{1-x}}\,. \qquad (30.26)$$

The first term in (30.26) comes from the linear interpolation scheme and the second term accounts for the effects of alloying.

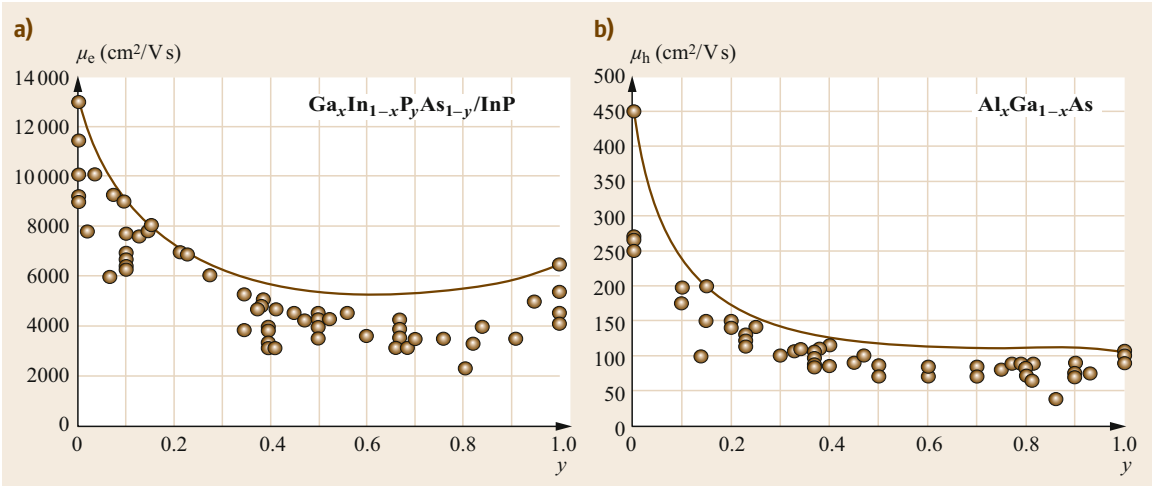

Fig. 30.10 **(a)** Electron Hall mobility μ_e in the $Ga_xIn_{1-x}P_y\,As_{1-y}$/InP quaternary and **(b)** the hole Hall mobility μ_h in the $Al_xGa_{1-x}As$ ternary, respectively. The experimental data correspond to those for relatively pure samples. The *solid lines* in **(a)** and **(b)** represent the results calculated using (30.26) with $\mu_{al,0} = 3000$ and $50\,cm^2/(V\,s)$, respectively

We plot in Figs. 30.10a and 30.10b the electron Hall mobility in the $Ga_xIn_{1-x}P_yAs_{1-y}/InP$ quaternary (μ_e) and the hole Hall mobility in the $Al_xGa_{1-x}As$ ternary, respectively. The experimental data correspond to those for relatively pure samples [30.28]. The solid lines in Figs. 30.10a,b represent the results calculated using (30.26) with $\mu_{al,0} = 3000$ and $50\,cm^2/(V\,s)$, respectively. The corresponding binary endpoint values for μ_{tot} are listed in Table 30.25. For $Ga_xIn_{1-x}P_yAs_{1-y}/InP$, we have considered the quaternary to be an alloy of the constituents $Ga_{0.53}In_{0.47}As$ ($y = 0$) and InP ($y = 1.0$) and we have used the value of μ_{tot} ($Ga_{0.47}In_{0.53}As$) $= 13\,000\,cm^2/(V\,s)$. It is clear that (30.26) can successfully explain the peculiar composition dependence of the carrier mobility in the semiconductor alloys.

31. Group III Nitrides

Romualdo A. Ferreyra, Congyong Zhu, Ali Teke, Hadis Morkoç

Optical, electrical, mechanical, and thermal properties of group III nitrides, inclusive of AlN, GaN, InN and their ternary and quaternary alloys, are discussed. The driving force for group III nitride semiconductors is their important applications in optoelectronics, microwave amplifiers, and high voltage power switches. Owing to the aforementioned applications, the fundamental properties of each III nitride binary, as well as the alloys that have been acquired, are discussed in this chapter. In general, an appropriate assessment of the material properties for any material is not straightforward to begin with and the nitride family is no exception, particularly considering that group III nitrides are prepared on foreign substrates as low-cost native substrates are not yet available. Understandably, precise measurements of the mechanical, thermal, electrical and optical properties of the semiconductor nitride family are imperative for further advances. Notwithstanding the great progress that has already been made to further understand and exploit group III nitrides, especially GaN, reliable data for AlN and InN are still in the state of evolution, and naturally the subject of some controversy. This is, in part, a consequence of measurements having been performed on samples of widely varying quality. When possible, the spurious discrepancies have been disregarded. For some materials, too few measurements are available to yield a consensus, in which case the available data are simply reported. Defects in group III nitrides as well as GaN-based nanostructures are also discussed.

During the last three decades, developments in the field of group III nitrides have been spectacular, with major breakthroughs taking place in the 1990s. They have been viewed as a highly promising material system for electronic and optoelectronic applications. As members of the group III nitrides family, AlN and GaN and their alloys with InN are all wide-bandgap materials (except for InGaN with very high In content) and can crystallize in both wurtzite and zincblende polytypes. The bandgaps of the wurtzite polytypes are direct and range from a possible value of ≈ 0.8 eV for InN, to 3.4 eV for GaN, and to 6.1 eV for AlN. GaN alloyed with AlN and InN may span a continuous range of direct-bandgap energies throughout much of the visible spectrum, well into ultraviolet (UV) wavelengths. This makes the nitride system attractive for optoelectronic applications, such as light-emitting diodes (LEDs), laser diodes (LDs), and UV detectors. Commercialization of bright

blue and green LEDs and the possibility of yellow LEDs paved the way for developing full-color displays. If the three primary-color LEDs, including red, produced by the InGaAlAs system are used in place of incandescent light bulbs in some form of a color-mixing scheme, they would provide not only compactness and longer lifetime, but also lower power consumption for the same luminous flux output. Additional possible applications include use in agriculture as light sources for accelerated photosynthesis, and in health care for diagnosis and treatment. Unlike display and lighting applications, digital information storage and reading require coherent light sources because the diffraction-limited optical storage density increases approximately quadratically with decreasing wavelength. The nitride material system, when adapted to semiconductor lasers in blue and UV wavelengths, offers increased data storage density, possibly as high as 50 Gb per disc with 25 Gb promised soon in the blu-ray system. Other equally attractive applications envisioned include printing and surgery. When used as UV sensors in jet engines, automobiles, and furnaces (boilers), the devices would allow optimal fuel efficiency and control of effluents for a cleaner environment. Moreover, visible-blind and solar-blind nitride-based photodetectors are also an ideal candidate for a number of applications including early missile-plume detection, UV astronomy, space-to-space communication, and biological effects. Another area gaining a lot of attention for group III–V nitrides is high-temperature/high-power electronic applications, such as radar, missiles, and satellites as well as in low-cost compact amplifiers for wireless base stations and high-voltage power switches, due to their excellent electron transport properties, including good mobility and high saturated drift velocity. The strongest feature of the group III nitrides compared to other wide-bandgap counterparts is the heterostructure technology that it can support. Quantum wells, modulation-doped heterointerfaces, and heterojunction structures can all be made in this system, giving access to new spectral regions for optical devices and new operational regimes for electronic devices. Other attractive properties of the nitrides include high mechanical and thermal stability, and large piezoelectric constants.

One of the main difficulties that has hindered group III nitride research is the lack of a lattice-matched and thermally compatible substrate material. A wide variety of materials have been studied for nitride epitaxy, including insulating metal oxides, metal nitrides, and other semiconductors. In practice, properties other than the lattice constants and thermal compatibility, including the crystal structure, surface finishing, composition, reactivity, and chemical and electrical properties, are also important in determining suitability as a substrate. The substrate employed determines the crystal orientation, polarity, polytype, surface morphology, strain, and the defect concentration of the epitaxial films. The most promising results on more conventional substrates so far have been obtained on sapphire, and SiC, however, accelerating progress has been made on Si substrates due to marketing issues, such as low-cost and compatibilities with Si processes. Also coming on the scene are thick freestanding GaN templates. Group III–V nitrides have been grown on Si, NaCl, GaP, InP, SiC, W, ZnO, $MgAl_2O_4$, TiO_2, and MgO. Other substrates have also been used for nitride growth, including Hf, $LiAlO_2$ and $LiGaO_2$. Lateral (lattice constant a) mismatched substrates lead to substantial densities of misfit and threading dislocations in broad-area epitaxially deposited GaN on foreign substrate, in the range 10^9–$10^{10}\,cm^{-2}$. An appropriate surface preparation such as nitridation, deposition of a low-temperature (LT) AlN or GaN buffer layer, selective epitaxy followed by a type of coalescence called lateral epitaxial overgrowth (LEO) or epitaxial lateral overgrowth (ELOG) can reduce dislocation densities down to $10^6\,cm^{-2}$. However, these numbers are still high compared to extended-defect densities of essentially zero for silicon homoepitaxy, and 10^2–$10^4\,cm^{-2}$ for gallium arsenide homoepitaxy. Vertical (lattice constant c) mismatch creates additional crystalline defects besetting the layers, including inversion domain boundaries and stacking faults. In addition, mismatch of thermal expansion coefficients between the epitaxial films and the substrate induces stress, which can cause crack formation in the film and substrate for thick films during cooling from the deposition temperature. A high density of defects, which increases the laser threshold current, causes reverse leakage currents in junctions, depletes sheet charge-carrier density in heterojunction field-effect transistors, reduces the charge-carrier mobility and thermal conductivity, and is detrimental to device applications and the achievement of their optimal performance. Thus, substrates capable of supporting better-quality epitaxial layers are always needed to realize the full potential of nitride-based devices. Nearly every major crystal-growth technique has been developed, including molecular beam epitaxy (MBE), hydride vapor-phase epitaxy (HVPE), and metalorganic chemical vapor deposition (MOCVD), in relation to nitride semiconductors. Several modifications to the conventional MBE method have been implemented for group III nitride growth: growth with ammonia or hydrazine (the latter is not attractive due to safety reasons and success of ammonia), plasma-assisted MBE (PAMBE), metalorganic MBE (MOMBE), pulsed laser deposition (PLD), and so on. Among other methods, radio-frequency (RF) and

electron-cyclotron resonance (ECR) plasma sources are the most commonly employed devices to activate the neutral nitrogen species in the MBE environment. Although all of these epitaxial methods contend with problems related to the lack of native GaN substrates, and difficulty with nitrogen incorporation, remarkable progress in the growth of high-quality epitaxial layers of group III nitrides by a variety of methods has been achieved. Additionally, growth of bulk GaN substrates by HVPE and ammonothermal methods have made tremendous progress in terms of dislocation density, impurities, growth speed, and so on.

Although many applications based on nitride semiconductors have emerged, and some of them are commercially available, as discussed throughout this chapter, there are many contradictions in identification of the basic physical properties of these materials. In this respect, they are not yet mature. Additionally, knowledge of the fundamental properties is crucial not only from the physics point of view but also when understanding and optimizing the device structures for better performance. In this chapter, therefore, we present the updated fundamental properties of GaN, AlN and InN, including structural, mechanical, thermal, electrical, and optical properties. The aim is to assist readers newly entering this field and other interested researchers in accessing the most recent available data. The reader is also urged to peruse the following publications for more detailed information on several aspects of ongoing research in group III nitrides. These consist of handbooks [31.1–3], and regular and review papers [31.4–31].

31.1 Crystal Structures of Nitrides

The group III nitrides share three crystal structures, which are wurtzite, zincblende, and rocksalt, where the thermodynamical stable phase is wurtzite for bulk AlN, GaN, and InN, and the cohesive energy per bond for the wurtzite phase is 2.88 eV (63.5 kcal/mol), 2.20 eV (48.5 kcal/mol), and 0.67 eV (15.5 kcal/mol) for AlN, GaN, and InN respectively [31.32]. The calculated energy difference between wurtzite and zincblende is small, which is -18.41 meV/atom for AlN, -9.88 meV/atom for GaN, and -11.44 meV/atom for InN; however, the wurtzite phase is energetically favorable for all three nitrides compared to zincblende. Being in the space group of $P6_3mc$, the wurtzite structure has a hexagonal unit cell with the a and c lattice parameters in the ratio of $c/a = \sqrt{8/3} = 1.633$. The wurtzite structure is composed of two interpenetrating hexagonal close-packed (hcp) sublattices, but displaced with respect to each other along the three-fold c-axis by an amount of $u = 3/8 = 0.375$, where each sublattice consists of four atoms per unit cell and every group III atom is surrounded tetrahedrally by four nitrogen atoms, or vice versa, these being located at the edges of a tetrahedron. The actual nitrides deviate from the above-mentioned ideal structure, which is signified by the c/a ratio or the u value [31.33]. These deviations come with the feature that the u parameter increases when the c/a ratio decrease while the four tetrahedral distances remain nearly constant through a distortion of the tetrahedral angles due to long-range polar interactions. These two slightly different bond lengths will be equal if the following equation holds

$$u = \left(\frac{1}{3}\right)\left(\frac{a^2}{c^2}\right) + \frac{1}{4}\,. \tag{31.1}$$

The c/a ratio also depends on the dispersion in the electronegativities of the two constituents in group III nitrides with larger differences resulting in larger departures from an ideal c/a ratio [31.34]. These two parameters can be measured by using the four-circle diffractometry technique. In the case of GaN, the c/a ratio and the u parameter are measured as 1.627 and 0.377, respectively, which are close to the ideal values [31.35], while the available AlN deviates significantly from ideal parameters: $c/a = 1.601$ and $u = 0.382$. Thus, the interatomic distance and angles differ by 0.01 Å and 3°, respectively. Due to the lack of suitable size single-crystal InN for single-crystal diffractometry measurement, reported values are rare and may not be reliable. One popularly cited c/a value is 1.611 [31.36], which is consistent with data reported later in InN crystalline films grown by MBE [31.37] and MOCVD [31.38].

A phase transition to the rocksalt (NaCl) structure in group III nitrides can take place at very high external pressures due to the reduction of the lattice dimensions, which causes inter-ionic Coulomb interaction to favor ionicity over covalent nature. The structural phase transition was observed to occur at the following pressure values: 22.9 GPa for AlN [31.39], 52.2 GPa for GaN [31.40], and 12.1 GPa for InN [31.41]; however, the rocksalt structure of group III nitrides is not stable during epitaxial growth. With a six-fold coordinated structure, the rocksalt type of structure belongs to space-group symmetry of $Fm3m$.

The zincblende structure can be stabilized only by heteroepitaxial growth on cubic structure substrates, such as cubic SiC [31.42], Si [31.43], MgO [31.44], and GaAs [31.45]; however, they are metastable and tend to

form the wurtzite phase due to the inherent tendency. Thus in the case of highly mismatched substrates, there can be a certain amount of zincblende phase of nitrides separated by crystallographic defects from the wurtzite phase. However, over the years with considerably improved preparation techniques, this polyphase issue has substantially diminished. The crystal structure of the zincblende structure is composed of two interpenetrating face-centered cubic (fcc) sublattices displaced by one quarter of a body diagonal, which belongs to the space group of $F\bar{4}3m$. The unit cell is composed of four atoms, where every atom of one type is tetrahedrally coordinated with four atoms of other type, and vice versa. The overall equivalent bond length for zincblende structures is about 1.623 Å.

Although zincblende and wurtzite structures share the same tetrahedral coordination, the main difference between these two structures comes from the stacking sequence of close-packed diatomic planes. The stacking sequence for the wurtzite structure in the ⟨0001⟩ direction is AaBbAaBb taking Ga and N pairs as an example. In contrast, the close-packed (111) planes along the ⟨111⟩ direction in the zincblende structure have a 60° rotation that causes a stacking order of AaBbCcAaBbCc, where the small and large letters stand for the two different kinds of constituents. Because none of the three available structures for group III nitrides possess inversion symmetry, the crystal structure exhibits crystallographic polarity. The (0001) planes are terminated by group III (Al, Ga, or In) atoms and denoted as Ga polarity (*c*-plane), while $(000\bar{1})$ planes are terminated by nitrogen and denoted as N polarity, and these two planes are referred to as polar planes. Many material properties strongly depend on the polarity, thus it is critical to choose certain planes for desired device properties. For example, GaN-based heterojunction field effect transistors (HFETs) are predominantly based on *c*-plane GaN films due to the large polarization charge. While for the purpose of LED applications, nonpolar (i. e., $(10\bar{1}0)$ plane or *m*-plane, and $(11\bar{2}0)$ plane or *a*-plane) or semipolar $(11\bar{2}2)$ planes are preferred due to the reduced polarization induced internal electric field under these planes [31.3], on the condition that all else are equal, which is not the case because of technological disparity. Considering the cost and maturity, *c*-plane wurtzite nitrides are the most commonly used planes for device applications, although active research is underway for other secondary planes and directions.

31.2 Lattice Parameters of Nitrides

The lattice parameters of nitride-based semiconductors, as with other semiconductors [31.46, 47], depend on the following factors [31.48]:

1. Free electron concentration, which expands the lattice proportionally to the deformation potential of the conduction-band minimum
2. The concentration of impurities and intrinsic defects, and the difference between their ionic radii and the substituted matrix ions
3. External strains (for example, those induced by substrate or heterostructures)
4. Temperature.

High-resolution x-ray diffraction (HRXRD) is the most common tool to measure the lattice parameters of any crystalline material, and the results are usually obtained at a standard temperature of 21 °C [31.49] by using the Bond method [31.50] for a set of symmetrical and asymmetrical reflections. Because the lattice parameters of ternary compounds depend on the composition, the measured lattice parameters can also be used to determine the composition of the compounds, where the strain must be taken into consideration for precise determination of the composition. For nitrides, an accuracy of about 0.1% or less can be achieved in determining the composition, equivalently down to a mole fraction of about 1%, if the elastic parameters of all nitrides and lattice parameters of AlN and InN are taken into consideration. Considering that different growth techniques and/or substrates are used, which inevitably induce different strain states, defect densities and free-carrier concentrations, there is a wide dispersion in the reported values. Table 31.1 shows a comparison of measured and calculated lattice parameters reported by several groups for AlN, GaN, and InN crystallized in the wurtzite structure. The AlN crystal has a molar mass of 20.495 g/mol when it crystallizes in the hexagonal wurtzite structure. The measured lattice parameters for AlN in either bulk or epitaxial films range from 3.110–3.112 Å for the *a* parameter and from 4.980–4.982 Å for the *c* parameter, which gives a c/a ratio in the range of 1.600 and 1.602. The deviation from that of the ideal wurtzite crystal is most likely due to lattice stability, iconicity, and defects. The influence of carbon dopant concentration on the lattice parameters of AlN substrates grown by hydride vapor phase epitaxy using AlN substrates prepared by the physical vapor transport technique has been reported [31.51]. For samples with concentrations of carbon in the HVPE substrates from $< 2\times10^{17}$ to $< 1\times10^{19}\,\mathrm{cm}^{-3}$, while the concentrations of oxygen and silicon remained below $5\times10^{17}\,\mathrm{cm}^{-3}$ for all substrates, the HVPE-AlN

Table 31.1 Measured and calculated lattice constants of wurtzite AlN, GaN and InN

Compound	Sample	a (Å)	c (Å)	Reference

substrates did not show significant deviation in the lattice parameters. The average lattice parameters are $a = 3.1110$ Å and $c = 4.9809$ Å with $3\sigma = 0.0002$ Å. There are several reports on the lattice parameters of the cubic form of AlN with a lattice parameter of $a = 4.38$ Å [31.66], which is consistent with the theoretically estimated value [31.67]. However, the zincblende polytype AlN is in a metastable state. While for the rocksalt phase of AlN, which is pressure induced, a lattice parameter of 4.043–4.045 Å was obtained at room temperature [31.68, 69].

The wurtzite (WZ) crystal structure of GaN has a molecular weight of 83.7267 g/mol with four atoms per cell. Its lattice parameters depend on a variety of factors including free-electron concentration, impurities, and growth techniques. It has been reported that free charge is the dominant factor responsible for expanding the lattice [31.48]. The lattice parameters were found to be proportionally dependent on the deformation potential of the conduction-band minimum and inversely proportional to the carrier density and bulk modulus. Impurities, intrinsic point defects and extended defects, such as threading dislocations, are also important factors determining the lattice parameters of WZ-GaN, especially because bulk or epitaxial GaN is generally obtained on foreign substrates at high temperature, and thus suffers from both the lattice constant and thermal conductivity mismatch. Depending on the growth techniques, the defect density and impurity levels vary, which can have a direct influence on the lattice parameters. For example, solution growth at high pressure (15–20 kbar) and high temperature (in the range of 1600 K) can achieve high structural quality GaN material with a dislocation density as low as 100 cm^{-2}. However, the high level of background impurities, for example oxygen, can often result in free-carrier concentration exceeding levels of 10^{19} cm^{-3}. The free-carrier density for undoped ammonothermally grown GaN substrates also reported a similar level of 10^{19} cm^{-3} [31.70–72] but can be as low as 2×10^{18} cm^{-3} [31.73]. The lattice parameters from ammonothermally grown nonpolar and semipolar GaN bulk substrates are around $a = 3.1890$–3.1900 Å and $c = 5.185$–5.186 Å [31.58, 59]. It was found that doping has a strong effect on the lattice parameters for HVPE-grown WZ-GaN [31.74]. Undoped HVPE-grown GaN has a free-carrier density of 1×10^{16} cm^{-3} and has $a = 3.18914$ Å, which increased to 3.18921 Å in oxygen-doped bulk GaN substrates with free-carrier concentrations of 3×10^{18} cm^{-3}. For Si- and Fe-doped bulk GaN substrates with free-carrier concentrations of 1×10^{18} cm^{-3} and 2×10^{13} cm^{-3} respectively, the a parameters decrease to 3.18868 and 3.18841 Å respectively. The trend for the change of lattice constant is generally consistent with the theoretical predictions based on the impurity size effect and deformation-potential effects as discussed in [31.75].

A precise analysis of the effect of doping on the lattice constant of GaN, however, requires a low-defect-density bulk material with controlled doping concentration. When and if the impurity levels can be controlled, attention then needs to be paid to the intrinsic defects. For zincblende GaN, the calculated lattice constant using the measured Ga–N bond distance in WZ-GaN is $a = 4.503$ Å. The measured lattice constant in epilayers ranges from 4.49–4.55 Å [31.42–44], where the fully relaxed lattice parameter was obtained to be 4.5036 ± 0.0004 Å [31.76]. The lattice parameter for freestanding cubic GaN grown by plasma-assisted molecular beam epitaxy on GaAs substrates, which subsequently is removed, demonstrated a lattice parameter of 4.510 ± 0.005 Å [31.77]. A high-pressure phase transition from the WZ to the rocksalt structure decreases the lattice constant down to $a_0 = 4.22$ Å in the rocksalt phase [31.78].

Due to the difficulties in the crystal growth of InN, reports on the physical properties of InN are limited. Nearly all the available data have been obtained from nonideal thin films. Indium nitride normally crystallizes in the wurtzite structure and has a molecular weight of 128.827 g/mol. The measured lattice parameters using a powder technique are in the range of $a = 3.530–3.548$ Å and $c = 5.960–5.704$ Å. By analyzing the strain in the InN film grown by MBE on sapphire substrates, the lattice parameters for strain-free InN are estimated to be in the range of $a = 3.535 \pm 0.005$ Å and $c = 5.699 \pm 0.004$ Å [31.37]. Zincblende (cubic) InN grown on sapphire (0001) using cubic indium oxide as a buffer layer generated an estimated lattice parameter of 4.9(8) Å [31.79], which is close to other reported values for epilayers grown on InAs (001) (5.04 Å) [31.80], on GaAs (001) (4.98 Å) [31.81], and on *r*-plane sapphire (4.986 Å) substrates [31.82].

31.3 Mechanical Properties of Nitrides

The mechanical properties of materials are usually characterized by parameters such as hardness, stiffness constant, Young's and bulk modulus and yield strength, and so on. For group III nitride semiconductor materials, the precise determination of the mechanical properties is hindered by various complexities, the most important of which is the lack of large size high-quality single crystals. Nevertheless, attempts have been made to estimate and measure the mechanical properties of both thin and thick epitaxial layers, and bulk crystals. The most precise technique to determine the elastic moduli of compound semiconductor materials is believed to be the ultrasonic measurement, which requires thick (about 1 cm-thick) single-crystalline samples to enable measurement of the timing of plane-wave acoustic pulses with sufficient resolution. Thus, this technique is almost inapplicable to the group III nitrides materials except wurtzite GaN where large size bulk substrates are commercially available. Brillouin scattering can determine the elastic constant and bulk moduli through the interaction of light with thermal excitation, in particular acoustic phonons, in the crystalline material. Various forms of x-ray diffraction, such as energy dispersive x-ray diffraction (EDX), angular dispersive x-ray diffraction (ADX) and x-ray absorption spectroscopy (XAS) can be used to determine the pressure dependence of the lattice parameters. By assuming that the bulk modulus has a linear dependence on the applied pressure to the crystal, it can be deduced as [31.83]

$$V = V_0 \left(1 + \frac{B'P}{B}\right)^{-\frac{1}{B'}} , \qquad (31.2)$$

where B and V_0 represent the bulk modulus and unit volume at ambient pressure respectively, and B' is the derivative of B with respect to pressure. X-ray diffraction can be used to determine the isothermal bulk modulus, and Brillouin scattering can determine the adiabatic bulk modulus. In the case of solids other than molecular solids, these two thermodynamic quantities bear no measurable difference. Predictive calculations of the structural and mechanical properties of group III nitrides can also be undertaken in addition to the above-mentioned experimental investigations. The most popular calculations are based on density functional theory within the local density approximation (LDA) using various types of exchange correlation functionals.

There are five independent elastic constants in hexagonal crystals, which are c_{11}, c_{33}, c_{12}, c_{13} and c_{44}. Among them, c_{11} and c_{33} correspond to longitudinal modes along the [1000] and [0001] directions respectively, while c_{44} and $c_{66} = (c_{11} - c_{12})/2$ can be determined from the speed of sound of the transverse modes propagating along the [0001] and [1000] directions respectively. c_{13} and the other four moduli relate to the velocity of the modes propagating in directions with lower symmetry, such as [0011]. The bulk modulus can be determined by the elastic constants through the following equation [31.84]

$$B = \frac{(c_{11} + c_{12})c_{33} - 2{c_{13}}^2}{c_{11} + c_{12} + 2c_{33} - 4c_{13}} .$$

If the material is isotropic, the Young's modulus E and shear modulus G can be evaluated by $E = 3B(1 - 2v)$

Table 31.2 Some mechanical properties of wurtzite AlN, GaN, and InN obtained by experimental measurements and theoretical calculations. The units are in GPa

Parameters	AlN (GPa)	GaN (GPa)	InN (GPa)
c_{11}	394 ± 1^{a}, 401.2 ± 0.5^{b}, 345^{c}, 396^{d}, 398^{e}	296^{r}, 390^{s}, 377^{t}, 370^{u}, 373^{an}, 367^{d}, 396^{e}	225 ± 7^{ae}, 223^{d}, 271^{e}
c_{12}	134 ± 1^{a}, 135.0 ± 0.5^{b}, 125^{c}, 137^{d}, 140^{e}	120^{r}, 145^{s}, 160^{t}, 145^{u}, 141^{an}, 135^{d}, 144^{e}	109 ± 8^{ae}, 115^{d}, 124^{e}
c_{13}	95 ± 1^{a}, 96.3 ± 22.1^{b}, 120^{c}, 108^{d}, 127^{e}	158^{r}, 106^{s}, 114^{t}, 106^{u}, 80^{an}, 103^{d}, 100^{e}	108 ± 8^{ae}, 92^{d}, 94^{e}
c_{33}	402 ± 1^{a}, 368.2 ± 27.9^{b}, 395^{c}, 373^{d}, 382^{e}	267^{r}, 398^{s}, 209^{t}, 398^{u}, 387^{an}, 405^{d}, 392^{e}	265 ± 3^{ae}, 224^{d}, 200^{e}
c_{44}	121 ± 1^{a}, 122.6 ± 0.2^{b}, 118^{c}, 116^{d}, 96^{e}	24^{r}, 105^{s}, 81^{t}, 105^{u}, 94^{an}, 95^{d}, 91^{e}	55 ± 3^{ae}, 48^{d}, 46^{e}

and $G = E/2(1 + v)$ respectively, where the term v is the Poisson's ratio and is given by $v = c_{13}/(c_{11} + c_{12})$ [31.97].

The hardness of group III nitrides can be determined by micro- and nano-indentation methods over a wide range of size scales and temperatures. The measurements are usually conducted on the (0001) surface using a conventional pyramidal or spherical diamond tip, or alternatively, a sharp triangular indenter (Berhovich). Complete information on the hardness and pressure-induced phase transformation of semiconductor materials can be obtained via depth-sensing indentation measurements. Table 31.2 shows experimental as well as theoretical results of the mechanical parameters for wurtzite AlN, GaN and InN single crystals as well as polycrystallites reported by several groups.

Because the quality of the crystals varies, especially for InN, the experimental results are widely scattered

as demonstrated in Table 31.2. A clear example is the hardness data on InN, where the nanohardness of InN significantly depends on the growth temperature, which varies from 3.6 to 9.1 for an InN growth temperature from 440–500 °C [31.116]. The difference between the elastic moduli measured with the same technique (Brillouin scattering) for even GaN, which has a much better crystal quality than InN, is further evidence that the quality and nature (bulk single-crystal or epitaxial layer) of the samples is of significant importance. It has been demonstrated by *Moram* et al. [31.100] that the Poisson's ratio of GaN has a strong dependence on the strain state of the films. With the help of HR-XRD while inducing a series of different biaxial strain states in the same wafer, a Poisson's ratio of 0.183 ± 0.003 was estimated for a strain-free GaN film. Stress in GaN was also demonstrated to influence the Young's modulus. For high-quality suspended GaN microstructures fabricated from GaN-on-patterned-silicon techniques where the underlying silicon is removed, the stress in GaN decreases by 47%, which results in a 36% increase of the Young's modulus [31.101], nearly identical to the value deduced from the Brillouin scattering measurement on GaN films [31.120]. Except for InN, group III nitrides can be considered as hard and incompressible material family members with elastic and bulk moduli comparable to the magnitude of diamond. The hardness of a semiconductor relates to the bonding distance or shear modulus, which may explain why the InN is soft. InN has a smaller shear modulus and larger bonding distance (0.214 nm) compared to GaN (0.196 nm) and AlN (0.192 nm). Reports on the temperature dependence of the mechanical properties of group III nitrides are rare. It has been shown that the macroscopic dislocation motion and plastic deformation of GaN and AlN may start at around 1100 °C [31.121, 122]. The yield strength of bulk single-crystal GaN is found to be 100–300 MPa at 900 °C, while that for AlN was deduced to be $\approx$ 300 MPa at 1000 °C.

Many applications of group III nitrides utilize their high thermal conductivity, thus the precise knowledge of the vibrational modes in single crystals should be obtained in order to understand the fundamental thermal properties of nitrides. Infrared reflection and Raman spectroscopy are very useful techniques to derive zone-center and some zone-boundary phonon modes in nitrides. The A_1 and E_1 modes are each split into longitudinal optic (LO) and transverse optic (TO) components, giving a total of six Raman peaks. These A_1 and E_1 branches are both active for Raman and infrared techniques, while the E_2 branches are Raman-active only and B_1 branches are inactive. Table 31.3 gives a list of experimental as well as calculated values for the zone-center optical-phonon wave numbers of AlN, GaN, and InN.

The phonon dispersion spectrum of AlN has a total of twelve branches, including three acoustic and nine optical branches. The E_1 (LO), E_1 (TO), A_1 (TO), and E_2(high) peak positions were found to show a linear relationship with applied pressure up to 7 GPa [31.136]. Because the E_2 (high) peak position is reported to be sensitive to the in-plane strain due to its comparatively large strain coefficients, its stress-free values were obtained by linear fits to Raman frequencies of AlN layers under different biaxial strains and a stress-free value of $657.4 \pm 0.2\,\mathrm{cm}^{-1}$ is reported in AlN [31.146]. In contrast, the E_2 (low) phonon frequency is essentially constant under pressure, which indicates an approximate cancellation of the effects of central and noncentral forces on the pressure dependence of the phonon frequency [31.136]. The influence of impurities on E_2 (high) peak position showed controversial results. The E_2 (high) peak position showed no change for bulk AlN with carbon impurities up to $3 \times 10^{19}\,\mathrm{cm}^{-3}$. However, the principle Raman peaks are influenced by oxygen-related complexes [31.92], and the widths of principal Raman modes increase with increasing oxygen content, but at high oxygen concentrations ($\approx$ 5 at.%) the lowest values of these widths were obtained [31.103]. Through temperature-dependent Raman measurement, it was found out that both the lifetime of E_2 (high) and A_1 (LO) symmetry phonons of AlN are limited by two-phonon decay, where the E_2 (high) decays symmetrically while the A_1 (LO) asymmetrically decays into A_1 (TO) and LA phonons [31.125, 127].

The phonon frequencies in GaN also spread out due to different strain and defects states in different materials. Besides, the high phonon frequencies due to the strong bond in GaN and the light N atoms limit the range of observable impurity-related local vibrational modes to even lighter elements at higher frequencies. The E_1-TO and the E_2-(high) phonon modes in GaN possess comparatively large strain coefficients, thus their values are especially sensitive to the strain in the crystal. Therefore, care must be taken when measuring temperature-dependent phonon frequencies as different substrates have different thermal expansion coefficients and hence induce different strains at different temperatures [31.147]. Heretofore, few reports have appeared for the infrared and Raman modes of impurities, dopants, and hydrogen complexes [31.148, 149], and most of the reports focused on the hydrostatic pressure dependence of the zone-center phonon modes in bulk GaN [31.134, 136, 138, 150], and mode pressure coefficients up to a hydrostatic pressure of 6 GPa have been determined by Raman measurements [31.136].

Table 31.3 Optical phonon frequencies of wurtzite AlN, GaN, and InN at the center of the Brillouin zone in the units of cm^{-1}

Symmetry	AlN (cm^{-1})	GaN (cm^{-1})	InN (cm^{-1})
A_1-TO	613.64[b], 607.3[c], 609[e], 610[f], 609[g], 612[h], 601[i]	531.0[j], 531.4[l], 533.54[m], 531.2[n], 531.7[o], 540[p]	440[t], 446[u], 440 [31.123], 480[w], 445[x], 440[x]

The E_2 (low) phonon mode in GaN exhibits a weak softening, which is qualitatively similar to that of the zone-boundary transverse acoustic modes of zincblende III–V semiconductors. An increase of the LO-TO splitting has been observed with hydrostatic pressure. Splitting of the GaN E_1 (TO), E_1 (LO), and E_2 phonons under anisotropic strain in the basal plane were also investigated, and their phonon deformation potentials were determined [31.135]. Phonon modes on virtually strain-free freestanding bulk GaN have been reported as well [31.138].

Strain-free Raman frequencies of the E_2 (high) and A_1 (LO) modes of hexagonal InN have been determined to be 490.1 ± 0.2 and $585.4 \pm 0.4\,cm^{-1}$ by Raman measurements on freestanding InN film grown by MBE [31.110]. The strain-free Raman frequencies were further verified by measuring biaxial strain-dependent Raman frequencies, where the strain-free values were extrapolated by a linear fit of the curve. The slope of the linear fit gave the Raman linear biaxial stress coefficients for the E_2 (high) and A_1 (LO) modes of InN to be 9.0 ± 0.8 and $8.4 \pm 0.8\,cm^{-1}\,GPa^{-1}$ respectively. Another set of pressure-dependent Raman frequencies demonstrated the phonon modes to be 440, 491, and $592\,cm^{-1}$ for A_1 (TO), E_2 (high), and A_1 (LO) respectively. Smaller stress coefficients of 5.81, 5.56, and $5.96\,cm^{-1}\,GPa^{-1}$ were also demonstrated for the above three phonon modes [31.151]. The wurtzite to rocksalt phase transition was also evidenced to be at a pressure of 13.5 ± 0.5 GPa as analyzed by means of Raman spectroscopy measurements conducted under high pressure (up to 50 GPa) [31.141]. Temperature-dependent Raman analysis of A_1 (LO) and E_2 phonon lifetimes from 80–700 K indicated that among the various possible decay channels, the A_1 (LO) phonon decays asymmetrically into a high energy and a low energy phonon, whereas the E_2 phonon predominantly decays into three phonons [31.152]. Possible decay channels of A_1 (LO) phonon may involve combinations of transverse optical and acoustic phonons.

31.4 Thermal Properties of Nitrides

31.4.1 Thermal Expansion Coefficients

The lattice parameters of semiconductors are temperature dependent, and the change of the lattice parameters are defined by thermal expansion coefficients (TEC), which are defined as $\Delta a/a$ or α_a and $\Delta c/c$ or α_c, for the *in* and *out of plane* orientations respectively. The importance of such parameters is owed to the expansion-caused strain during material growth, which is particularly important for group III nitrides as many applications of group III nitrides rely on successful growth of heterostructures, for example AlGaN/GaN HFETs and InGaN LEDs. What matters most is the lack of easily available substrates for group III nitride growth, thus the difference of TEC will cause strain and even cracking during the growth or cooling-down process for tensile strain, which is the case when grown for example on Si and SiC substrates. TEC is dependent on the stoichiometry and defects as well as the free-carrier concentration. A large scatter in the published data exists for TEC, partially due to the varying foreign substrates used for the growth.

The TEC was reported to be 4.03×10^{-6} in the temperature range of 298–473 K by assuming linear expansion in hot pressed aluminum nitride [31.155]. Ceramic AlN has been demonstrated to show a negative TEC at a temperature range of from 0 K to around 100 K [31.156]. Another TEC investigation on AlN powder showed that experimental data indicate no minimum for the a parameter and a possible shallow minimum for the c parameter, however, the magnitude of experimental errors does not allow confirmation of the existence/absence of negative thermal expansion without additional experimental efforts [31.157].

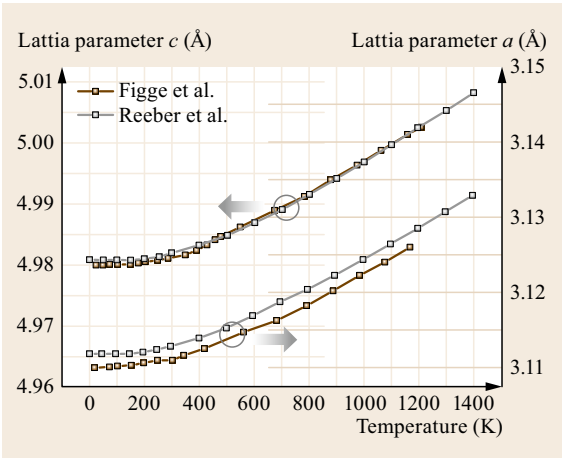

Fig. 31.1 Temperature-dependent lattice parameters of AlN in the c-direction and the a-direction. (After [31.153, 154])

Using x-ray techniques across a broad temperature range (77–1269 K), it has been noted that AlN demonstrated an isotropic thermal expansion with a room-temperature value of $2.56\times10^{-6}\,\mathrm{K}^{-1}$ [31.158]. Mean values of 4.20×10^{-6} and $5.30\times10^{-6}\,\mathrm{K}^{-1}$ were reported for $\Delta a/a$ and $\Delta c/c$, respectively, in the temperature range of 293–1073 K [31.159].

The thermal expansion coefficient of AlN bulk crystals were also investigated in the temperature range of 20–1300 K with the measured lattice parameters from both (002) and (006) reflections [31.153], and the lattice parameters were plotted at different temperature as shown in Fig. 31.1. In both lattice directions almost no thermal expansion is observed at low temperatures and an almost linear expansion at temperatures above 750 K, which is consistent with models based on the intrinsic phonon energy of a solid system. By fitting the experimental data to models based on Debye- and Einstein-like phonon dispersion, the lattice parameter c with its temperature dependence can be described as

$$c(T) = c(0\,\mathrm{K})\left[1+\alpha_\infty\,\Theta f\left(\frac{\Theta}{T}\right)\right], \tag{31.3}$$

where α_∞ is the lattice expansion coefficient in the high temperature limit, Θ is a characteristic temperature, and $f(x)$ is either the Debye or Einstein function defined as below

$$f_\mathrm{D}(x) = 3\int_0^1 \frac{t^3}{\mathrm{e}^{tx}-1}\mathrm{d}t$$

$$f_\mathrm{E}(x) = \frac{1}{\mathrm{e}^{x}-1}\,. \tag{31.4}$$

The thermal expansion coefficients were reported to be 3.38×10^{-6} and $2.68\times10^{-6}\,\mathrm{K}^{-1}$ for $\Delta a/a$ and $\Delta c/c$ at room temperature, respectively.

Thermal expansion of single-crystal wurtzitic GaN has been investigated in the temperature range of 300–900 K [31.160], with a mean thermal expansion coefficient of $5.59\times10^{-6}\,\mathrm{K}^{-1}$ for $\Delta a/a$.

A superlinear dependence on temperature was also shown for the c parameter with mean thermal coefficients of 3.17×10^{-6} and $7.75\times10^{-6}\,\mathrm{K}^{-1}$, over the temperature ranges of 300–700 and 700–900 K respectively. Other values were also reported for α_a of 3.1×10^{-6} and $6.2\times10^{-6}\,\mathrm{K}^{-1}$ for the temperature ranges of 300–350 and 700–750 K respec-

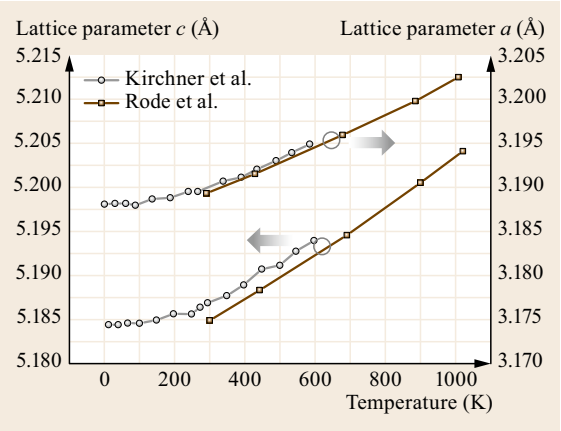

Fig. 31.2 Temperature-dependent lattice parameters of GaN in *c*-direction and *a*-directions. (After [31.162, 163])

tively [31.161]. The α_c values of 2.8×10^{-6} and $6.1\times10^{-6}\,K^{-1}$ were also reported in the same report. Thermal expansion coefficients should be obtained from freestanding bulk GaN substrates with minimal dislocations, defects and impurities, so that the influence by the substrate and defect states can be minimized. Thermal expansion coefficients for freestanding GaN bulk substrates with dislocation densities below $10^5\,cm^{-2}$ and room-temperature free-electron concentrations below $2\times10^{19}\,cm^{-3}$ were investigated in the temperature ranges of 0–600 K [31.162] and 300–1000 K [31.163] respectively. The temperature dependence of the lattice parameters are shown in Fig. 31.2. The thermal expansion coefficients at the very high temperature limits were reported to be $\alpha_c = 5.7\times10^{-6}\,K^{-1}$ and $\alpha_a = 6.2\times10^{-6}\,K^{-1}$, comparable to those proposed by *Reeber* and *Wang* [31.164]. The experimental results were also fitted to both Debye and Einstein models, and the results were demonstrated and compared with AlN as tabulated in Table 31.4. By comparing the lattice parameters of AlN and GaN at different temperatures, it was found that the maximum thermal mismatch between these two materials occurs at around 700 K [31.153]. Because the typical growth temperatures for AlN/GaN systems are much higher, the heterostructures suffer a larger strain during cool-down than during growth.

There is limited information available regarding the thermal expansion of InN. The first published experimental data in the temperature range of 190–560 K demonstrated that the TECs increase with temperature: α_a from 3.4×10^{-6} to $5.7\times10^{-6}\,K^{-1}$, α_c from 2.7×10^{-6} to $3.7\times10^{-6}\,K^{-1}$ [31.165]. More recent experimental data in the 100–673 K range based on diffraction data demonstrated average TECs of $\alpha_a = 3.6(2)\times10^{-6}\,K^{-1}$ and α_a from $\alpha_c = 2.6(3)\times10^{-6}\,K^{-1}$ [31.65]. However, due to the scatter of experimental data points obtained with the use of conventional equipment, there is lack of detectable TEC variation in the investigated temperature range. Lattice parameters and TECs were also calculated in the temperature range of 50–800 K based on a semi-empirical model [31.166]. More recently, results of Rietveld refinement for InN data collected in the temperature range of 105–295 K were published [31.167], wherein acicular microcrystals of InN were prepared by reaction liquid indium with nitrogen plasma and lattice parameters were measured by XRD. The TECs derived from linearly approximated lattice-parameter dependencies are $\alpha_a = 3.09(14)\times10^{-6}\,K^{-1}$ and $\alpha_c = 2.79(16)\times10^{-6}\,K^{-1}$. The temperature-dependent lattice parameters of InN are presented in Fig. 31.3a,b.

31.4.2 Thermal Conductivity

One key issue that enables group III nitrides to be useful for high-power/high-temperature electronic and optoelectronic devices is the high thermal conductivity (k), which is determined by the contributions from the vibrational, rotational, and electronic degrees of freedom, and as such is related to the mechanical properties of the material. The electronic thermal conductivity contribution is negligible for carrier concentrations $\leq 10^{19}\,cm^{-3}$. Heat transport is predominantly determined by phonon-phonon Umklapp scattering as well as phonon scattering by point and extended defects, such as vacancies, impurities, isotope fluctuations, grain boundaries, and dislocations. For the case when the effect of defects is trivial, phonon-phonon scattering, which is ideally proportional to T^{-1} above the Debye temperature, is the limiting process. However, due to the defective nature of group III nitride

Table 31.4 Thermal expansion parameters determined by XRD for AlN and GaN. (After [31.153] and [31.163] respectively)

Direction	Material	Debye model		Einstein model	
		α_∞ ($10^{-6}\,K^{-1}$)	Θ (K)	α_∞ ($10^{-6}\,K^{-1}$)	Θ (K)
out of plane	AlN	5.8 ± 0.1	1317 ± 25	5.6 ± 0.1	937 ± 25
	GaN	5.73 ± 0.44	898 ± 24	5.71 ± 0.43	662 ± 18
in-plane	AlN	7.1 ± 0.3	1455 ± 25	6.9 ± 0.3	1025 ± 25
	GaN	6.24 ± 0.41	868 ± 20	6.21 ± 0.35	636 ± 13

materials, point defects play a significant role for single crystals during heat transport.

The thermal conductivity of AlN at room temperature was theoretically estimated to be $3.19\,\mathrm{W\,cm^{-1}\,K^{-1}}$ for pure AlN single crystals [31.168], and experimental values of 2.5 [31.169] and $2.85\,\mathrm{W\,cm^{-1}\,K^{-1}}$ [31.158] were reported at 300 K for AlN single crystals obtained by the sublimation technique. However, a more recent calculation predicted thermal conductivity of $5.4\,\mathrm{W\,cm^{-1}\,K^{-1}}$ for a pure AlN single crystal, which is much larger than commonly reported experimental data [31.170]. One type of impurity that impacts the thermal conductivity of AlN is identified to be oxygen, and the thermal conductivities of AlN with various oxygen concentrations were demonstrated in Fig. 31.4. Although it was found that higher oxygen concentration reduced the thermal conductivity, it was believed that the reduction of the thermal conductivity was due to the oxygen-induced Al vacancies [31.171], which is supported by another report showing that AlN crystals with comparable oxygen vacancies ($\approx 1\times10^{19}\,\mathrm{cm^{-3}}$) exhibited decreasing thermal conductivity with increasing Al vacancies [31.172]. As shown in Fig. 31.4, the reduction of thermal conductivity due to oxygen vacancies only occurs below room temperature. For high temperatures, the role of defects in affecting the thermal conductivity vanishes and the role of anharmonicity becomes dominant [31.173]. Recent AlN single-crystals have demonstrated higher room-temperature thermal conductivity values in the range of $3.0–3.3\,\mathrm{W\,cm^{-1}\,K^{-1}}$ for freestanding [31.174] and 300–800 μm-thick AlN samples grown originally on Si (111) substrate by HVPE with a $10^8\,\mathrm{cm^{-2}}$ dislocation density [31.175]. The thermal conductivity of polycrystalline or ceramic AlN has a much smaller value than that of single-crystalline AlN due to the larger amount of defects and grain boundaries [31.176], and the reported maximum value is $2.2\,\mathrm{W\,cm^{-1}\,K^{-1}}$ [31.177].

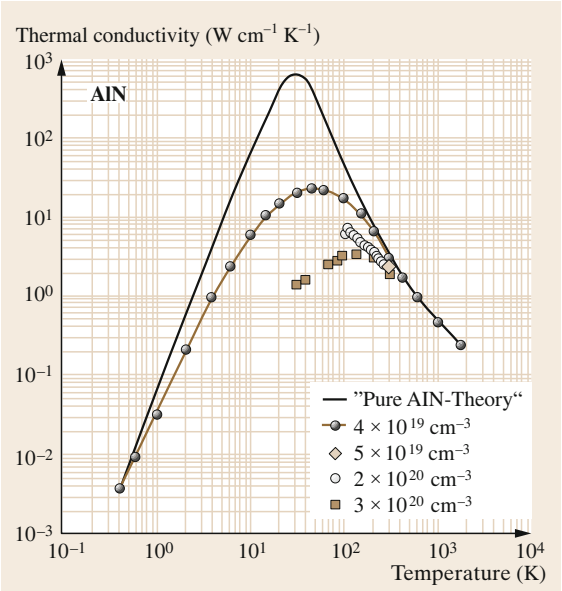

Fig. 31.4 Thermal conductivity of single-crystal AlN. The solid line represents the calculated data for pure AlN, while others represent AlN with various concentrations of oxygen impurities. (After [31.171])

Although a theoretical thermal conductivity of $k \approx 4.10\,\mathrm{W\,cm^{-1}\,K^{-1}}$ at room temperature was predicted for pure GaN [31.170], experimental results yield much smaller values. The thermal conductivity of GaN layers grown on sapphire substrate by HVPE were measured as a function of temperature (25–60 K) using a heat-flow method, and a room-temperature thermal

Table 31.5 Thermal conductivity of high-quality GaN

Reference	Growth condition	Dislocation density (cm^{-2})	Impurity concentration (cm^{-3})	Carrier density (cm^{-3})	$k_{(300\,K)}$ ($W\,cm^{-1}\,K^{-1}$)	$k_{(max)}$ ($W\,cm^{-1}\,K^{-1}$)	Power n at 300 K
[31.178]	HVPE GaN boule	6×10^5	$\approx 6\times10^{16}$	1×10^{16}	2.94 ± 0.44		
[31.171]	HVPE		$\approx 2\times10^{16}$		2.27	20	-1.22
[31.179]	High-pressure-grown GaN		$\approx 10^{20}$	5×10^{19}	2.3	16	≈ -1.43
[31.180]	HVPE	$\approx 5\times10^6$	$\approx 2\times10^{17}$		2.53		
[31.181]	HVPE	$\approx 6.2\times10^6$	$\approx 3\times10^{16}$		2.25		≈ -1

conductivity of $\approx 1.3\,W\,cm^{-1}\,K^{-1}$ was recorded in the early days of GaN technology [31.182]. More recently, the room-temperature thermal conductivity of GaN was calculated to be $2.27\,W\,cm^{-1}\,K^{-1}$ assuming no isotope scattering [31.171]. This prediction is close to the generally reported value for high-quality bulk GaN as shown in Table 31.5. However, as also demonstrated in Table 31.5, the highest thermal conductivity is reported as $2.94\pm0.44\,W\,cm^{-1}\,K^{-1}$ for HVPE-grown GaN boule with very low dislocation density ($6\times10^5\,cm^{-2}$) and impurity concentrations $\approx 6\times10^{16}\,cm^{-2}$) [31.178], which in turn demands for more accurate predictions of thermal conductivity for high-quality GaN. From theoretical calculations, the highest possible thermal conductivity of bulk GaN can only be realized when point impurities such as oxygen and silicon are in small concentrations ($\approx 10^{16}\,cm^{-3}$ or less) and other defects are either absent or present in very small concentrations [31.183]. For GaN with relatively high quality, the measured thermal conductivity of GaN in the temperature range of 80–300 K has a $T^{-1.22}$ temperature dependence as demonstrated in Fig. 31.5, whose slope is typical of pure adamantine crystals below the Debye temperature, indicating acoustic phonon transport. Thus, the phonon-phonon scattering is a combination of acoustic–acoustic and acoustic–optic interactions, which means that thermal conductivity is mainly limited by the intrinsic phonon-phonon scattering instead of phonon-impurity scattering [31.171]. When the dislocation density (ρ_{TD}) exceeds $10^7\,cm^{-2}$, phonon-dislocation scattering will become nonnegligible compared to phonon-phonon scattering at room temperature [31.184], and an empirical relation indicated that thermal conductivity would be inversely proportional to $\rho_{TD}^{0.12}$ as ρ_{TD} goes to infinity. Another limiting factor of the thermal conductivity is the extent of dopants, and thermal conductivity decreased linearly with log n, where n is the electron concentration, the variation being about a factor of two decrease in k for every decade increase in n [31.185, 186].

Thermal conductivity measurements on InN are rare, partially due to the difficulty of growing high-quality InN films and single crystals. The first report of thermal conductivity was based on ceramic InN, which demonstrated a room-temperature value of $k = 0.45\,W\,cm^{-1}\,K^{-1}$ measured using the laser-flash method [31.187]. A more recent investigation is on single-crystalline InN films grown by MBE on c-sapphire substrate with a GaN buffer layer [31.188]. With background electron concentrations between 8×10^{17} and $3\times10^{18}\,cm^{-3}$ and mobilities between 1500 and $1045\,cm^2/Vs$, a room-temperature thermal conductivity of $1.2\,W\,cm^{-1}\,K^{-1}$ was obtained, which is closer to the theoretical thermal conductivity of $1.8\,W\,cm^{-1}\,K^{-1}$ estimated from $k_{theoretical} = C_\upsilon l\upsilon/3$, where c_υ is the molar specific heat, υ is the Debye-averaged acoustic phonon velocity, and $l = a/(\alpha_\upsilon\gamma T)$ is the phonon mean free path [31.188]. The effect of He^{2+} implantation on the thermal conductivity of InN

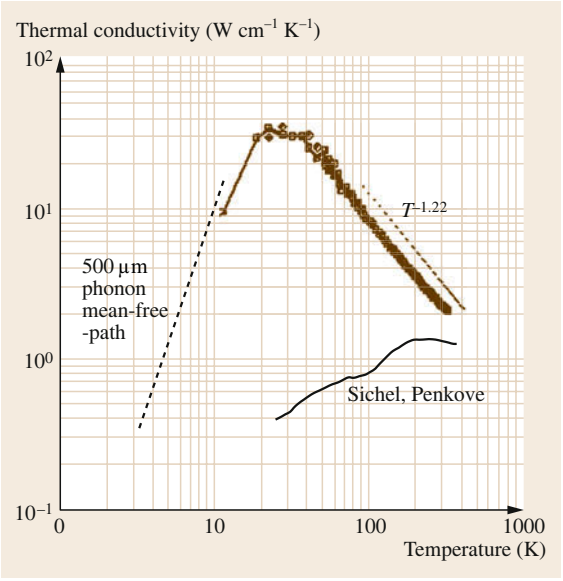

Fig. 31.5 Thermal conductivity of a 200 µm-thick free-standing GaN sample as a function of temperature. The *dashed line* indicates a calculation using the boundary scattering limit for a phonon mean free path of 500 µm. Also shown is the $T^{-1.22}$ dependence in the range of 80–300 K, and earlier results from [31.182] measured using a 400 µm HVPE sample. (After [31.171])

was also investigated, where the thermal conductivity reduced to around 0.1 W cm^{-1} K^{-1} when the implantation dose increased to 10^{16} cm^{-2}.

31.4.3 Specific Heat

The specific heat of a semiconductor can have various contributors, such as those by lattice vibrations, free carriers, point defects, and extended defects. For an ideal case where the semi-insulating crystals have good quality, the specific heat is only determined by the lattice vibrations. Due to the defective nature of group III nitrides, the specific heat is affected by contributions from free carriers and defects, especially at low temperatures. The temperature dependence of the specific heat can be expressed by the Debye expression as

$$C_\mathrm{p} = 18R\left(\frac{T}{\Theta_\mathrm{D}}\right)^3 \int_0^{x_\mathrm{D}} \frac{x^4 \mathrm{e}^x}{(\mathrm{e}^x - 1)^2}\mathrm{d}x\,, \tag{31.5}$$

where $x_\mathrm{D} \equiv \Theta_\mathrm{D}/T$, and $R = 8.3144\,\mathrm{J/(molK)}$ is the molar gas constant. The coefficient in front of the term R has been multiplied by 2 to take into account the two constituents making up the group III nitrides. The Debye temperature Θ_D can be obtained by fitting the measured temperature-dependent capacity to the Debye expression.

The constant pressure specific heat C_p of AlN in the temperature range of 298–1800 K was approximated using the following expression [31.189]

$$C_\mathrm{p} = 45.94 + 3.347\times10^{-3}T - 14.98\times10^{-5}T^2\,\mathrm{J/(mol\,K)}\,. \tag{31.6}$$

By using the specific heat of $C_\mathrm{p} = 51.5\,\mathrm{J/mol\,K}$ at $T = 1800\,\mathrm{K}$ and the estimated value of $C_\mathrm{p} = 58.6\,\mathrm{(mol\,K)}$ at $T = 2700\,\mathrm{K}$, the specific heat at higher temperature range of 1800–2700 K, can be approximated as [31.190]

$$C_\mathrm{p} = 37.34 + 7.86\times10^{-3}T\,\mathrm{J/(mol\,K)}\,. \tag{31.7}$$

The above equations show the general and simplified trends for the specific heat of AlN. However, the exact values vary from sample to sample because the specific heat is a function of free electrons (very effective at low temperatures), impurities, defects (including point defects), and lattice vibrations.

The experimental temperature-dependent specific heat results are shown in Fig. 31.6. Also shown are the calculated specific heat results using the Debye equation for Debye temperature values of 800–1100 K with 50 K increments. The best fit between the experimental data and the Debye specific-heat expression reveals

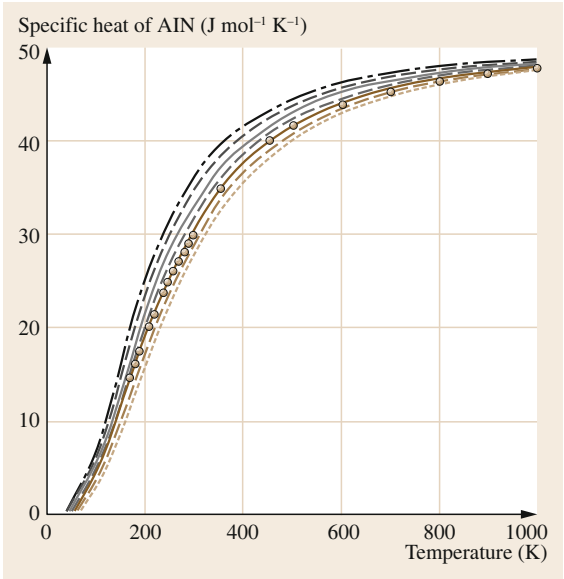

Fig. 31.6 Temperature-dependent molar specific heat of AlN at constant pressure C_p. *Brown dots* represent experimental data. The *lines* are for calculated data based on the Debye model for Debye temperature Θ_D in the range of 800–1100 K with 50 K increments. The best fit is obtained for a Debye temperature of 1000 K, which is close to the value of 950 K reported. (After [31.191])

a Debye temperature of 1000 K, which is close to the value of 950 K reported in reference [31.191].

The temperature-dependent specific heat for powdered GaN was obtained in a temperature range of 200–1400 K [31.192], which is in good agreement with the heat content data reported by *Itagaki* and *Yamaguchi* [31.193]. The combined data can be approximated by the following equation

$$C_\mathrm{p} = (49.552 \pm 2.279) + (5.440 \pm 2.936)\times10^{-3}\,T - (2.190 \pm 0.288)\times10^{6}\,T^{-2} + (2.460 \pm 0.459)\times10^{8}\,T^{-3}\,\mathrm{J/(mol\,K)}\,. \tag{31.8}$$

The specific heat for single-crystal GaN was also investigated in the temperature range of 20–1400 K by *Kremer* et al. [31.195] as demonstrated in Fig. 31.7, where the data below 300 K are in very good agreement with a later report by *Danilchenko* et al. [31.194]. Measured data in the range of 300–1400 K from *Kremer* can be best described with a Debye temperature of 863 K, which is consistent with the value calculated by *Nipko* et al. [31.196] from inelastic neutron scattering data. The dependence of the heat capacities of GaN, as a canonical binary material, on each of the Ga and N masses was also investigated, and it was shown that Ga

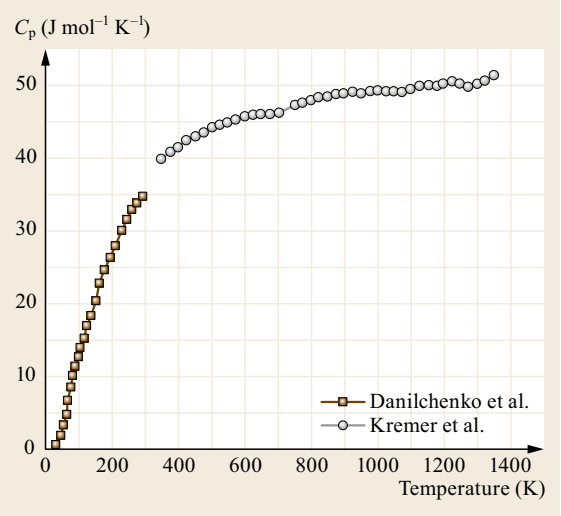

Fig. 31.7 Dependence of measured heat capacity on temperature measured in the range of 5–300 K [31.194] for single-crystal GaN, which overlaps with the data obtained from [31.195] in the same temperature range. The open circles represent measurement results by *Kremer* et al. in the temperature range of 300 to 1400 K

mass affects mainly the acoustic while N affects the optic phonons [31.195]. The temperature dependence of specific heat on bulk hexagonal GaN was also investigated [31.194], and it was shown that, for the studied specimens, the electron contribution to the C_p is negligible due to the fact that lattice C_p exhibits T^3 behavior and thus a C_p/T versus T^2 plot results in a straight line through the origin. From the measurement results in the temperature range of 20–300 K, a Debye temperature of 365 K was obtained.

A Debye temperature of 660 K was obtained for single-crystal InN based on fitting the measurement results in the temperature range of 150–300 K to the Debye expression [31.187]. However, due to the narrow temperature range of these measurements, it is difficult to compare these results to the Debye curve. The heat capacity and heat content of powdered InN were also measured by Calvet calorimetry (305–390 K) and by drop calorimetry (427–774 K), and the temperature dependence of heat capacity can be fitted as the following equation [31.197]

$$C_p = 43.886 + 8.194\times10^{-3}T - 1.007\times10^{6}T^{-2} + 8.353\times10^{7}T^{-3}\,\mathrm{J/(mol\,K)}\,. \tag{31.9}$$

Similar measurements were also conducted for powdered InN with 8.4% indium impurities in the temperature range of 314–978 K [31.198], and the temperature dependence of the heat capacity was presented in the following form

$$C_p = 41.400 + 0.499\times10^{-3}\,T - 1.355\times10^{5}\,T^{-2} - 2.617\times10^{7}\,T^{-3}\,\mathrm{J/(mol\,K)}\,. \tag{31.10}$$

For both cases, liquid droplets of pure indium were observed on the surface of InN after experiments at high temperature, thus a recalculation had to be conducted to determine only the heat capacity of indium nitride. Also due to the difficulty of growing high-quality pure InN crystals, the heat capacity of InN samples may have significant contributions from nonvibrational modes, which limits the credibility of the data presented above.

31.5 Electrical Properties of Nitrides

GaN and related nitrides, being direct and large bandgap materials, lend themselves to a variety of electronic and optoelectronic applications. Advantages associated with a large bandgap include relatively high breakdown voltages, the ability to sustain large electric fields, low noise generation, and high temperature and high power operation. Reasonable low-field mobility, large satellite energy separation, and high phonon frequency are among the other attributes. A high thermal conductivity, large electrical breakdown fields, and resistance to hostile environments also support the group III nitrides as true materials of choice for device applications. The electron transport in semiconductors, including nitrides, can be considered at low and high electric field conditions. At sufficiently low electric fields, the energy gained by the electrons from the applied electric field is small compared to the thermal energy of electrons, and therefore, the energy distribution of electrons is unaffected by such a low electric field. Since the scattering rates determining the electron mobility depend on the electron distribution function, electron mobility remains independent of the applied electric field, and Ohm's law is obeyed. When the electric field is increased to a point where the energy gained by electrons from the external field is no longer negligible compared to the thermal energy of the electron, the electron distribution function changes significantly from its equilibrium value. These electrons become hot electrons characterized by an electron temperature larger than the lattice temperature. Furthermore, as the

dimensions of the device are shrunk to the submicron regime, transient transport occurs where there is minimal or no energy loss to the lattice. The transient transport is characterized by the onset of ballistic or velocity overshoot phenomena, not that they have been demonstrated in the nitride semiconductor family. Since the transient electron drift velocity is higher than its steady-state value one can design a device operating at higher frequency, which is yet to be demonstrated for GaN based devices as of the time of this writing.

31.5.1 Low Field Transport

The Hall effect is the most widely used technique to measure the transport properties and assess the quality of epitaxial layers. For semiconductor materials, it yields the carrier concentration, its type, and carrier mobility. More specifically, temperature-dependent Hall measurements over a wide range (4.2−300 K) give information on impurities, imperfections, uniformity, scattering mechanism, and so on. The Hall coefficient and resistivity are experimentally determined and then related to the electrical parameters through $R_H = r_H/ne$ and $\mu_H = R_H/\rho$, where n is the free-carrier concentration, e is the unit of electrical charge, μ_H is the Hall mobility, and r_H is the Hall scattering factor. The drift mobility, μ, is the average velocity per unit electric field in the limit of zero electric field and is related to the Hall mobility through the Hall scattering factor by $\mu_H = r_H\mu$. The Hall scattering factor depends on the details of the scattering mechanisms in play, which limits the drift velocity. As the carriers travel through a semiconductor, they encounter various scattering mechanisms that govern the carrier mobility in the electronic system. The parameter for characterizing the various scattering mechanisms is the relaxation time τ, which determines the rate of change in electron momentum as it moves about in the semiconductor crystal. Mobility is related to the scattering time by

$$\mu = \frac{q\langle\tau\rangle}{m^*} , \tag{31.11}$$

where m^* is the electron effective mass, q is the electronic charge, and $\langle\tau\rangle$ is the relaxation time averaged over the energy distribution of electrons. The total relaxation time, τ_T, when various scattering mechanisms are operative is given by Matthiessen's rule

$$\frac{1}{\tau_T} = \sum_i \frac{1}{\tau_i} , \tag{31.12}$$

where i represents each scattering process. The major scattering mechanism that generally governs the electron transport in III-V semiconductors is also valid for group III nitrides. They are briefly listed as follows:

1. Ionized impurity scattering is due to deflection of free carriers by the long-range Coulomb potential of the charged centers caused by defects or dopants/impurities. This can be thought of as a local perturbation of the band edge, which affects the electron motion.
2. Polar longitudinal-optical (LO) phonon scattering is caused by the interaction of a moving charge with an electric field induced by electric polarization associated with lattice vibration due to the ionic nature of the bonds in polar semiconductors such as nitrides.
3. Acoustic phonon scattering through deformation potential arising from the energy change of the band edge induced by strain associated with acoustic phonons, where the scattering rate increases with the wave vector of the phonons.
4. Piezoelectric scattering arises from the electric fields that are produced by the strain associated with phonons in a crystal without inversion symmetry, such as wide bandgap nitrides.
5. Because of the high density of dislocations and native defects induced by nitrogen vacancies in GaN, dislocation scattering and scattering through nitrogen vacancies have also been considered as a possible scattering mechanism. Dislocation scattering is due to the fact that acceptor centers are introduced along the dislocation lines, which capture electrons from the conduction band in an n-type semiconductor. The dislocation lines become negatively charged and a space charge region is formed around them, which scatters electrons traveling across the dislocations, thus reducing the mobility.

Gallium Nitride

Electron mobility in GaN is one of the most important parameters associated with the material with great impact on devices. It has been the subject of intensive studies in recent years from both experimental and theoretical points of view. Experimental investigation of the temperature-dependent carrier mobility and concentration can be used to determine the fundamental material parameters and understand the carrier scattering mechanisms along with an accurate comparison with theory [31.200, 201]. Despite the many attributes of GaN, the lack of high-quality material, until very recently, prevented detailed investigations of carrier transport. The earlier transport investigations had to cope with poor crystal quality and low carrier mobility, well below predictions [31.202, 203]. Early MBE layers exhibited mobilities as high as 580 $cm^2/(Vs)$ on SiC

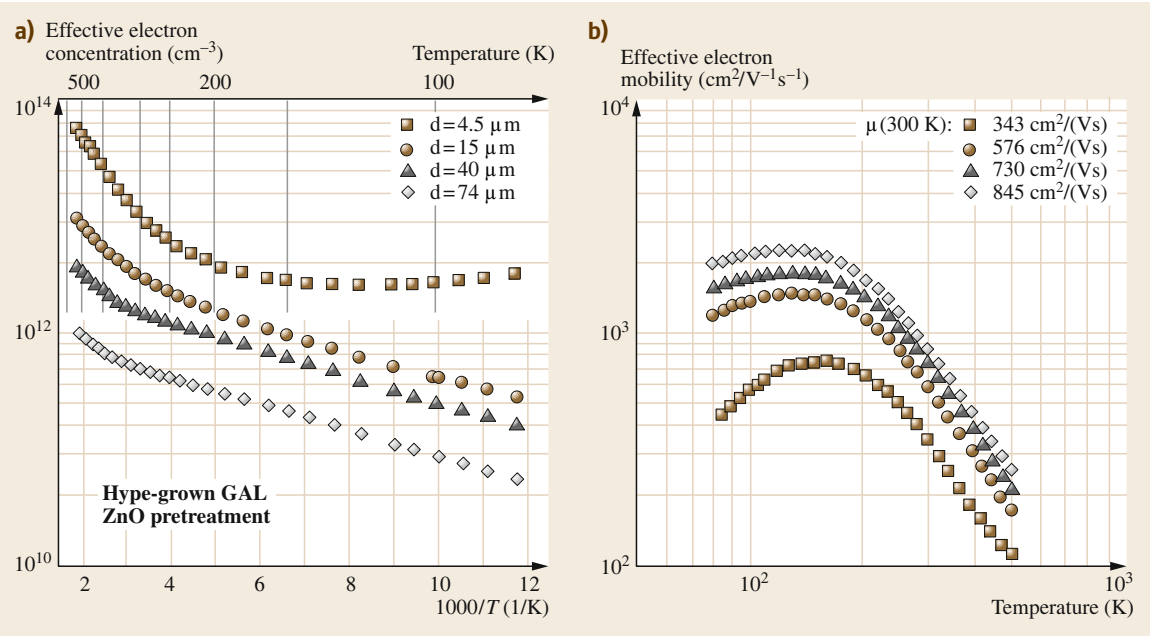

Fig. 31.8a,b Effective electron concentration versus reciprocal temperature in unintentionally doped n-type GaN films grown by HVPE on sapphire substrates **(a)** and effective electron mobility versus temperature **(b)** as determined from Hall-effect measurements under the assumption of uniform film properties. (After [31.199])

substrates, which at that time were not as commonly used as in recent times [31.204]. Typically however, the MBE-grown films produce much lower mobility values of 100–300 cm^2/(Vs) [31.205]. Different models were used to explain the observed low electron mobilities in GaN, especially at low temperatures. The scattering of electrons at charged dislocation lines [31.205–209] and scattering through elevated levels of point defects [31.210, 211], such as nitrogen vacancies [31.212, 213] were considered as possible mechanisms responsible for these observations. These scattering mechanisms were investigated by studying the temperature dependence of the carrier concentration and electron mobility. It has been argued that mobility is related to the dislocation density (N_{dis}) and free-carrier concentration (n) via a $\mu_{dis} \propto \sqrt{n}/N_{dis}$ relationship [31.207]. At low carrier concentrations ($< 5\times10^{17}$ cm^{-3}), the mobility decreases due to charged dislocation scattering, while at higher carrier concentrations ionized impurity is the dominant mechanism determining the mobility. The temperature dependence of mobility for samples where dislocations play a dominant role shows that the mobility increases monotonically with temperature following a $T^{2/3}$ dependence. Moreover, electron mobility limited by nitrogen vacancy scattering was taken into account in n-type GaN grown by MOVPE by *Zhu* and *Sawaki*, [31.212] and *Chen* et al. [31.213]. A good fitting was obtained between the calculated and experimental results. The estimated mobility shows $T^{-1/2}$ temperature dependence and it was argued that the measured mobility is dominated by ionized impurity and dislocation scattering at low temperatures, but by polar optical phonon and nitrogen vacancy scattering at high temperatures.

Hall mobility and electron concentration in undoped GaN were investigated as a function of thickness of the buffer layers and epilayers. *Nakamura* [31.215] reported Hall effect data for undoped GaN layers grown by MOVPE on GaN buffer/sapphire substrates. As the thickness of the initial buffer layer increased from 100 Å, the mobility also increased up to a thickness of 200 Å. For larger thicknesses the mobility began to decrease. The value of the mobility was 600 cm^2/(V s) at room temperature for a 200 Å-thick initial buffer layer. The electron concentration was minimal at 520 nm buffer thickness and increased monotonically as buffer thickness increased. The mechanism responsible for this observation is not clearly established. *Götz* et al. [31.199] have studied the effect of the layer thickness on the Hall mobility and electron concentration in unintentionally doped n-type GaN films grown by HVPE on sapphire substrates, which were pretreated with either ZnO or GaCl. They found that the mobility increased and the carrier concentration decreased as the thickness of the epilayers increased as shown in Fig. 31.8.

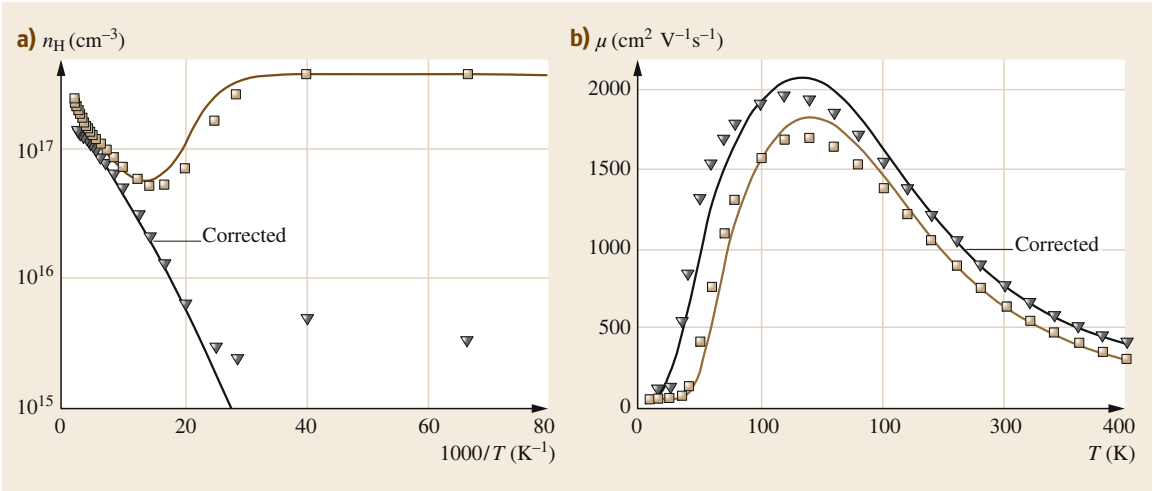

Fig. 31.9a,b GaN on sapphire: **(a)** Uncorrected Hall concentration data (*squares*) and fit (*solid line*), and corrected data (*triangles*) and fit (*dashed line*) versus inverse temperature. **(b)** Uncorrected Hall mobility data (*squares*) and fit (*solid line*), and corrected data (*triangles*) and fit (*dashed line*) versus temperature. (After [31.214])

Götz et al. related this variation to a nonuniform distribution of electrically active defects through the film thickness for both types of film. For GaCl-pretreated sapphire the presence of a highly conductive, 200 nm-thick, near-interface layer was assumed to account for the observed phenomena. For ZnO-pretreated sapphire, the Hall-effect data indicated a continuous reduction of the defect density with increasing film thickness. Since GaN layers are often grown on foreign substrates with very different properties, a degenerate layer forms at the interface caused by extended defects and impurities. Experiments show that, even for thick GaN grown by HVPE, the degenerate interfacial layer has an important contribution to the Hall conductivity.

Look and *Molnar* [31.214] investigated the Hall effect in the temperature range of 10–400 K in HVPE-grown layers on sapphire substrates by assuming a thin, degenerate n-type region at the GaN/sapphire interface. This degenerate interfacial region dominates the electrical properties below 30 K, but also significantly affects those properties even at 400 K, and can cause a second, deeper donor to falsely appear in the analysis. The mobility versus temperature curve is also affected in that the whole curve is shifted downward from the true, bulk curve. A model consisting of two layers was constructed to interpret these observations and the result is shown in Fig. 31.9.

The dependence of Hall mobilities on electron concentrations was also investigated in the electron concentration range of $\approx 10^{16}$–$10^{19}\,\mathrm{cm}^{-3}$ for undoped and intentionally doped (commonly used Si and Ge, which substitute for Ga, are shallow donors with almost identical binding energies) GaN layers grown

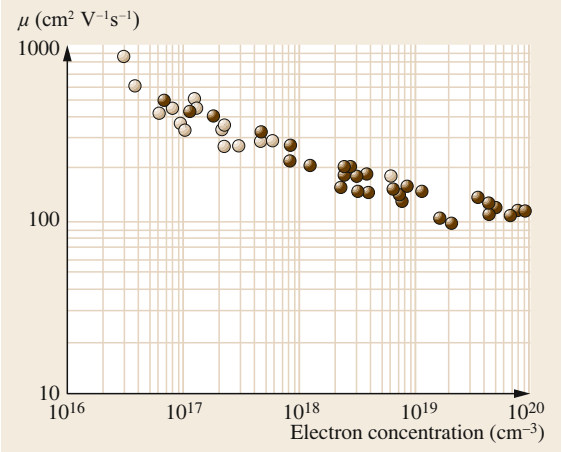

Fig. 31.10 The 300 K Hall mobility versus free-electron concentration for GaN from various groups using both MOVPE and MBE. The *open circles* are from unintentionally doped samples and the *solid circles* are for samples doped with either Si or Ge. (After [31.216])

by different growth techniques, and the results are displayed in Fig. 31.10. The most clearly observed trend is that the mobility shows no signs of leveling, down to the lowest carrier concentration reported, and the mobility values are practically the same irrespective of growth techniques and dopants used, which reflects transport properties inherent to GaN, not to extrinsic effects. Returning to the data of *Nakamura* et al. [31.218] the room-temperature mobility of $600\,\mathrm{cm}^2/(\mathrm{V\,s})$ for an electron concentration of $\approx 3\times10^{16}\,\mathrm{cm}^{-3}$ decreased slowly with increas-

The *solid line* is the calculated result using $N_a = 2.4\times10^{10}\,\mathrm{cm}^{-3}$, representing the best fit to the measured results. The *upper* and *lower dotted lines* are the calculated results using $N_a = 1.4\times10^{15}$ and $3.4\times10^{15}\,\mathrm{cm}^{-3}$. **(b)** The measured Hall densities n_H (*solid squares*) as a function of reciprocal temperature from the GaN template grown by HVPE. The *open circles* represent the carrier density corrected by the Hall factor, $n = n_H r_H$. The *solid line* is the fit to the theoretical expression of charge balance with hole and neutral acceptor densities neglected. **(c)** Temperature dependence of the calculated Hall factor, r_H. (After [31.217])

ing carrier concentration, dropping down to a value of about $100\,\mathrm{cm}^2/(\mathrm{V\,s})$ at a carrier concentration of $3\times10^{18}\,\mathrm{cm}^{-3}$. For an electron concentration of $1\times10^{18}\,\mathrm{cm}^{-3}$, the mobility was $250\,\mathrm{cm}^2/(\mathrm{V\,s})$. A higher room-temperature mobility of $845\,\mathrm{cm}^2/(\mathrm{V\,s})$ at an electron concentration of $\approx 6\times10^{16}\,\mathrm{cm}^{-3}$ was achieved by *Götz* et al. [31.199]. In later publications, due to the advent of the high-quality samples grown by several growth techniques, there was a significant improvement in reported room-temperature mobility values. *Nakamura* et al. [31.219] and *Binari* and *Dietrich* [31.220] were able to obtain $900\,\mathrm{cm}^2/(\mathrm{V\,s})$ room-temperature mobility at an electron concentration of 3×10^{16} and $5\times10^{16}\,\mathrm{cm}^{-3}$ respectively. Later on even higher electron mobilities of $1100\,\mathrm{cm}^2/(\mathrm{V\,s})$ at room temperature and $1425\,\mathrm{cm}^2/(\mathrm{V\,s})$ at 273 K were reported by *Yun* et al. [31.221] and *Huang* et al. [31.217] respectively, for a 200 μm thick freestanding n-type GaN template grown by HVPE. This achievement was attributed to the excellent crystalline structure of the GaN sample with low levels of compensation and the defect-related scattering. A quantitative comparison with theoretical calculations demonstrated that the one-layer and one-donor conductance model is sufficient to account for the measured data in the entire temperature range without considering any dislocation scattering and any adjustable parameters other than the acceptor concentration. The measured temperature-dependent Hall mobility, carrier concentration, and Hall scattering factor are shown in Fig. 31.11 along with the best-fit theoretical calculation based on an iterative solution of the Boltzmann equation.

As shown, a quantitative agreement with the measured mobility in the entire temperature range was obtained to within about 30%. *Heying* et al. [31.222] investigated both the morphology and electrical properties of homoepitaxial GaN layers grown by MBE as a function of Ga/N ratio during growth. GaN films grown with higher Ga/N ratios (intermediate regime) showed fewer pits with areas of atomically flat surface, which gives the highest mobility $\approx 1191\,\mathrm{cm}^2/(\mathrm{V\,s})$ reported at the time at room temperature. *Koleske* et al. [31.223] investigated the effect of the AlN nucleation layer on transport properties of GaN films grown on 6H- and 4H-SiC substrates. Room-temperature electron mobilities of 876, 884, and $932\,\mathrm{cm}^2/(\mathrm{V\,s})$ were obtained on 6H-SiC, 4H-SiC, and 3.5° off-axis 6H-SiC substrates respectively. The authors attributed the observed high electron mobilities to the improved AlN morphology and reduction in screw dislocation density near the AlN/GaN interface.

The thermal activation energy of free carriers has also been extracted from the temperature-dependent Hall concentration and mobility measurements by fitting simple exponential dependence of the carrier concentration on inverse temperature, by a two-band model and by other theoretical fitting techniques. It was concluded that the activation energy of n-type GaN free carriers lies in the range 14–36 meV depending on the extent of screening [31.217, 218, 224–226]. In the di-

lute limit, the values are close to 30 meV. In order to analyze the mobility data, one must understand the scattering processes that dominates mobility at different temperatures. Monte Carlo simulations of the electron velocity in GaN as a function of electric field at different doping concentrations and temperatures predicted a peak drift velocity of 2×10^7 cm/s at an electric field of $\approx 1.4\times10^5$ V/cm for an electron concentration of $10^{17}\,\mathrm{cm}^{-3}$ [31.227, 228]. These values show that an electron mobility as high as $900\,\mathrm{cm}^2/(\mathrm{V\,s})$ could be achieved in the case of uncompensated GaN at room temperature with $\approx 10^{17}\,\mathrm{cm}^{-3}$ doping concentration. As discussed above, in the case of high-quality samples with very low compensation, a mobility of even more than $900\,\mathrm{cm}^2/(\mathrm{V\,s})$ at room temperature with a similar doping concentration has been reported.

Albrecht et al. [31.229] calculated the electron mobility for different concentrations of the ionized impurities and at different temperatures by using a Monte Carlo simulation technique based on empirical pseudopotential band structure calculations. For practical use they have also derived an analytical expression describing the dependence of the mobility on temperature and ionized impurity concentration as

$$\frac{1}{\mu_\mathrm{e}} = a\left(\frac{N_\mathrm{I}}{10^{17}\,\mathrm{cm}^{-3}}\right)\ln\left(1+\beta_\mathrm{cw}^2\right)\left(\frac{T}{300\,\mathrm{K}}\right)^{-1.5} + b\left(\frac{T}{300\,\mathrm{K}}\right)^{1.5} + c\frac{1}{\exp\left(\frac{\Theta}{T}\right)-1}\,, \tag{31.13}$$

where

$$\Theta = \frac{\hbar\omega_\mathrm{LO}}{k_\mathrm{B}} = 1065\,\mathrm{k}\,,$$

$$\beta_\mathrm{WC}^2 = 3.00\left(\frac{T}{300\,\mathrm{K}}\right)^2\left(\frac{N_\mathrm{I}}{10^{17}\,\mathrm{cm}^{-3}}\right)\,,$$

$$N_\mathrm{I} = \frac{(1+k_\mathrm{c})}{N_\mathrm{D}}\,,$$

and

$$a = 2.61\times10^{-4}\,(\mathrm{V\,s})/\mathrm{cm}^2\,,$$

$$b = 2.90\times10^{-4}\,(\mathrm{V\,s}/\mathrm{cm}^2)\,,$$

$$c = 1.70\times10^{-2}\,(\mathrm{V\,s})/\mathrm{cm}^2\,.$$

Here N_D is the ionized donor concentration in cm^{-3} and $k_\mathrm{c} = N_\mathrm{A}/N_\mathrm{D}$ is the compensation ratio. Comparing the mobility calculated using this analytical expression and that calculated by Monte Carlo simulations, a reasonable agreement with a maximum error of 6% is realized between the temperature range of 300–600 K, and ionized donor concentration from 10^{16}–$10^{18}\,\mathrm{cm}^{-3}$.

The calculation of low field electron mobility in GaN has also been carried out by using different techniques. *Chin* et al. [31.202] have used the variational principle to calculate low field electron mobilities as a function of temperature for carrier concentrations of 10^{16}, 10^{17} and $10^{18}\,\mathrm{cm}^{-3}$ with the compensation ratio as a parameter. GaN exhibits maximum mobilities between 100 and 200 K, depending on the electron density and compensation ratio, with lower electron density peaking at lower temperature. This behavior is related to the interplay of piezoelectric acoustic phonon scattering at low carrier concentrations and ionized impurity scattering at higher carrier concentrations. The polar mode optical phonon scattering-limited maximum room-temperature mobility in GaN is found to be about $1000\,\mathrm{cm}^2/(\mathrm{V\,s})$. Although a degree of correlation is achieved with the experimental data, there is a disparity, which is attributed to the structural imperfections and an overestimated compensation ratio (compensation reduces electron mobility in GaN for a given electron concentration). Typical compensation ratios observed for MOCVD- and MBE-grown films are about 0.3, though a lower ratio of ≈ 0.24 was reported for HVPE-grown crystals.

Rode and *Gaskill* [31.203] have used an iterative technique, which takes into account all major scattering mechanisms for low field electron mobility in GaN, to investigate the dependence of mobility on electron concentration, but not on temperature. The result was applied to the Hall mobility data published by *Kim* et al. [31.231] and a good fitting between theory and experiment was demonstrated within 2.5% error for the lowest doped samples with free-electron concentrations of 7.24×10^{17} and $1.74\times10^{17}\,\mathrm{cm}^{-3}$. However, there is a significant disagreement for the more heavily doped samples having much higher free-electron concentrations, where the Born approximation applied for the ionized impurity scattering might be the reason for poor fitting at high electron concentrations. By assuming uncompensated material and carrier freeze-out onto donors, the ionization energy was theoretically determined to be about 45 and 57 meV for the best-fitted samples with free-electron concentrations of 7.24×10^{17} and $1.74\times10^{17}\,\mathrm{cm}^{-3}$ respectively. Recent developments in major growth techniques such as HVPE, MOCVD, and MBE for GaN and other group III nitride semiconductors have led to the growth of high-quality epitaxial layers [31.232–234], which allowed the comparison of the Hall data with theory at a finer scale. *Dhar* and *Gosh* [31.230] have calculated the temperature and doping dependencies of the electron mobility using an iterative technique, in which the scattering mechanisms have been treated beyond the Born approximation. The compensation ratio was used

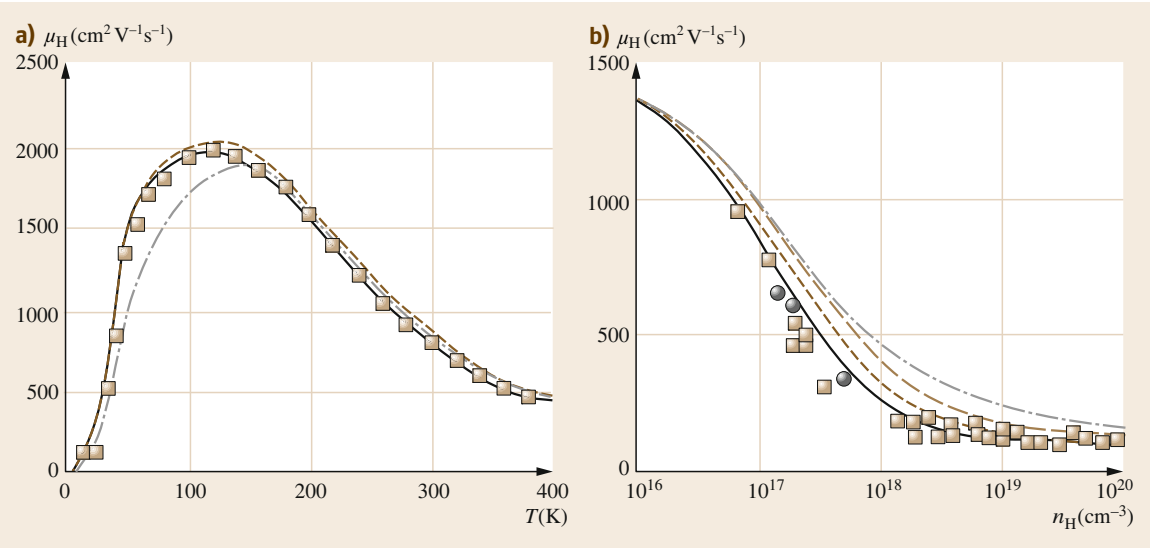

Fig. 31.12 **(a)** Temperature dependence of the calculated electron Hall mobility. The *dashed curve* shows the calculated mobility using the BH technique. The solid curve shows the calculated mobility using phase-shift analysis with multi-ion screening correction and electron-plasmon scattering. Experimental data are taken from different references. (After [31.230])

as a parameter with a realistic charge neutrality condition. They tested their model with the experimental Hall data taken from literature [31.199, 202, 214, 218, 219, 225, 235]. Reasonable agreement was achieved between these data points and the calculation over a wide range of temperatures and electron concentrations, as shown in Fig. 31.12. They also investigated the effect of the degenerate layer at the GaN/substrate interface to extract reliable experimental values of the bulk electron mobility and concentration.

GaN samples from Kyma Technologies, Inc. (grown by hydride vapor phase epitaxy – HVPE) with a thickness of 40 µm were characterized by *Wang* et al. [31.236]. Undoped and Si-doped samples exhibited carrier densities of 4.58×10^{15} and $2.41\times10^{18}\,\mathrm{cm}^{-3}$ with mobilities of 1050 and $286\,\mathrm{cm}^2/(\mathrm{Vs})$ respectively. The decreased mobility in Si-doped GaN samples is, according to the authors, due to the increase of ionized impurity scattering. GaN grown by HVPE on an MOCVD-grown GaN/sapphire template with a photolithographically patterned Ti mask and ammonothermally grown GaN crystals (Am-GaN) was compared by *Sochacki* et al. [31.237]. Carrier concentration and carrier mobility were $2\times10^{16}\,\mathrm{cm}^{-3}$ and $1107\,\mathrm{cm}^2/(\mathrm{Vs})$, and $4\times10^{16}\,\mathrm{cm}^{-3}$ and $883\,\mathrm{cm}^2/(\mathrm{Vs})$ for GaN grown on MOCVD-GaN/sapphire and Am-GaN (at 800 mbar), respectively. The resistivity was in the range of 0.1–0.3 Ω cm in both cases. Higher mobility and lower carrier concentration suggests that HVPE-GaN grown on MOCVD-GaN/sapphire templates incorporated fewer unintentional impurities, which was also consistent with the low-temperature PL spectra (not sown here). It is believed that the better electrical characteristic of HVPE-GaN grown on MOCVD-GaN/sapphire template is the result of a higher growth rate, which fosters a higher purity of the material.

Besides the numerical simulation techniques mentioned above, recently, *Mnatsakanov* et al. [31.238] derived a simple analytical approximation to describe the temperature and carrier concentration dependencies of the low-field mobility in wide temperature $50 \le T \le 1000\,\mathrm{K}$ and carrier concentration ($10^{14} \le N \le 10^{19}\,\mathrm{cm}^{-3}$ ranges. As the first step of this model, an adequate approximation of the doping level dependence of the mobility at room temperature is used on the basis of the Goughey–Thomas approximation [31.239]

$$\mu_i(N) = \mu_{\min,i} + \frac{\mu_{\max,i} - \mu_{\min,i}}{1 + \left(\frac{N}{N_{g,i}}\right)^{\gamma_i}}\,, \qquad (31.14)$$

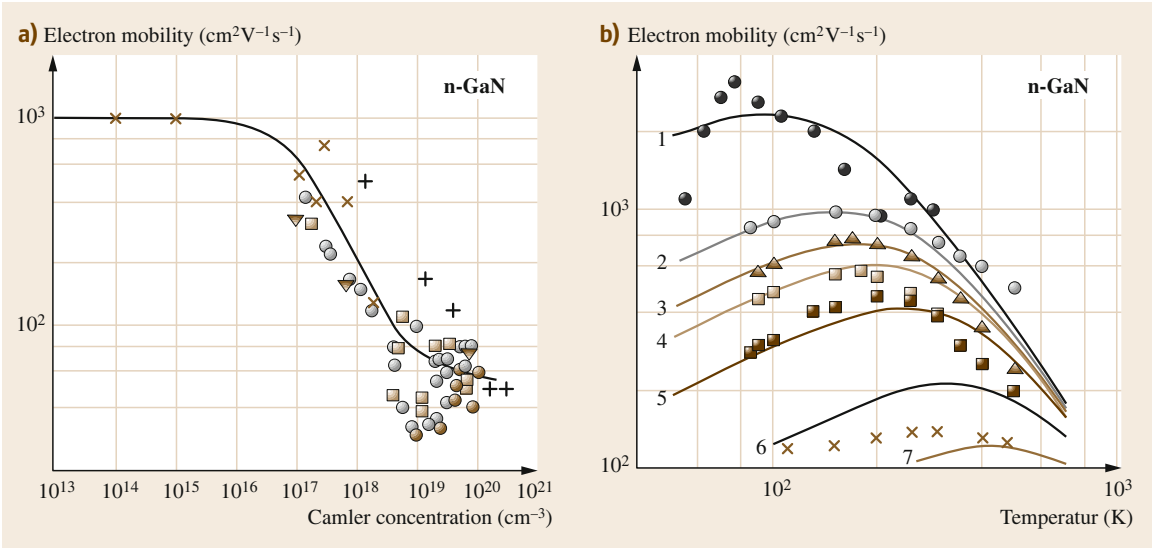

Fig. 31.13 **(a)** Low-field electron mobility as a function of doping concentration in GaN at room temperature. The *curve* represents the best approximate equation. The symbols (*crosses*, *open circles*, and *pluses*) are experimental data taken from different references for wurtzite GaN and zincblende. **(b)** Temperature dependencies of low-field electron mobility in wurtzite GaN at different values of doping concentration. Curves represent the best approximate equations. 1: $N = 3\times 10^{16}$ cm^{-3}, 2: $N = 10^{17}$ cm^{-3}, 3: $N = 1.5\times 10^{17}$ cm^{-3}, 4: $N = 2\times 10^{17}$ cm^{-3}, 5: $N = 3.5\times 10^{17}$ cm^{-3}, 6: $N = 10^{18}$ cm^{-3}, 7: $N = 3\times 10^{18}$ cm^{-3}. (After [31.230])

where i= n, p for electrons and holes respectively, $\mu_{\min,i}$, $\mu_{\max,i}$, $N_{g,i}$ and γ_i are the model parameters dependent on the type of semiconductor materials, and N is the doping concentration. Figure 31.13a shows the comparison between the calculated low-field electron mobility as a function of doping level and some experimental data on the room-temperature electron mobility in GaN.

The proposed approximation provides a rather good agreement with the experimental data. For the temperature-dependent mobility calculation, the authors derived the following equation by taking into account the main scattering mechanisms

$$\mu_i(N,T) = \mu_{\max,i}(T_0)\frac{B_i(N)\left(\frac{T}{T_0}\right)^{\beta_i}}{1+B_i(N)\left(\frac{T}{T_0}\right)^{\alpha_i+\beta_i}}\,, \tag{31.15}$$

where

$$B_i(N) = \left(\frac{\mu_{\min,i}+\mu_{\max,i}\left(\frac{N_{g,i}}{N}\right)^{\gamma_i}}{\mu_{\max,i}-\mu_{\min,i}}\right)\Bigg|_{T=T_0}\,.$$

Figure 31.13b presents the calculated temperature-dependent electron mobility and experimental data reported in the literature and a good agreement is realized. Although ionized impurity scattering is the dominant mechanism at low temperatures, where the mobility increases with increasing temperature, at high temperatures mobility is limited by polar optical phonon scattering where mobility decreases with increasing temperature. Although a good agreement was achieved between theoretical calculations and experimental data, many material and physical parameters of GaN were not available for some of the previous simulations where those parameters were treated as adjustable parameters. This underscores the need for reliable parameters in the calculation of the electron mobility and in the interpretation of experimental results to gain more accuracy.

Aluminum Nitride

Due to the low intrinsic carrier concentration, and the deep native defect and impurity energy levels (owing to the wide bandgap of AlN ≈ 6.2 eV at 300 K), the electrical transport properties of AlN have not been studied extensively and have usually been limited to resistivity measurements. Resistivities in the range of $\rho = 10^7$–$10^{13}\,\Omega$ cm have been reported for unintentionally doped AlN single crystals [31.240, 241], a value consistent with other reports [31.242–244]. The conductivity exhibited an Arrhenius behavior for all crystals and the activation energies were reported to be 1.4 eV for temperatures between 300 and 400 K and 0.5 eV between 300 and 330 K. Intentional doping of AlN has resulted

in both n- and p-type AlN by introducing Hg and Se respectively (caution is warranted here). *Gorbatov* and *Kamyshon* [31.245] obtained n-type conductivity of polycrystalline AlN with the incorporation of Si. Unintentionally doped n-AlN films grown by a modified physical transport technique by *Rutz* [31.246] had a resistivity as low as 400 Ω cm. Although the source of the electrons has not been determined, *Rutz* et al. [31.247] observed an interesting transition in their AlN films in which the resistivity abruptly decreased by two orders of magnitude with an increase in the applied bias. This observation found applications to switchable resistive memory elements that are operated at 20 MHz. Based on an ab initio density functional calculation, *Fara* et al. [31.248] concluded that energy levels are deep for acceptors, donors, and native defects in AlN, due to the semi-insulating characteristic of AlN. For example, acceptors are deeper (Be ≈ 0.25, Mg ≈ 0.45) and less soluble in AlN than that in GaN, and both the extrinsic donors Si_{Al} and C_{Al}, and the native donor V_N are found to be deep (about 1 to 3 eV below the conduction band). Consequently, doped AlN may in general turn out to be semi-insulating, when attained using Al-rich conditions, in agreement with the known doping difficulties of high Al-content AlGaN alloys.

As far as the mobility of AlN is concerned, in early studies, *Edwards* et al. [31.240] and *Kawabe* et al. [31.241] carried out Hall measurements in p-type AlN, which produced a very rough estimate of the hole mobility; $\mu_p = 14\,cm^2/(V\,s)$ at 290 K. Later work on carbon-doped materials has resulted in highly conductive p-type AlN with hole mobilities in the range of $60\,cm^2/(V\,s)$ for carbon doping of $10^{18}\,cm^{-3}$ (*Wongchotigul* et al. [31.249] – again caution should be exercised here). The theoretical calculations have only been made to estimate the mobility in AlN by *Chin* et al. [31.202]. Since AlN is a semi-insulator with extremely low carrier concentration, only phonon-limited scattering processes were considered in the calculation of the temperature-dependent mobility as shown in Fig. 31.14. The mobility was found to decline rapidly at high temperatures, with a value of about $2000\,cm^2/(V\,s)$ at 77 K and dropping to $300\,cm^2/(V\,s)$ at 300 K for optical phonon-limited mobility.

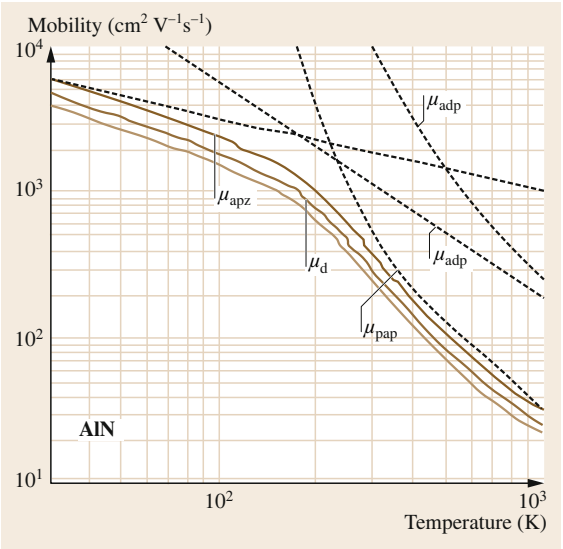

Fig. 31.14 The phonon-limited electron drift mobility in AlN plotted as a function of temperature for $m^* = 0.48$. The *upper* and *lower solid curves* are for the phonon-limited electron drift mobility calculated using $m^* = 0.42$ and 0.52 respectively. (After [31.202])

Indium Nitride

InN suffers from the lack of a suitable substrate material as well, causing a high concentration of extended defects in the films. A sapphire substrate is usually used for InN growth, but the difference in lattice constants between InN and sapphire is as large as 25% and even more than 19% with the other nitrides. A large disparity of the atomic radii of In and N is an additional contributing factor to the difficulty of obtaining InN of good quality. Because of all these factors, the electron mobilities obtained from various films have varied significantly. Electrical properties also vary substantially depending on the growth techniques. A range of film deposition techniques, such as reactive ion sputtering, reactive RF magneton sputtering, metal organic vapor phase epitaxy and MBE, have been used. Table 31.6 gives values of electron mobility and concentration in InN films grown by various growth techniques.

The transport properties reported in the literature are mostly based on Hall effect measurements, assuming the Hall scattering factor to be unity. In the majority of the samples, electron mobilities often remain relatively poor, despite predicted values as high as $3000\,cm^2/(V\,s)$ at room temperature for InN [31.268]. It is widely believed that nitrogen vacancies lead to large background electron concentrations, which are responsible for the observed low electron mobility. An empirical linear relationship between the electron mobility and electron concentration can be deduced from Table 31.6 for a series of InN films, although not all films exhibit this type of behavior. A systematic study carried out by *Tansley* et al. indicates that the electron concentration decreases as the nitrogen density is increased in the plasma in reactive ion sputtering. Although the reported time is relatively old, the maximum mobility of $2700\,cm^2/(V\,s)$ at an electron concentration of $5\times10^{16}\,cm^{-3}$ was reported for RF reactive ion sputtered growth of InN. Early studies of the electron

Table 31.6 A compilation of electron mobilities obtained n wide-bandgap InN on different substrates and for various deposition conditions in InN

mobility of InN as a function of the growth temperature indicate that the mobility of ultrahigh vacuum-electron cyclotron resonance-radio-frequency magnetron sputtering (UHV-ECR-RMS)-grown InN can be as much as four times the mobility of conventionally grown (vacuum deposition) InN [31.257]. However, more recent work indicates a progressive improvement in electrical properties of InN films grown by MBE and MOVPE. The value of electron mobility as high as $1420\,cm^2/(V\,s)$ at an electron concentration of $1.4\times10^{18}\,cm^{-3}$ was reported for the InN layers grown by plasma-assisted MBE using a low-temperature-grown GaN intermediate layer and a low-temperature-grown InN buffer layer. Hall measurements in InN films grown on AlN buffer layers, which are in turn grown on sapphire, indicated an electron mobility to be $2100\,cm^2/(V\,s)$ with a relatively low electron concentration ($4\times10^{17}\,cm^{-3}$) at room temperature in material grown by MBE. Very high inadvertent donor concentrations, $>10^{18}\,cm^{-3}$, seem to be one of the major problems for further progress of device applications of InN. O_N and Si_{In} and possible interstitial H have been proposed to be the likely dominant defects responsible for high electron concentration in the state-of-the-art MBE-grown InN due to their low formation energies [31.269, 270].

Electron mobility in InN has been calculated using the variational principle for a range of temperatures, carrier concentrations, and compensation ratios [31.202]. Figure 31.15 shows the theoretical results with experimental mobility values taken from [31.251]. The calculated peak mobilities are found to be 25 000, 12 000, and $8000\,cm^2/(V\,s)$ for carrier concentrations of 10^{16}, 10^{17} and $10^{18}\,cm^{-3}$ respectively, at different temperatures (between 100–200 K) depending on the electron density and compensation ratio. This is due to the interplay of piezoelectric acoustic phonon scattering at low concentrations and ionized impurity scattering at high temperatures. These two mechanisms are the dominant scattering mechanisms below 200 K, while polar-mode optical phonon scattering is the most significant process above this temperature. The low-concentration limit for room-temperature mobility in uncompensated InN is estimated to be $4400\,cm^2/(V\,s)$.

31.5.2 High Field Transport

Ensemble Monte Carlo simulations have been the popular tool to theoretically investigate the steady-state electron transport in nitrides. In particular, the steady-state velocity-field characteristics have been determined for AlN [31.271, 272], GaN [31.229, 271, 273–276], and InN [31.277, 278]. These reports show that the drift velocity initially increases with the applied electric field to reach a maximum and decreases with further increase in the field strength. The intervalley electron

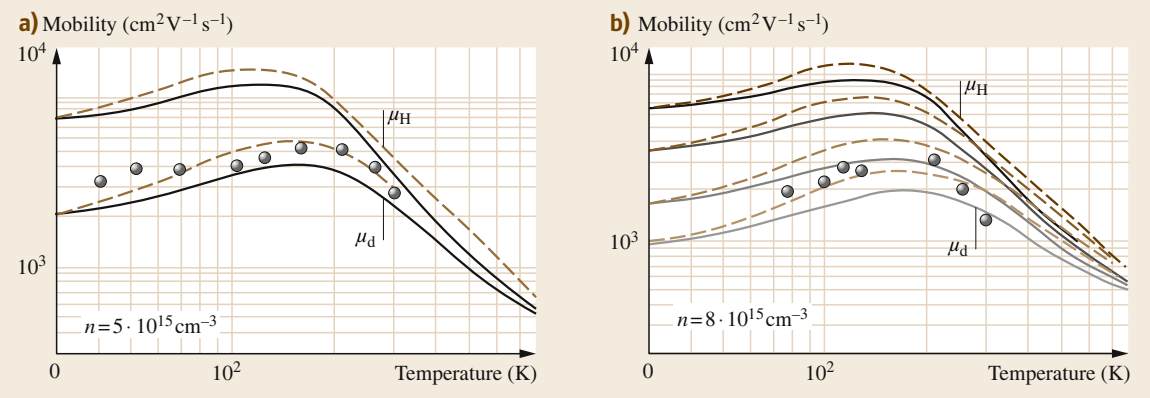

Fig. 31.15a,b The electron drift and Hall mobilities in InN as a function of temperature for **(a)** $n = 5 \times 10^{16}\,\mathrm{cm}^{-3}$ for compensation ratios of 0.00 and 0.60; and **(b)** $8 \times 10^{16}\,\mathrm{cm}^{-3}$ for compensation ratios of 0.00, 0.30, 0.60, and 0.75. (After [31.202])

transfer plays a dominant role at high electric fields leading to a strongly inverted electron distribution and to a large negative differential resistance (NDR). Note that credible experimental confirmation of intervalley scattering is still pending. The reduction in the drift velocities was attributed to transfer of electrons from the high-mobility Γ-valley to the low-mobility satellite X-valley. The onset electric field and peak drift velocities, however, show some disparity among the reported calculations due to the variety of the degree of approximation and used physical constants of the materials. A typical velocity-field characteristic for bulk group III nitrides at room temperature is shown in Fig. 31.16 along with the well-studied GaAs data used to test the author's Monte Carlo model. For the doping concentration set to $10^{17}\,\mathrm{cm}^{-3}$, InN has the highest steady-state peak drift velocity; $4.2 \times 10^7\,\mathrm{cm/s}$ at an electric field of 65 kV/cm. In the case of GaN and AlN, steady-state peak drift velocities are rather low and occur at larger electric fields; $2.9 \times 10^7\,\mathrm{cm/s}$ at 140 kV/cm for GaN and $1.7 \times 10^7\,\mathrm{cm/s}$ at 450 kV/cm for AlN.

Another interesting aspect of electron transport is its transient behavior, which is relevant to short channel devices with dimensions smaller than 0.2 μm where a significant overshoot is expected to occur in the electron velocity over the steady-state drift velocity. Transient electron transport and velocity overshoot in both wurtzite and zincblende GaN, InN, and AlN have been studied theoretically by a number of groups. *Foutz* et al. [31.279] employed both Monte Carlo simulations and one-dimensional energy-momentum balance techniques. They used a three-valley model for the conduction band by taking the main scattering mechanisms, such as ionized impurity, polar optical phonon, acoustic phonon through deformation potential and

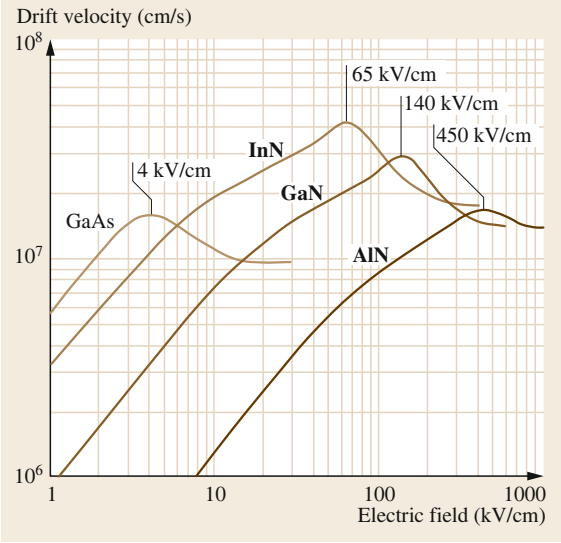

Fig. 31.16 The velocity-field characteristics associated with wurtzite GaN, InN, AlN, and zincblende GaAs. In all cases, the temperature was set to 300 K and the doping concentration was set to $10^{17}\,\mathrm{cm}^{-3}$. The critical fields at which the peak drift velocity is achieved for each velocity-field characteristic are clearly marked: 140 kV/cm for GaN, 65 kV/cm for InN, 450 kV/cm for AlN, and 4 kV/cm for GaAs. (After [31.279])

piezoelectric, and intervalley scatterings, into account. In particular, they examined how electrons, initially in equilibrium, respond to the instant application of a constant electric field. Figure 31.17 shows the average velocity of the electrons in AlN, GaN, and InN as a function of distance.

According to their calculation, electron velocity overshoot only occurs when the electric field exceeds

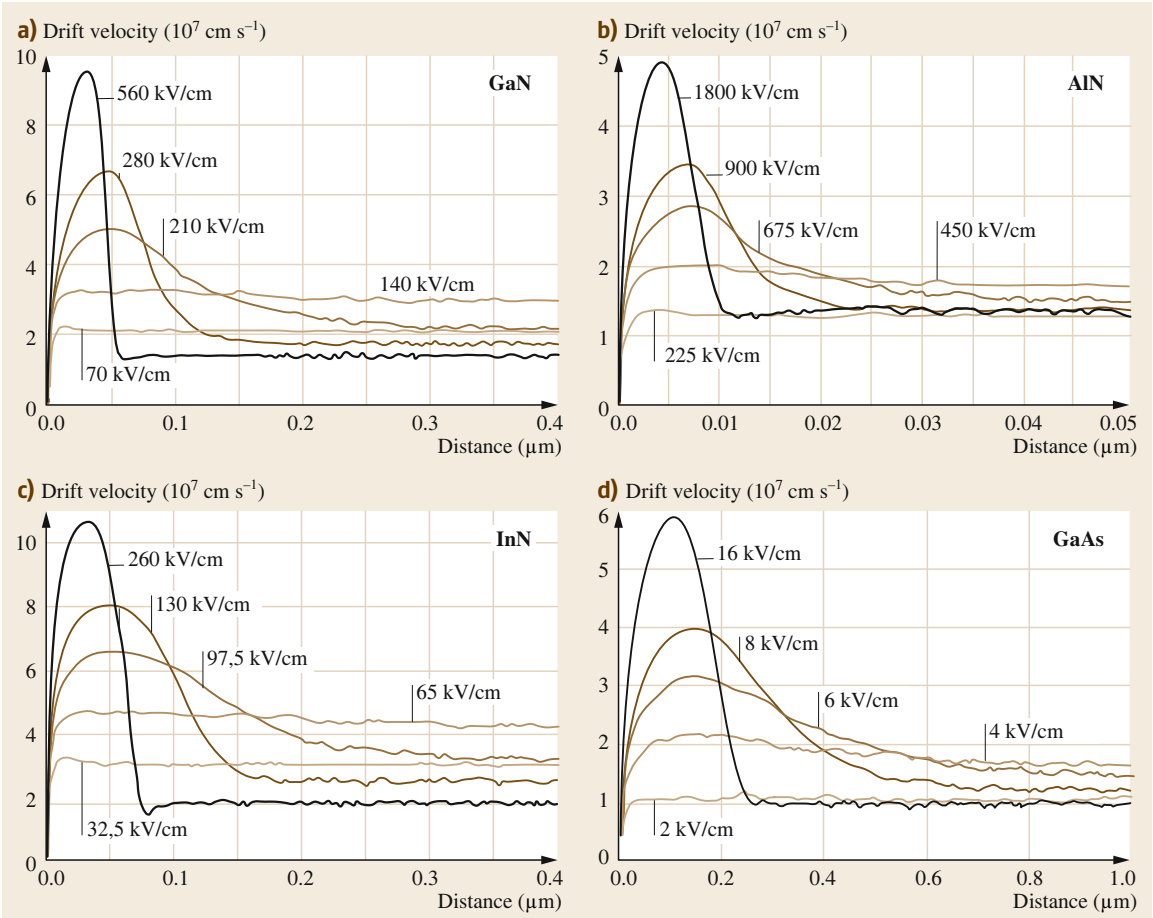

Fig. 31.17a–d The average electron velocity as a function of the displacement for various applied fields for the cases of **(a)** GaN, **(b)** InN, **(c)** AlN, and **(d)** GaAs. In all cases, we have assumed an initial zero-field electron distribution, a crystal temperature of 300 K, and a doping concentration of 10^{17} cm^{-3}. (After [31.279])

a certain critical value unique to each material and it lasts over a certain distance dependent on applied field. These critical fields are points where the highest steady-state peak drift velocities are achieved and being reported as 65, 140, and 450 kV/cm with corresponding peak velocities of 2.9×10^7, 1.7×10^7, and 1.6×10^7 cm/s for InN, GaN, and AlN respectively. Among them, InN exhibits the highest peak overshoot velocity on the order of 10^8 cm/s at 260 kV/cm and the longest overshoot relaxation distance on the order of 0.8 μm at 65 kV/cm. The variation of the velocity with respect to the field, not just the peak velocity, must be considered in our attempts to minimize the transit time. The upper bound for the cutoff frequency of InN- and GaN-based HFETs benefits from larger applied fields and accompanying large velocity overshoot when the gate length is less than 0.3 μm in GaN- and 0.6 μm in InN-based devices. However, all measured cutoff frequencies are gate-length-dependent and well below these expectations, indicating that devices operate in the steady-state regime and other effects, such as real-space transfer, should also be considered. On the other hand, there is some controversy in the reports related to the onset of velocity overshoot in nitride semiconductors. For example, *Rodrigues* et al. [31.280] reported overshoot onsets at 10 kV/cm in InN, 20 kV/cm in GaN, and 60 kV/cm in AlN by using a theoretical model based on a nonlinear quantum kinetic theory, which compares the relation between the carriers' relaxation rate of momentum and energy. Experimental investigations of the transient transport in group III nitrides are very limited and only a few results are reported by using different techniques. *Wraback* et al. [31.281] employed a femtosecond time-resolved electroabsorption technique to study the transient electron velocity overshoot for trans-

port in the AlGaN/GaN heterojunction p-i-n photodiode structures. It has been reported that electron velocity overshoot can be observable at electric fields as low as 105 kV/cm. The velocity overshoot increases with electric fields up to ≈ 320 kV/cm with a peak velocity of 7.25×10^7 cm/s relaxing within the first 0.2 ps after photoexcitation. The increase in electron transit time across the device and the decrease in peak velocity overshoot with increasing field beyond 320 kV/cm is attributed to a negative differential resistivity region of the steady-state velocity-field characteristic in this high field range. *Collazo* et al. [31.282] used another experimental technique based on the measurement of the energy distribution of electrons, which were extracted into a vacuum through a semitransparent Au electrode, after their transport through intrinsic AlN heteroepitaxial films using an electron spectrometer. They observed electron velocity overshoot as high as five times the saturation velocity and a transient length of less than 80 nm at the field of 510 kV/cm. In order to design an electronic device that is expected to operate at high power and high frequency, one could consider harnessing velocity overshoot in group III nitride semiconductor heterojunctions. However, the strong coupling between hot electrons and LO phonons appear to limit the velocity attainable by electrons, being dependent on the LO phonon decay time. A systematic investigation of InN, GaN, AlN and their alloys as a function of various parameters in dynamics mode would be very beneficial for the development of higher performance, next generation electronic and optoelectronic devices.

31.6 Optical Properties of Nitrides

The optical properties of a semiconductor have vital importance due to the wide range of useful information that can be obtained in our attempts to understand the semiconductor properties, especially the direct bandgap material for optoelectronic applications. For ideal defect-free semiconductors, the optical transitions occur between conduction band and valence band, including excitonic effects due to the Coulomb interaction, where excitons can be classified into free and bound varieties. For high-quality samples with low defect concentrations, the free excitons can also exhibit excited states in addition to their ground state. Bound excitons are those that are bound to dopants or defects, which usually create a discrete energy below the bandgap energy, and therefore influence the optical behavior of the excitons as well as optical absorption and emission. Excitons could be bound to neutral or charged donors and acceptors. It is generally assumed that the dominant coupling is of the like particles for principal bound exciton (BEs) states associating with neutral donors and acceptors [31.283]. For the case of shallow neutral donor-bound excitons (DBEs), the two electrons in the BE state are assumed to pair off into a two-electron state with zero spin, where the additional hole is assumed to be weakly bound in the net hole-attractive Coulomb potential set up by this bound two-electron aggregate. A similar scenario applies to acceptor-bound excitons (ABEs). The DBEs and ABEs are by far the most important cases for bound excitons in direct-bandgap materials, and thus attract intensive investigation. Various techniques can be used to investigate the optical properties of group III nitrides, and the most commonly used ones are optical absorption, transmission, photoreflection, photoluminescence, time-resolved photoluminescence, cathodeluminescence, calorimetric spectroscopy, pump-probe spectroscopy, and so on. This section will only summarize some important optical properties of group III nitride materials.

31.6.1 Gallium Nitride

Free Exciton in GaN

The conduction band (Γ_7^c) of wurtzite GaN is mainly constructed from the s state of gallium, while the valence band is mainly constructed from the p state of nitrogen. Due to the crystal-field and spin-orbit interactions, the valence band splits into three bands, namely the highest Γ_9^v (heavy hole), upper Γ_7^v (light hole), and lower Γ_7^v (crystal-field split band). The optical transitions between the conduction and valence bands are usually denoted as $\mathrm{A} \equiv \Gamma_7^c \leftrightarrow \Gamma_9^v$, $\mathrm{B} \equiv \Gamma_7^c \leftrightarrow \Gamma_7^v$ (the upper one), and $\mathrm{C} \equiv \Gamma_7^c \leftrightarrow \Gamma_7^v$ (the lower one), which have almost the same binding energy of around 25–26 meV [31.284]. For optical one-phonon processes, these three excitons of the wurtzite structure obey the following selection rules: for σ polarization ($E \| c$ and $k \perp c$ axis), C all excitons are allowed although C exciton is quite weak. For π polarization ($E \| c$ and $k \perp c$ axis), C exciton is strongly allowed and B exciton is weakly observable while A exciton is forbidden in this geometry. In the α polarization ($E \perp c$ and $k \| c$), all three transitions are clearly observable [31.285]. The A exciton consists of a two-fold degenerate spin-singlet state with Γ_5 symmetry and a two-fold degenerate spin-triplet state with Γ_6 symmetry. Both the B and C

excitons consist of a two-fold degenerate spin-singlet state with Γ_5 symmetry, a spin-triplet state with Γ_2 symmetry, and a mixed singlet-triplet state with Γ_1 symmetry. Among all the exciton states, only those with Γ_5 and Γ_1 symmetry are dipole-allowed and can be seen in reflectance or photoluminescence spectra, where the Γ_5 states are allowed for $E \perp c$ polarization while the Γ_1 states are allowed for $E \| c$ polarization. In order to reveal the fine structure of the exciton states, which have splitting on the order of 1–2 meV [31.286], the spectroscopic line width in optical spectra (such as photoluminescence) needs to be a fraction of an meV. The line width is determined by microscopic electric field and strain fields, which in practice requires single crystals with a low residual doping ($< 10^{16}\,\mathrm{cm}^{-3}$) and a low structural defect density ($\leq 10^{6}\,\mathrm{cm}^{-2}$). These requirements can only be achieved for nominally undoped freestanding GaN with a thickness of at least several hundred μm, which is not possible for most commonly available GaN grown on foreign substrates, such as sapphire, SiC or silicon. The commonly employed techniques for investigating the exciton properties are photoluminescence (PL), absorption, and/or derivative techniques like photoreflectance (PR) and calorimetric absorption and reflection techniques [31.287, 288], which are powerful techniques to determine the exciton binding energy, exciton Bohr radii, dielectric constant, and spin-orbit and crystal-field parameters with the aid of the quasicubic model.

There have been intensive studies on the emission properties of GaN during the last decade. The energy position, relative intensities, and linewidth of the emission peaks have been found to strongly depend on the residual strain, crystal line defects, and impurity incorporation, thus making the interpretation of the spectra in heteroepitaxial GaN layers rather difficult and even leading to confusing conclusions. With the availability of high-quality freestanding and homoepitaxial GaN layers, correct identifications of the emission peaks becomes possible. There are reports in the literature on the reflectance study for thick GaN epilayers [31.289–293] as well as homoepitaxial layers [31.294–298] and bulk GaN [31.58, 294, 299–303]. Studies by Monemar et al. on thin and thick GaN layers on various substrates, including homoepitaxial layers on GaN substrates, concludes that the A, B, and C excitons in GaN, with an accuracy of ±2 meV, are at 3.478, 3.484, and 3.502 eV respectively, at 2 K. These values are consistent with results obtained from freestanding or bulk GaN samples published in the literature as demonstrated in Table 31.7. An example of a reflectance spectrum obtained in the α polarization for a 2 μm-thick GaN epilayer on sapphire is displayed in Fig. 31.18, where the corresponding excitonic transition energies were

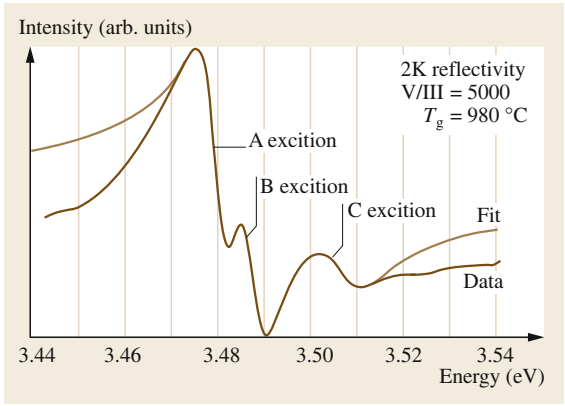

Fig. 31.18 Reflectance spectrum taken at 2 K for a 2 μm-thick GaN film grown on a sapphire substrate. The experimental data was fitted using a damped-oscillator theoretical model. (After [31.304])

evaluated using a classical damped-oscillator transition model [31.304].

Another powerful technique for studying the exciton structure is photoluminescence (PL), and Fig. 31.19 displays a typical PL spectrum taken at 2 K, which is dominated by donor-bound excitons, for an almost strain-free thick GaN epilayer grown on sapphire by HVPE. The free excitons appear at relatively higher energies, at their ground states as well as the $n = 2$ excited states of the A exciton [31.307]. The splitting between the A, B, and C exciton ground states, Δ_{AB} and Δ_{AC}, are (5.5 ± 0.1) and (22.0 ± 0.1) meV, which are close to recently reported values for quasibulk GaN samples grown by HVPE [31.303]. Based on the exciton energies, the crystal-field splitting and spin-orbit splitting of the top three valance bands were estimated to be $\Delta_{cr} = 20 \pm 2$ meV and $\Delta_{so} = 10 \pm 2$ meV respectively [31.288]. Other reported values are $\Delta_{cr} \approx \Delta_{so} \approx 16 \pm 2$ meV [31.240], and $\Delta_{cr} \approx 12.3 \pm 0.1$ meV and $\Delta_{so} \approx 18.5 \pm 0.1$ meV.

Another interesting feature of exciton lines is the fine structure near the band edge of GaN due to various splitting mechanisms. As mentioned earlier, the A, B, and C excitons have spin-related degenerate states. Based on experimental results as well as theoretical calculation, the following splittings have been reported [31.314]: $\Gamma_5(\mathrm{A}) - \Gamma_6(\mathrm{A}) = 0.53$ meV, $\Gamma_5(\mathrm{B}) - \Gamma_2(\mathrm{B}) = 0.4$ meV, $\Gamma_1(\mathrm{B}) - \Gamma_2(\mathrm{B}) = 0.41$ meV, $\Gamma_5(\mathrm{C}) - \Gamma_2(\mathrm{C}) = 0.23$ meV and $\Gamma_1(\mathrm{C}) - \Gamma_2(\mathrm{C}) = 0.75$ meV, where we can find out that the Γ_1 and Γ_1 states of the B exciton are almost degenerate with only 0.1 meV difference. For wavevector $k \perp c$, the long-range exchange interaction splits the spin-singlet states Γ_5 into a transverse and a longitudinal state. The longitudinal-transverse splitting of $\Gamma_5(\mathrm{A})$,

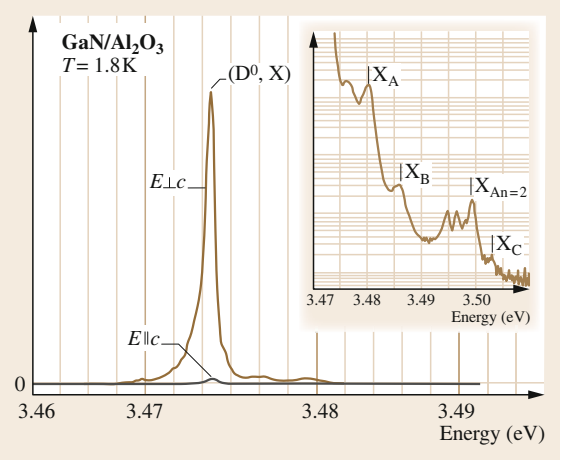

Fig. 31.19 Photoluminescence spectra at 1.8 K for a 400 µm-thick GaN grown on a sapphire substrate, where the spectrum is dominated by the donor-bound exciton transition. The intrinsic exciton states are resolvable after magnification as demonstrated in the *inset*. (After [31.313])

Γ_5(B) and Γ_5(C) states has been found to be 1.02, 0.85 and 0.34 meV respectively, in a homoepitaxial GaN layer [31.298].

Discrepancies on the reported results of free-exciton energies can be noted as indicated in Table 31.7, most of which is due to the in-plane strains induced by the foreign substrates. For most of the earlier studies of free excitons in GaN, the substrates used were either sapphire or SiC, thus inducing compressive or tensile strains respectively. When the strain is isotropic the crystal symmetry and correspondingly the symmetry of the exciton states are not changed. Instead, the strain will mix the states with different symmetry, modifying their energies and oscillator strengths [31.303]. For compressive strains, caused by for example sapphire, the bandgap, the three free-exciton energies, and the splittings, are blueshifted compared to that of unstrained GaN layers. The A and B free-exciton energies have been found to increase by as much as 20 meV at 2 K, while the C free-exciton energy increased about 50 meV [31.291]. An opposite trend was observed for tensile-strained GaN, which decreases the bandgap, overall exciton energies, and the splittings among the three exciton energies. The dependence of the free-exciton energies on the in-plane strains of GaN films is displayed in Fig. 31.20. A frequently cited set of free-exciton energies is 3.4776, 3.4827, and 3.5015 eV for the A, B, and C excitons respectively, as measured on ammonothermally grown bulk GaN [31.294].

The temperature dependence of free-exciton energies was also found to be dependent on the particular sample and strain as demonstrated in Fig. 31.21, where comparisons of temperature dependence were based on three samples: relaxed (bulk GaN), compressed (grown on sapphire), and under tension (grown on SiC). The temperature dependence of the excitonic resonance, in the absence of localization, can be described by the Varshni empirical relation

$$E(T) = E_0(0) - \frac{\alpha T^2}{(\beta + T)} , \qquad (31.16)$$

where $E_0(0)$ is the transition energy at 0 K, and α and β are the temperature coefficients.

Similar to other direct-bandgap semiconductors, the dipole-allowed exciton states in GaN encounter strong coupling with photons, which results in formation of a mixed-mode state (so called exciton-polariton) with

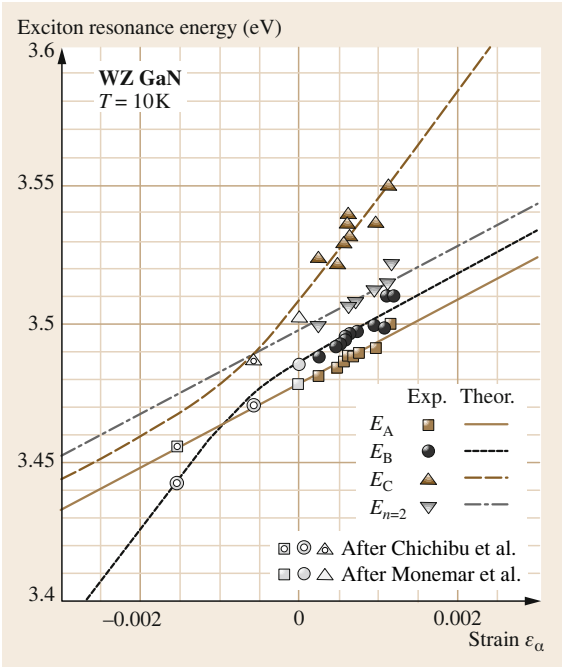

Fig. 31.20 Dependence of free-exciton energies on strain in wurtzite GaN grown on a sapphire substrate, where the strain values were obtained from measured lattice parameters. Also shown is the theoretical modeling of the strain dependence of exciton energies. (After [31.315])

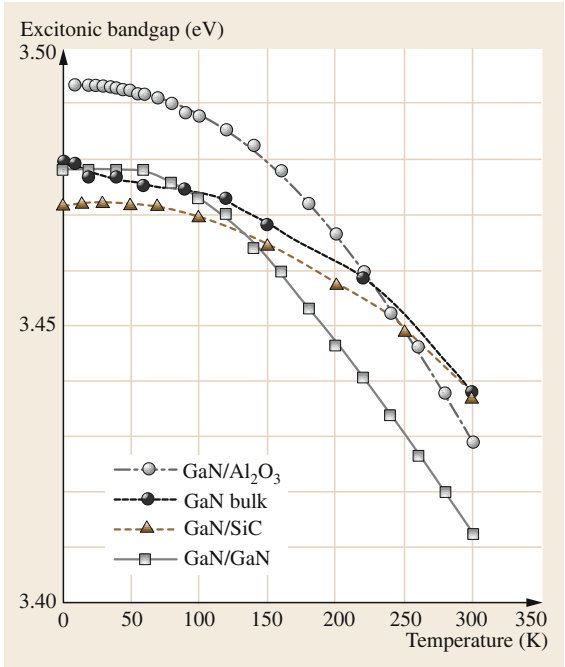

Fig. 31.21 Temperature dependence of the A free exciton energy in samples grown on different substrates. (After [31.297, 316])

a two-branch dispersion curve in the energy region near the intersection of the original exciton and photon dispersion curves [31.317]. The existence of the exciton-polariton has a profound effect on the optical emission in GaN, making the exciton recombination a propagation of polariton waves to the crystal surface and subsequent transmission to the outside as photons instead of transition from the exciton state to the photon state and subsequent photon propagation [31.318]. Thus, the emission line width does not reflect the inherent lifetime broadening of the free excitons. Instead, the emission peaks are usually quite broad and their line shapes are not exactly symmetric and are determined by the spectral dependence of the density of states, group velocity, and transmission coefficient of the different polariton branches [31.301]. Although it is difficult to study the emission of exciton-polaritons, the experimentally observed exciton-polariton spectrum is usually a doublet peak with a dip around the energy of the longitudinal exciton as demonstrated in heteroepitaxial [31.319], homoepitaxial [31.320], and freestanding GaN layers [31.321], where the doublet peaks were interpreted as an emission from the lower and upper polariton branches. An example of excitonic spectra taken at 4.2 K for homoepitaxial GaN layers is illustrated in Fig. 31.22, where the A exciton line splits into two components about 2 meV apart with the lowest component at about 3.477 eV.

Free-exciton transitions in wide-bandgap materials have a characteristic of coupling to phonons, which results in homogeneous broadening of the free-exciton states. At low temperatures, the coupling is dominated by exciton-acoustic phonon scattering, while at high temperatures the longitudinal-optical (LO) phonon Fröhlich scattering is dominant. The exciton line width is composed of three parts as [31.322]

$$\Gamma(T) = \Gamma_0 + \gamma_{\mathrm{ph}} T + \frac{\Gamma_{\mathrm{LO}}}{\left[\exp\left(\frac{E_{\mathrm{LO}}}{k_{\mathrm{B}}T}\right) - 1\right]} ,$$

where Γ_0 is the inhomogeneous line width due to the scattering by defects and impurities, and exciton-exciton interaction, γ_{ph} is the exciton-acoustic-phonon coupling strength, Γ_{LO} is the exciton-LO-phonon coupling strength, and E_{LO} is the energy of the LO-phonons involved in the scattering event (≈ 92 meV for GaN [31.323]). The temperature dependence of the line width has been investigated by many groups with various methods including absorption, PL, reflectance, spectroscopy ellipsometry, and four-wave mixing; however, the reported values have a large spread (varies between 10 and 25 meV) as summarized by *Zhang*

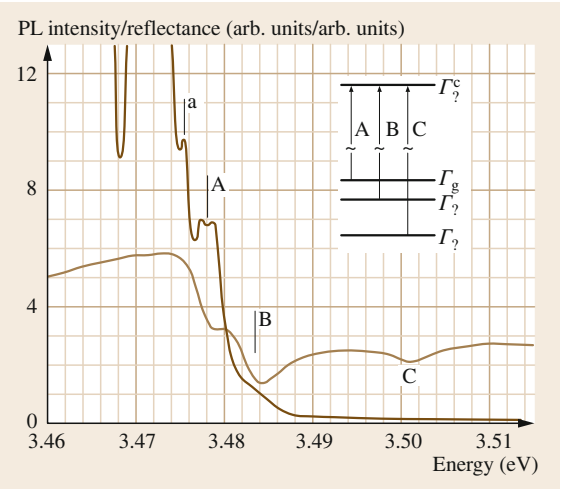

Fig. 31.22 Doublet structure of the A exciton as measured by photoluminescence (*darker line*) at 4.2 K for a homoepitaxial GaN layer. Also shown is the corresponding reflectance spectrum for the same sample (*lighter line*). (After [31.311])

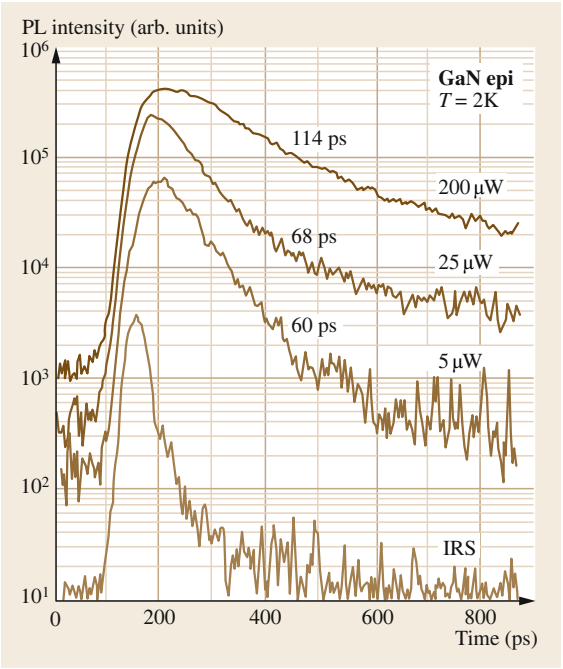

Fig. 31.23 Photoluminescence transients at 2 K for a GaN epilayer grown on sapphire, measured at different excitation power intensities. IRS denotes the instrumental response in the experiment. (After [31.288])

et al. [31.324]. The exciton-LO-phonon coupling is strongest for the first two replicas, and the 3-LO and 4-LO replicas are also clearly observable. As predicted by theory, the LO-phonon replicas are linearly proportional to the temperature, and this behavior is experimentally confirmed for the A exciton for temperatures below 100 K [31.325]. The line shape of the 1-LO and 2-LO replicas can be fitted to a good accuracy with $\approx E^{3/2}\exp(-E/k_BT)$ and $\approx E^{1/2}\exp(-E/k_BT)$ respectively, where E is the exciton kinetic energy and the exponential terms represent the equilibrium Maxwell distribution [31.326, p. 177].

The binding energies of the excitons determine the bandgap of the materials, which also denote the thermal stability of the excitons. There is large discrepancy on the binding energies of excitons in GaN, ranging from 18 to 26 meV as reviewed by [31.316], which was explained due to the strain in the studied layers or misinterpretations of some features in the optical spectra. The exciton binding energies can be obtained indirectly using temperature dependence of the free-exciton transition in PL [31.327] or the position of the excited states if the positions of the excited states of the excitons are known [31.328–330]. The temperature dependence of the excitons energies showed a monotonic shift to lower energies, which can be satisfactorily fitted by Varshni or Bose–Einstein formulas [31.331]. If exciton energies shift to higher energies, it is indicative of the transition from free-exciton to a band-to-band recombination. The survival of the free excitons at room temperature in GaN is supported by the exciton binding energies of around ≈ 25 meV for the A, B, and C excitons [31.298, 332]. This value is comparable to the thermal energy at room temperature ($k_BT = 25.8$ meV). Another fact that supports the presence of excitons at room temperature is that the exciton Bohr radius is very small (≈ 3.5 nm) and a high carrier density ($< 10^{18}$ cm^{-3}) is needed to screen the Coulomb interaction [31.303].

The transient behavior of free-exciton recombination in GaN can be investigated by time-resolved PL spectroscopy, while noting that PL transient of the free excitons is very complicated, partially due to the presence of exciton polaritons (EPs). The intrinsic lifetime of this EP was estimated to be about 300 ps (based on acoustic phonon scattering only) [31.333]. The much shorter lifetimes observed in experiments are most likely due to the nonradiative recombination in GaN. Typical transients are shown in Fig. 31.23, which were obtained for different excitation intensities for a GaN epilayer grown on sapphire. The decay time at 2 K was found to vary between 60 and 115 ps, which strongly indicates a contribution from defect-related nonradiative processes. Thus, the decay in luminescence is described by a combination of fast processes followed by a slower processes with a decay time of about 300 ps, although the free-exciton lifetime was estimated to be about 2 ns at low temperatures, deduced from the free-exciton

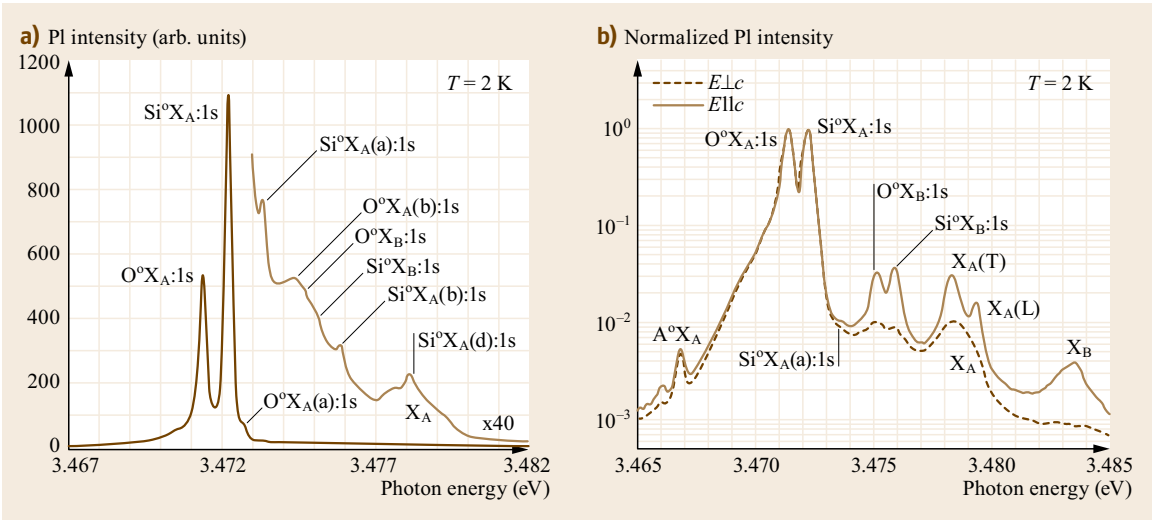

Fig. 31.24a,b PL spectra measured at 2 K for Ga-face bulk GaN for the following configurations: **(a)** α polarization ($k\|c, E\perp c$); **(b)** $\sigma(k\perp c, E\perp c)$ and $\pi(k\perp c, E\|c)$ polarizations. (After [31.303], courtesy of Dr. B. Monemar)

lifetime with two-photo spectroscopy on freestanding HVPE samples [31.334].

Bound Excitons in GaN

Due to the abundance of impurities in GaN, the neutral shallow donor-bound exciton is often dominant in optical spectra. For samples containing acceptors, the acceptor-bound exciton is also observable. Each donor, acceptor, or neutral defect typically is associated with a bound exciton. The recombination of bound excitons typically gives rise to sharp lines, and can easily be identified for each BE. The neutral donor BE is a four-particle complex with two electrons and one hole located around the positive impurity ion. For excited BEs, an electron will be excited into a series of exciton states, where the first excited state shifts away from the ground state by about three-quarters of the donor binding energy. If the hole in the neutral DBE is excited instead of an electron, this state is called a rotational states, which is quite weak in PL spectra, and is difficult to resolve unless selective excitation is used [31.335]. Oxygen and silicon are the two most dominant residual shallow donors in GaN, thus induce a series of oxygen- and silicon-related DBE states in PL spectra. An example of PL spectra for a bulk GaN sample featuring oxygen and silicon-related DBE states is displayed in Fig. 31.24.

The two dominant PL lines at 3.4714 and 3.4723 eV presented in Fig. 31.24 are believed to be due to the principal recombination of an A exciton bound to a neutral O donor on the N site and a neutral Si donor on the Ga site respectively [31.303]. Emission peaks at very similar energies of 3.4718 and 3.4755 eV were also reported in a high-quality MBE-grown GaN layer on a GaN substrate, where the two peaks are also believed to be associated with Si- and O-related shallow donor states [31.336]. Weak excited rotational states of the O and Si DBEs were observed as well at 3.4727 eV (O^0X_A(a):1s) and 3.4735 eV (Si^0X_A(a):1s) respectively. The energy separation between these lines and the correspondingly principal DBE lines are found to be consistent with previously reported values [31.335, 337]. For even the higher energy DBE region, the DBEs related to the B valence band come into the picture, where the major peaks at 3.4755 eV [31.336] or 3.4751 and 3.4759 eV [31.303, 335] were observed. The peaks at 3.4751 and 3.4759 eV were believed to correspond to O^0X_B:1s and Si^0X_B:1s respectively. These two peaks are more pronounced in the PL spectra measured in π ($k\perp c, E\|c$) polarization as demonstrated in Fig. 31.24. For a complete review of the commonly observed and reported peak positions and localization energies of DBE in GaN grown by various growth techniques on different substrates, readers can refer to *Viswanath*'s review [31.338, p. 63]. In addition to the emission lines discussed above, there also exist the so-called two-electron transitions (TETs) of the shallow DBEs in the PL spectra with energies ranging from 3.43 to 3.46 eV [31.303]. The origin of these PL lines is attributed to the neutral donor in the final state of the DBE recombination that remains in an excited donor state [31.339]. Strong O- and Si-related TETs pave the way for determining the associated donor binding energies, which are 33.2 ± 0.4 and 30.4 ± 0.4 meV for O and Si donors respectively. These values are quite close to results reported by *Reshchikov* et al. with binding energies of 32.6 and 28.8 meV for O and Si

donors respectively, as measured in MBE-grown GaN on a freestanding GaN template [31.340]. Similar values were also reported by *Moore* et al. [31.341].

Similar to the transient behavior of free excitons, the transient behavior of DBEs also showed a variety of surprising properties. The radiative decay time τ can be estimated from the so-called giant oscillator strength F_{DBE} as $\tau \approx 1/F_{\mathrm{DBE}}$ [31.342]. Experimentally, the radiative lifetime can be measured from the low-temperature decay rate associated with the DBE PL lines. For a thick HVPE-grown ($\approx 100\,\mu$m) GaN layer on sapphire with dislocation density of $10^7\,\mathrm{cm}^{-2}$, a low-intensity decay time of about 200 ps was observed at 2 K as demonstrated in Fig. 31.25, which is believed to be a typical radiative lifetime for DBEs associated with shallow neutral donors [31.343]. For a thinner layer with higher defect density, a shorter lifetime was observed [31.344, 345], probably due to the excitation transfer to defect states. For a homoepitaxial GaN layer, a fast DBE decay was also observed, due to excitation transfer to point defects [31.288]. Recently, PL decay of a DBE no-phonon line for an HVPE-grown thick GaN layer at low temperatures showed a nonexponential behavior with a fast initial slope (a decay time of about 300 ps), and a much slower tail towards longer times (a decay time of about 1000 ps or higher) [31.303]. It is believed that the initial fast decay time may not be the true decay time of DBEs. Instead, it may be due to other processes, such as surface recombination or optical dispersion in the semiconductor medium with exciton resonances accompanied by resonant light scattering at the neutral donors [31.346]. In order to eliminate the contribution from such processes, the DBE decay time was derived from the transient behavior of the LO replicas of DBE, which should reflect the actual density of BE states. Since the two LO phonon replicas of the O- and Si-related donors are not spectrally resolved, average decay times of about 1.3–1.4 ns were observed for the DBE LO replicas in a 1 mm-thick freestanding HVEP sample with a relatively low donor concentration of $\approx 8\times10^{15}\,\mathrm{cm}^{-3}$, which may represent a close approximation to the radiative decay time of the DBEs [31.303]. For a 300 μm-thick freestanding sample with a donor concentration of $\approx 5\times10^{16}\,\mathrm{cm}^{-3}$, a shorter decay time of ≈ 600 ps was recorded. Since two-electron transitions (TETs) also rely on the population of DBE states, the transient behavior of TETs was also used to estimate the decay time of DBEs, and a similar decay time was observed as compared to the decay time extracted from the transient behavior of LO replicas of the DBEs. An example of the transient behavior is presented in Fig. 31.26.

Acceptor-bound excitons in GaN are not as well understood as DBEs, and a major ABE1 line at 3.466 eV

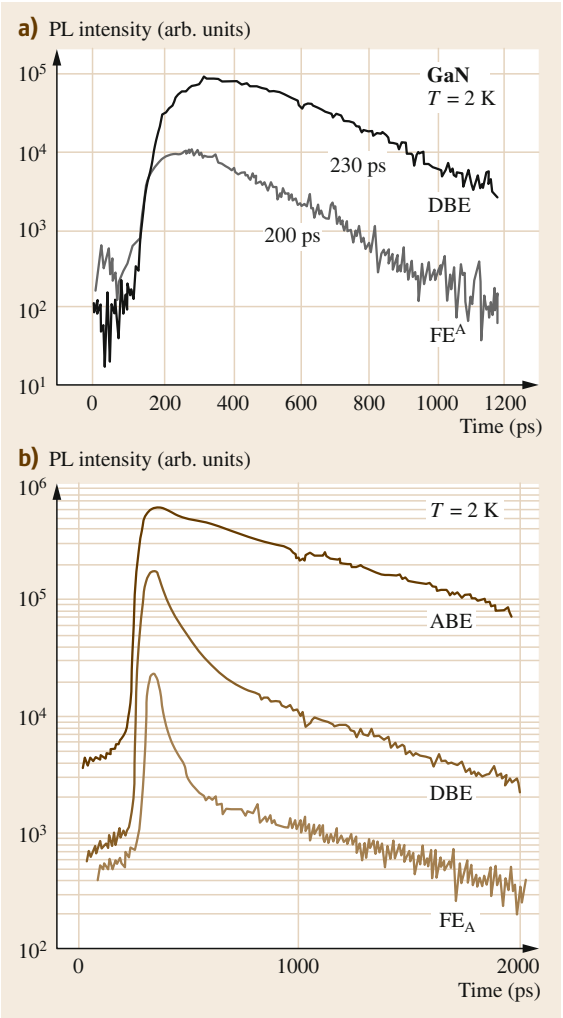

Fig. 31.25 Transient PL **(a)** for a 400 μm-thick GaN layer and **(b)** for a thin strained layer, of which both were grown on a sapphire substrate. (After [31.343])

was observed in strain-free GaN at 2 K [31.347–351], as demonstrated in Fig. 31.27. This peak has been found to be dominant in slightly Mg-doped GaN samples, thus a common assignment of this peak is $\mathrm{Mg_{Ga}}$. This ABE spectrum is stable for n-type or high resistivity materials. However, for p-type (Mg-doped) GaN the emission is clearly unstable and is quenched in a matter of minutes upon photoexcitation, indicating that the acceptor itself may not be stable under these conditions [31.352]. Contradictory evidence comes from the fact that this ABE line disappears in the cathodoluminescence (CL) spectrum under electron irradiation at low temperatures [31.352, 353]. However, one should keep in mind that electron irradiation has been proven to activate the Mg acceptor. Other proposed assignment

are: a different acceptor from the substitutional Mg_{Ga}, such as C_N [31.354], and charged donor-bound excitons [31.355–358]. Another broader peak at 3.455 eV (ABE2) has been attributed to Zn based on the fact that this line is close to the position of the dominant ABE observed in Zn-doped samples, if strain-induced shifts are considered [31.359]. However, this still needs further justification. Another tentative assignment for this peak is Mg_{Ga} acceptor due to the fact that the intensity of this broad ABE peak increases with Mg doping [31.360]. This naturally assumes that Mg doping does not facilitate any other process. Recently, both ABE1 and ABE2 lines were proposed to be caused by the Mg doping [31.361], with the ABE2 only observed in highly doped GaN:Mg, which suggest a possible correlation with structural defects, such as basal stacking faults (BSFs), induced by high-Mg doping [31.362]. It was proposed that the A1 acceptor (responsible for the ABE1 emission) will be perturbed by the nearby BSF potential and give rise to the A2 acceptor and its characteristic ABE2 spectrum [31.361]. Decay curves demonstrated the spectral shift of the PL signal from the ABE1 position to ABE2 position, mostly during the first 100 ps, which was interpreted as exciton transfer.

The broader peak at 3.44 eV is probably due to a low-energy acoustic-phonon wing connected to the main peak at 3.455 eV, which is a characteristic for ABEs [31.363, 364]. The decay curves for ABEs in GaN usually show a clean exponential shape as demonstrated in Fig. 31.25b. The radiative lifetime is about 0.7 ns for the shallowest ABE peaked at 3.466 eV, as compared to the much longer decay time of 3.6 ns for the deeper acceptors with an ABE peak in the range of 3.455–3.46 eV [31.348]. The decay time for

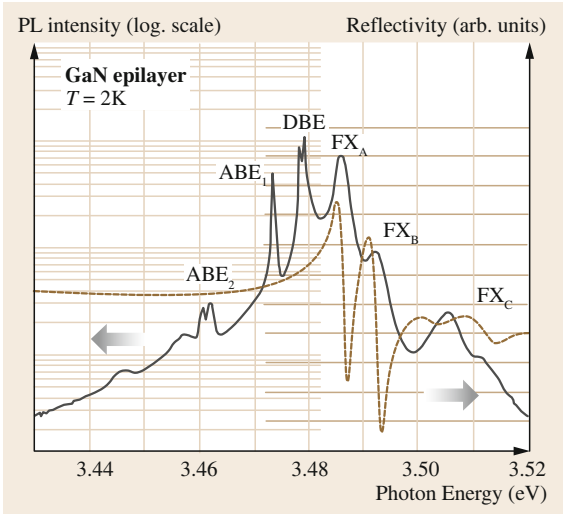

Fig. 31.27 Low-temperature PL spectrum (*solid line*) of a HVPE GaN layer shown on a semilog scale. The reflectivity spectrum (*dashed line*) of the same sample taken at normal incidence geometry is plotted on a linear scale. (After [31.343])

the 3.466 eV ABE peak varies for different samples, presumably due to a nonradiative contribution from excitation transfer effects [31.303].

Donor–Acceptor Transitions in GaN

Due to the various impurities and intrinsic defects, donors and acceptors usually coexist in the same semiconductor material. The electrons bound in the donor states can radiatively recombine with holes bound in the acceptor states, a process termed donor-acceptor

pair (DAP) transition. A commonly observed DAP peak in GaN is located at 3.27 eV, and well-resolved LO-phonon replicas at lower energies were also observed [31.285, 365, 366]. The emission peak is temperature dependent, which is indicative of the change from a DAP signature at low temperatures to a free-to-bound conduction-band-to-acceptor transition at higher temperatures (120 K). This is due to thermal ionization of the shallow donors ($E_D \approx 29$ meV), where an acceptor binding energy of 230 meV was obtained from the temperature-dependent measurements [31.340]. The acceptor responsible for this 3.27 eV DAP is generally believed to be due to the Mg_{Ga} acceptor. There are other interpretations, however, such as an Mg-H complex [31.367], but this interpretation implies that this peak will only be observable in p-type GaN, which is in conflict with the fact that this 3.27 DAP is also prominent in n-type GaN. Another DAP also exists in the blue PL band peaking at about 2.9 eV, which is strong only in MOCVD-grown GaN with high Mg doping. For the same material grown with MBE or HVPE, this blue PL peak does not appear, even though a similar concentration of Mg_{Ga} acceptor would be present. The identity of this blue PL peak is not clear yet, but suggestively it may be related to an H-related deep donor (binding energy 0.37 eV) and the shallow Mg acceptor [31.368, 369].

An interesting feature regarding the ABE as well as 3.27 eV DAP spectra is the long-term instability during prolonged excitation with above bandgap UV light, which was proposed to be due to the instability of the acceptor responsible for the ABE1 and 3.27 eV emission line [31.370]. Additional data suggest that the unstable acceptor might be the Mg-related acceptor as discussed above [31.361]. Short-term instability was also observed, which features a rapid degradation of the PL efficiency in the entire near-bandgap region, indicating a rapid nonradiative process induced by UV excitation. A downshift in energy of the 3.27 eV DAP peak was observed after long-term excitation, which means that the hole occupation of the Mg acceptor decreased [31.371, 372]. This can be explained as that the quasi-Fermi level is raised in the bandgap during the long-term excitation, which can be due to another deeper (nonradiative) defect level. During the recombination process, this deeper defect level is active and can capture photoexcited holes to a metastable state, which decreases the hole occupation in the Mg acceptor [31.361].

Defect-Related Transitions in GaN

Yellow Luminescence (YL). A broad PL band peaking at 2.2 ± 0.1 eV, the so-called yellow emission, has caused enormous debate regarding the nature of this peak for almost 30 years. This PL emission has been systematically observed in undoped or n-GaN [31.373, 374]. The activation energy (thermodynamic transition level) of the YL band was experimentally demonstrated to be 850 meV by fitting the temperature dependence of the YL intensity [31.375]. As studied extensively by *Ogino* and *Aoki* [31.376–379] there seems to be an agreement that this YL can be attributed to transitions from the conduction band or a shallow donor to a deep acceptor. Transition from a deep donor to a shallow acceptor was also proposed to explain the results of magnetic-resonance experiments [31.374]. Early works attributed the YL band to the V_{Ga}-C_{Ga} complex [31.376]. Theoretical calculation from density functional theory suggested that Ga vacancies, both isolated and bound into a complex with oxygen donors, are responsible for the observed YL [31.378, 379], which was supported by positron annihilation experiments, where the YL intensity was found to increase with the concentration of Ga vacancies. Other experimental findings indicated that lattice defects alone do not cause YL, rather its origin should be attributed to some impurities, possibly bound into complexes [31.380]. *Shalish* et al. [31.381] invoked a broad distribution of acceptor-like surface states to account for the YL band. The YL band was also found to shift to lower energies with decreasing energy of the below-gap excitation, which also indicates that the broadening of the YL band may be due to emission from several closely spaced traps [31.382]. More recently, carbon substituting for nitrogen C_N [31.383] and C_N-O_N [31.375] complexes were proposed to be responsible for the YL band by two different groups.

The transient behavior of the YL band has been investigated by several investigators, and a rather long and nonexponential decay in the range of $0.1-100\,\mu s$ at low temperature has been reported by *Hofmann* et al. [31.384] and *Korotkov* et al. [31.385] by using the Thomas–Hopfield model [31.371] of the donor-acceptor pair recombination. Similar work was also demonstrated by *Reshchikov* et al. [31.386] on freestanding high-quality GaN templates grown by HVPE, which concluded that, at temperatures below 40 K, the time decay of the yellow peak is nonexponential and can be explained in the framework of the Thomas–Hopfield model for DAP-type recombination involving shallow donors. For elevated temperatures, the decay becomes exponential with two components, suggesting transitions from the conduction band to two deep acceptors.

31.6.2 Aluminum Nitride

The optical properties of AlN have been investigated in many forms of it, including powders, sintered ce-

ramics, polycrystals, and single-crystal samples. Owing to the availability of large-size single-crystal bulk AlN in recent years, intensive studies on optical properties have been conducted. Because the AlN lattice has a very large affinity to oxygen dissolution, oxygen contamination is difficult to eliminate in AlN. AlN samples contaminated with 1–6% oxygen were found to have two broad emission peaks centered near 3.0 and 4.2 eV [31.387]. *Youngman* and *Harris* [31.388] and *Harris* et al. [31.389] found broad peaks centered at 2.7 and 3.8 eV in large single-crystal AlN with oxygen content of 380 ppm. However, *Strasburg* et al. [31.130] argued that oxygen alone is not able to generate such emission bands by comparing the obtained PL spectra with elemental analysis data obtained from glow discharge mass spectrometry (GDMS), where the emission intensities did not show a direct correlation to the oxygen concentration. GDMS analysis also revealed that in addition to O, Si and C were also present at concentrations that may have a significant influence on the luminescence properties of AlN. An absorption band around 265 nm (≈ 4.7 eV) was found to be more pronounced with the increase of the carbon concentration [31.51], and one possible origin of this absorption band is reported to be due to the substitution of C impurities on the nitrogen site (C_N), which becomes a deep acceptor in AlN [31.390]. Room-temperature PL spectra also showed that a peak at 3.9 eV only becomes prominent as long as the C concentration is much higher than the concentration of other impurities. This suggests a change in the compensation mechanism once the amount of C is not sufficient to act as the main acceptor [31.390], which is consistent with the assignment of C_N to a deep acceptor. However, in another report, the intensity ratios of deep CL bands at 4.6, 3.1 and 3.8 eV to the near-band-edge emission at 11 K were found to increase with V_{Al} concentration, where the V_{Al} concentration was detected from positron annihilation spectroscopy [31.391]. Another proposed origin for the 3.9 eV in the PL spectrum is due to a complex of an aluminum vacancy (V_{Al}) and an oxygen impurity on the N site (V_{Al}-O_N) [31.392]. Another 2.8 eV luminescence peak, whose intensity also increases with increasing carbon doping concentration, was observed even in HVPE-grown samples with relatively low concentrations of O and Si impurities, which reduces the concentration of V_{Al} by increasing the formation energy of V_{Al} [31.379]. One can then conclude that the deep emission around 2.8 eV may be either directly or indirectly related to C impurities [31.51].

The investigation of free-exciton energies has expanded considerably due to the availability of high-quality single-crystalline AlN layers, especially AlN bulk material. The majority of reported free-exciton energies of A are between 6.0–6.05 eV, depending on the strain state of the AlN material, while the free-exciton energies of B and C are difficult to fully resolve, but which would be in the range of 6.2–6.3 eV. A survey of the free-exciton energies is presented in Table 31.8. The free-exciton energy is strongly dependent on the biaxial strain of the AlN lattice, where the free-exciton energy is blueshifted in AlN/sapphire due to compressive strain and redshifted in AlN/SiC and AlN/Si due to tensile strain. A linear relationship between the free-exciton transition energy peak position and in-plane stress was obtained [31.393] with a linearity coefficient of 45 meV/GaP, which is about 88% higher than that in GaN (24 meV/GPa) [31.394]. The dependence of the free-exciton energies on the strain is demonstrated in Fig. 31.28 with four data points, including AlN/sapphire, AlN/AlN bulk, AlN/SiC, and AlN/Si. Based on the free-exciton energy of A and its first excited state, the AlN bandgap can be determined, and the reported values are 6.077 eV [31.395], 6.093(8) eV [31.396], 6.094 eV [31.397, 398], and 6.096 eV for unstrained bulk AlN at low temperatures [31.399]. The binding energy of free excitons can also be determined from the same technique, with reported values of 57 meV [31.400], 48 meV [31.395], 63 meV [31.401], 52.4 meV [31.397], 55 meV [31.402] and 51 meV [31.403] for FX(A). These reported binding energies are much larger than the thermal energy at room temperature, thus enabling one to clearly observe free-exciton luminescence at room temperature [31.404]. Based on a quasicubic model developed for the wurtzite crystal as well as other reported exper-

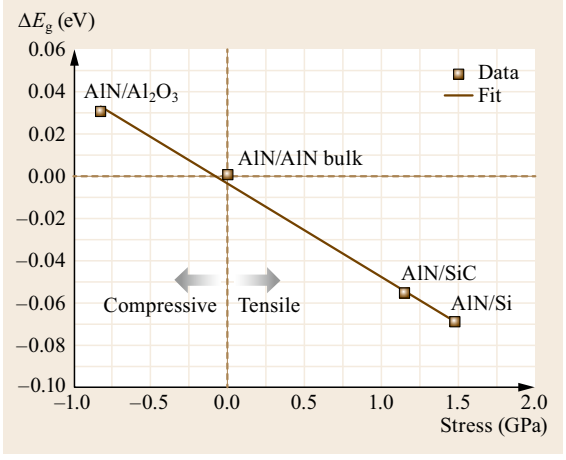

Fig. 31.28 Stress-induced shift of free-exciton energy in AlN epilayers as a function of the in-plane strain. The *solid line* is the least-square linear fit to the experimental data, where a value of 45 meV/GPa is obtained for the linear coefficient of stress-induced bandgap shift. (After [31.393])

imental exciton energy values, the AlN spin-orbit splitting and the crystal-field splitting were estimated to be $\delta = 36\,\text{meV}$ and $\Delta = 225\,\text{meV}$ respectively [31.395]. The obtained value for the crystal-field splitting is close to the value of 230 meV in unstrained AlN as reported earlier [31.399].

Due to the large free-exciton binding energy and strong oscillator strength, the excitons can stably exist at high excitation densities, enabling the study of the interaction between two or more excitons. This unique property can be characterized by the formation of biexcitons (excitonic molecules) and the inelastic scattering of excitons. Exciton-exciton scattering processes occur when, at high enough exciton densities, inelastic collisions of excitons occur. Following scattering, one exciton is scattered into a higher excited state while another decays with equal-energy loss. Excitons can not only be scattered into $n = 2$ state but also scattered to $n = 3 \ldots \infty$, where the number n is usually given as an index to distinguish the different scattering events therefore leading to P_2 to P_∞ bands. Note that under high excitation densities at room temperature, the electron-hole plasma (EHP) has been found to be the dominant recombination process in AlN [31.402]. Biexciton emission (also called the M band) has been observed in ELO-grown *a*-plane AlN epitaxial layers with an energy separation between free-exciton luminescence and biexciton luminescence of 19 meV, which is also the binding energy of biexcitons [31.400]. The PL plots of exciton and biexciton emissions at 7 K at different excitation densities are displayed in Fig. 31.29. By integrating the PL intensities of both the free-exciton line and the biexciton line for different excitation power densities, it was found out that the free-exciton line intensity grows almost linearly with the excitation power density (a power factor of 1) while the biexciton line intensity grows superlinearly with a power factor of around 1.5. This indicates that the biexciton density does not vary as the squares of the free-exciton density, which may be due to a relatively short recombination time of excitons and biexcitons in direct-bandgap semiconductors [31.405]. In the instant case, it may imply that the biexcitons have a shorter radiative lifetime than that of free excitons. Biexciton emission was also observed at a different energy, some 27 meV below the free-exciton emission in AlN layers grown on SiC and sapphire substrates [31.406]. In addition, another band was identified at 36 meV below the free A-exciton transition and was ascribed to the exciton-exciton scattering (P_2 band), which showed a power factor of 1.66 instead of 1.54 for the biexciton emission in the same report [31.406].

A few DBE emission lines have been reported as shown in Fig. 31.30, with D^0X occurring at 9.8, 13.3, 19.0, 22.5, and 28.5 meV below the free exciton X_A [31.396] in AlN layers grown homoepitaxially on AlN substrates, which were in turn grown by physi-

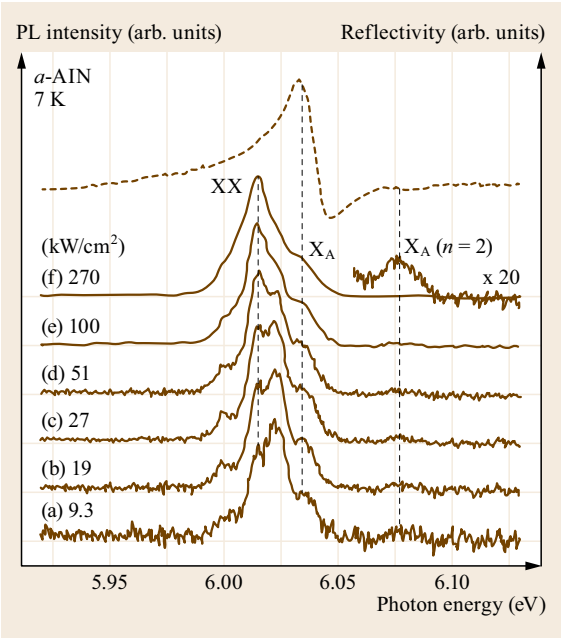

Fig. 31.29 Excitonic photoluminescence spectra (*solid lines*) at 7 K taken from an *a*-plane AlN epitaxial layer under different excitation-power densities ranging from 9.3 to 270 kW/cm^2. Each spectrum is normalized at the peak height. An optical reflectance spectrum is also demonstrated in the upper part by the *dashed line*. The symbol XX represents the biexciton. cal vapor transport. The tentative assignment of these emission lines to DBEs is based on the agreement with earlier reports, the temperature-dependent behavior of the emission bands, and their very narrow line widths (500 μV for the dominant line of 6.0125 eV in Fig. 31.30). The assignment to ABEs was discounted because, in analogy to GaN, the binding energies of common acceptors [31.366] are expected to be larger than those of donors [31.341]. With increasing silicon doping concentration from 1×10^{17} to $1\times10^{19}\,\mathrm{cm}^{-3}$, a clear increase in the intensity was observed for one single D^0X band with 28.5 meV exciton localization energy (located at 6.0125 eV) relative to the intensity of the free-exciton emission [31.396]. This assignment is in agreement with the available data for silicon in AlN, where the localization energy has been reported to be 24 meV [31.410], 22–29 meV [31.411], and 26 meV [31.412]. Based on the PL spectra, the donor binding energy of silicon in AlN was estimated to be 133 meV. The line width of this Si^0X line was broadened due to the increased Si doping, possibly due to the band filling as proposed earlier by *Yoshikawa* et al. [31.413] for silicon-doped GaN, and local potential fluctuations according to $\mathrm{FWHM} = E_0 + a\sqrt{N_{Si}}$ as reported by *Nam* et al. [31.412]. Additionally, Si doping also gave rise to a blue luminescence band at around 400 nm, which may be due to secondary defect creation processes or charge transfer due to higher silicon doping [31.396]. However, another report ascribed the DBE line with localization energy of 22.4 meV to the Si^0X line, most prominent in the sample having the highest silicon concentration, while other DBE lines remained unidentified and may be due to oxygen donors or intrinsic donors [31.397]. An ABE emission line due to an Mg acceptor was claimed to be observed in Mg-doped AlN epilayers at 6.02 eV at 10 K, which is about 40 meV below the free-exciton transition in undoped AlN epilayers [31.414]. The intensity of this ABE line is rather weak, which is about 40 times smaller than that of the free-exciton transition in undoped AlN epilayers.

Time-resolved PL measurement in 1 μm-thick AlN epilayers grown by MOCVD on sapphire substrates revealed that the recombination lifetimes were around 80 ps for DBE and 50 ps for free excitons [31.415]. For Mg-related ABE, the decay kinetics can be described by a single exponential with a decay lifetime constant of about 130 ps at 10 K [31.414]. In another report, time-resolved PL and CL were used to investigate the decay properties in AlN, and the excitonic radiative lifetime (τ_R) at 7 K was measured to be 10 ps, which increased up to 530 ps with increasing amount of impurities and V_{Al} concentrations, irrespective of the dislocation density [31.416]. It was found that radiative lifetime of excitons bound to neutral donors and *e-h* pairs bound in impurity-induced band-tails is much longer than for the intrinsic free excitons.

The temperature dependence of the optical bandgap of AlN has been investigated by a few groups with consistent results. As reported by *Guo* and *Yoshida* [31.417], the bandgap energy increases linearly from room temperature down to about 150 K with a temperature coefficient of 0.55 meV/K. Similar temperature behavior was reported by *Kuokstis* et al. [31.418] for single-crystal *c*-plane AlN with a temperature coefficient of 0.53 meV/K between 150 and 300 K. These two reports are close to each other and also close to the value of 0.51 meV/K reported by *Tang* et al. [31.419]. For temperatures below 150 K, it

was found that for all the measurements a new structure starts to form, where the bandgap does not change linearly with temperature and has a very small temperature coefficient, which is unusual for semiconductors.

31.6.3 Indium Nitride

InN is not as well understood compared to other group III nitrides. Due to the large background electron concentration as well as the relatively low crystalline quality, the excitonic features, neither in the absorption spectra nor in the band-edge photoluminescence spectra, have been observed. Many early efforts determined the bandgap to be in the range of 1.7–2.07 eV [31.421–423]. One widely cited bandgap value for InN was 1.89 eV obtained by *Transley* and *Foley* [31.424]. This value was also often used as an end-point value to interpret experimentally measured composition dependence of the bandgap of InN alloys [31.425]. With improved growth techniques for InN, a strong luminescence transition at energies around 1 eV appeared [31.426–428], which led to a sudden revision of the bandgap down to about 0.7 eV [31.429]. The sudden revision for the bandgap of InN came from the observation of an absorption edge at about 0.7 eV at low temperatures for moderately n-type samples (about $10^{18}\,\mathrm{cm}^{-3}$) [31.430, 431] and the value blueshifts for higher doping [31.427, 432, 433]. *Thakur* et al. [31.434] investigated the optical-absorption spectra of InN thin films with electron densities varying from $\approx 10^{17}$ to $\approx 10^{21}\,\mathrm{cm}^{-3}$. The optical-absorption edge was found to increase from 0.61 to 1.90 eV as the electron density of the film is increased from low to high density. Shifting of the optical-absorption edge is due to a corresponding up-shift of the Fermi level in the conduction band (the so-called Burstein–Moss shift). By subtracting the influence of self-energies and chemical potential from the optical-absorption edge energy, the intrinsic bandgap values were estimated to be ≈ 0.59 eV for the film with lowest carrier density, and ≈ 0.60 to ≈ 0.68 eV for the film with highest carrier density, where the dispersion was attributed to the variation in the electron effective mass and static dielectric constant. However, care must be taken to interpret the carrier density values obtained from the Hall measurements due to the presence of surface electron accumulation for InN [31.435–437] and due to a gradient in defect properties across the film [31.438].

Due to the fact that, in many highly doped samples, the main absorption edge occurs at much higher energies while the PL peak remains at about 0.7–0.8 eV [31.432, 439, 440], an alternative model of this absorption edge as being of extrinsic origin has been suggested in the literature [31.440–442], which ascribed the absorption edge to a deep level to conduction band transition. The value of the absorption coefficient at about 0.5 eV above the absorption edge was measured experimentally to be about $3\times10^{4}\,\mathrm{cm}^{-1}$ (within a factor of two) [31.443], which is a typical value for a direct band-to-band transition. In order for the deep level model to be consistent with the large absorption coefficient measured, the deep donor concentration was estimated to be close to $10^{20}\,\mathrm{cm}^{-3}$ [31.443]. In addition, this concentration has to be the same within

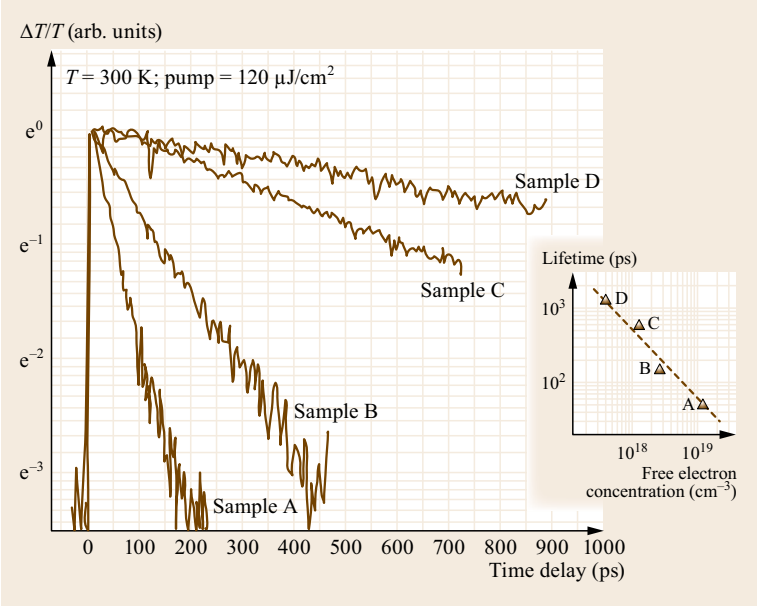

Fig. 31.31 Strength of the differential transmission signal versus time delay under a pump fluence of $120\,\mu\mathrm{J/cm}^2$ at room temperature. The *inset* shows the carrier lifetime as a function of free-electron concentration. (After [31.420], courtesy of Dr. A.N. Cartwright)

a factor of two in all samples studied, which appears implausible and no such deep level could be identified from SIMS data in the highest quality samples studied [31.270, 444]. Besides the optical measurement of absorption edge and direct band nature, the PL signal was found to depend linearly on the excitation laser intensity over a wide intensity range from 10 to 200 mW, indicating that the observed nonsaturable PL peak is due to the emission associated with the direct band-to-band recombination rather than the band-to-defect (or impurity) deep emission [31.445].

Ultrafast differential transmission measurements have been conducted on a series of InN epilayers to determine the carrier lifetimes [31.420], where a fast initial hot carrier cooling followed by a slow recombination process after pulse excitation was observed. The carrier lifetime was measured to be ranging from 48 ps to 1.3 ns, and an inverse proportionality between the carrier lifetime and the free-electron concentration was observed as demonstrated in Fig. 31.31. The ultrafast recombination was assigned to be due to nonradiative recombination related to defects or impurities, which was confirmed by the fact that the defect-related nonradiative lifetime, depending on the defect density, is independent of photogenerated carrier density. The carrier lifetimes were measured as a function of photogenerated carrier density by varying the pump fluence from 60 to 480 $\mu J/cm^2$, the decay curve was observed to remain as a single exponential and there was no observable change in the carrier lifetime.

The temperature dependence of the bandgap of InN has been studied by a few groups [31.421, 446], where a bandgap temperature coefficient of $1.3-1.8\times 10^{-4}$ eV/K was demonstrated near room temperature by using $E_g\ (300\,\mathrm{K}) = 1.89$ eV. For more recent InN samples with a ≈ 0.7 eV bandgap, a small blueshift (nearly linear at 0.1 meV/K) was observed with increasing temperature in the peak energy position [31.430]; although redshift of the peak energy position was also observed with increasing temperature [31.447]. The PL peak broadened with increasing temperature, which may indicate that longitudinal-acoustic phonon scattering dominates the emission broadening process in the InN samples studied [31.447].

31.7 Properties of Nitride Alloys

Many important applications of GaN-based devices require alloying GaN with other group III nitride materials to form, for example, AlGaN, InGaN, AlInN, and even AlInGaN. Ternary alloys of wurtzite polytypes of GaN, AlN, and InN have been obtained continuously whose direct bandgap ranges from ≈ 0.7 eV for InN to 6 eV for AlN. Many material as well as device properties, such as bandgap, effective mass of electrons and holes, and the dielectric constant, depend on the alloy composition. The lattice constants $a(x)$ and $c(x)$ of the wurtzite group III nitride alloys $A_xB_{1-x}N$ ($Al_xGa_{1-x}N$, $In_xGa_{1-x}N$ and $Al_xIn_{1-x}N$) are predicted to follow composition-weighted averages between the end-binary compounds AN and BN (Vegard's law) [31.55], which was confirmed within 2% error over the whole range of possible compositions between theoretical calculations and experimental measurements by a combination of techniques, such as HRXRD, Rutherford and elastic recoil detection analysis [31.63, 448, 449]. However, for pseudomorphic Al-rich $Al_xIn_{1-x}N$ films, the large present strain in the film was found to cause the dispersion between the In contents determined by XRD and RBS, suggesting a strain-driven deviation of the lattice parameters from the Vegard's rule in this case [31.450]. In fact, many materials' properties have been shown to deviate from Vegard's rule, such as the direct bandgap, polarization charge, and so on. The optical bandgap of ternary alloys can be predicted by the following empirical expression

$$E_g(A_xB_{1-x}N) = xE_g(AN) + (1-x)E_g(BN) - x(1-x)b\,, \tag{31.17}$$

where $E_g(AN)$ and $E_g(BN)$ are the optical bandgaps of material AN and BN respectively, and x and b are the AN molar fraction and bowing parameter respectively. For the case of $Al_xGa_{1-x}N$, this empirical equation has been determined to be [31.451]

$$E^g_{AlGaN}(x) = [6.0\,x + 3.42\,(1-x) - 1.0\,x(1-x)]\ \mathrm{eV}\,. \tag{31.18}$$

The above equation can be obtained by simultaneously determining the bandgap and alloy composition precisely. The alloy composition can be obtained from XRD or Rutherford back-scattering (RBS) or both. The bandgap can be determined by optical reflectance and absorption measurements. A plot of the bandgap versus the Al composition is given in Fig. 31.32, where a bowing parameter of 1.0 eV was obtained with a least-square fitting of the data to (31.17). The XRD peak positions as well as the peaks in optical measurement

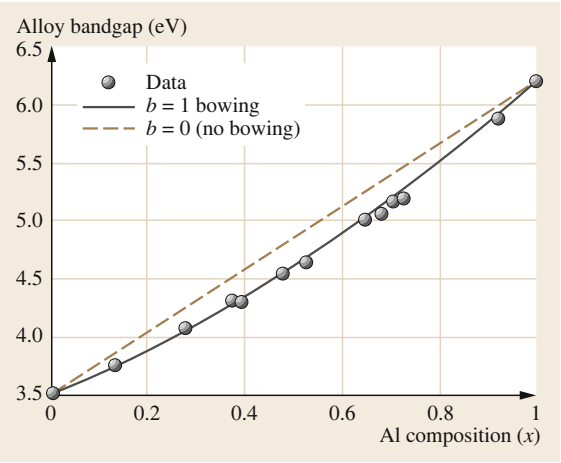

Fig. 31.32 Experimental data for the energy bandgap of AlGaN plotted as a function of Al composition in the whole Al composition range (*solid circle*). The *solid line* is a least-square fit, which gives a bowing parameter of $b = 1.0\,\text{eV}$. The *dashed line* represents the case of zero bowing parameter. (After [31.451])

techniques can be significantly affected by the material crystalline quality and purity, and thus can potentially influence the bowing parameter obtained. Temperature- and composition-dependent bandgaps of $Al_xGa_{1-x}N$ alloys were investigated in the temperature range between 10 and 800 K, where the temperature dependence of the bandgaps at each different composition can be fitted to the Varshini equation yielding the Varshini coefficients [31.452].

The optical properties of Ga-rich $Al_xGa_{1-x}N$ ($x =$ 0.019, 0.038, 0.057, 0.077, and 0.092) alloys in the form of epilayers have been investigated by temperature-dependent PL and time-resolved PL spectroscopy [31.453]. Thermal quenching was observed with two activation energies, which were attributed to the delocalization of excitons and thermal dissociation of excitons. The localization energy increased as the 1.7th power of the PL line width, which reflected a broadening of the density of localized exciton states. Additionally, the luminescence decay of the localized excitons for the five epilayers studied became longer with decreasing emission energy, indicating that the decay of excitons is caused not only by radiative recombination, but also by transfer to lower energy states.

As far as the electrical and doping properties are concerned, there exist several reports of n-type doping of AlGaN with various Al compositions. Hall measurement for n-$Al_{0.09}Ga_{0.91}N$ demonstrated a carrier concentration of $5\times10^{18}\,\text{cm}^{-3}$ and a mobility of $35\,\text{cm}^2/(\text{V s})$ at room temperature [31.454]. A 1.8 μm-thick Si-doped $Al_{0.3}Ga_{0.7}N$ was grown on sapphire by using a superlattice buffer layer that demonstrated a mobility of $80\,\text{cm}^2/(\text{V s})$ and a carrier concentration of $3\times10^{18}\,\text{cm}^{-3}$ at room temperature [31.455]. Crack-free $Al_{0.75}Ga_{0.25}N$ layers with electron concentrations as high as $1\times10^{18}\,\text{cm}^{-3}$ were also demonstrated with Hall mobility of about $50\,\text{cm}^2/(\text{V s})$ at room temperature [31.456]. Highly conductive n-type $Al_xGa_{1-x}N$ ($x = 0.7$) films have been achieved with resistivity as low as 8 mΩ cm (electron concentration $n = 2.6\times10^{19}\,\text{cm}^{-3}$ and mobility $\mu = 30\,\text{cm}^2/(\text{V s})$) for a Si-doping concentration of $3.5\times10^{19}\,\text{cm}^{-3}$ [31.457]. The resistivity was found to increase by one order of magnitude when the Al composition increased by 8%, which is due to the deepening of the Si donor energy level with increasing Al composition, and possibly increasing electron trap density. The Si donor activation energy was estimated to vary from 23 to 180 meV as Al composition was increased from 0.7 to 1.0 [31.457]. A similar trend was also observed that demonstrated that the activation energy of the Si donor increases linearly from 0.02 eV in GaN to 0.32 eV in AlN [31.458]. It should be noted that 23 meV is smaller than the well-established binding energy for dilute GaN, which means that the above-mentioned values represent somewhat screened figures. p-Type doping of the AlGaN alloy was achieved by Mg doping as in the case of GaN. The hole mobility in Mg-doped p-$Al_{0.08}Ga_{0.92}N$ was found to decrease with increasing temperature, reaching a value of about $9\,\text{cm}^2/(\text{V s})$ for a doping density of $1.48\times10^{19}\,\text{cm}^{-3}$, where the low mobility was ascribed to a high carrier concentration and the intergrain scattering present in the samples [31.459]. The Mg doping and resistivity correlation in AlGaN was also investigated [31.460]. In this particular study, the undoped AlGaN layer is highly resistive with resistivity of larger than $10^7\,\Omega\,\text{cm}$, which decreased to $10^3\,\Omega\,\text{cm}$ after doping to a Mg chemical concentration of $2\times10^{19}\,\text{cm}^{-3}$. When the Mg level reached $3.5\times10^{19}\,\text{cm}^{-3}$, the resistivity reduced to $10\,\Omega\,\text{cm}$ with corresponding hole concentration of $2.2\times10^{17}\,\text{cm}^{-3}$ and mobility of $2.7\,\text{cm}^2/(\text{V s})$. Resistivity values increased by several orders of magnitude for Mg concentrations beyond mid-$10^{19}\,\text{cm}^{-3}$ due to generation of structural defects, such as inversion domains and stacking faults, caused by Mg in the lattice. These issues will certainly influence the performance of devices, such as lasers, which depend critically on the overall device series resistance including the p-type AlGaN material. Another issue that needs to be considered for optimum device performance is the thermal conductivity of the $Al_xGa_{1-x}N$ alloy, which demonstrated strong reduction of the thermal conductivity due to even a small portion of alien atoms in host materials [31.461]. The thermal conductivity decreases with increasing Al composition and reaches the minimum

at $x = 0.5$; however, the largest reduction of the thermal conductivity took place when either the Al or Ga composition fell in the band from $x = 1.0$ to 0.9, indicating that profound phonon scattering was induced by even a small portion of alien atoms in host materials. The reduction was observed over a wide temperature range from about 10 to 800 K, but was more sensitive at temperatures higher than 200 K, suggesting that the point-defect and phonon-phonon scattering are the dominant phonon relaxation processes.

The InGaN alloy is used mostly for quantum wells in the active regions of LEDs and lasers, which can emit in the violet or blue wavelength range but can be extended to green. Although high efficiency blue and green LEDs utilizing InGaN active layers are commercially available, this technology might suffer from the phase segregation and other inhomogeneities due to the large disparity between Ga and In, making the determination of the bandgap of InGaN versus composition difficult. Extensive theoretical and experimental studies have been carried out to determine the value of the bowing parameter, which requires the precise information of strain, phase separation and inhomogeneities in InGaN grown by various techniques and on various substrates. Bowing parameter values ranging from 1 to 6 eV have been reported, a summary of which can be found in [31.462]. Considering using either ≈ 1.9 or ≈ 0.8 eV bandgap for InN to fit the experimental results, two bowing factors can be obtained as demonstrated in Fig. 31.33 with bowing parameter of $b = 1.43$ eV for the 0.77 eV bandgap for InN and $b = 2.63$ eV for the 1.9 eV bandgap for InN.

The incorporation of indium in growing InGaN alloys was found to increase with decreasing temperature [31.463–465]. For samples grown at high temperature ($T \geq 750\,^{\circ}$C), prominent near-band-edge emission was observed, while for samples grown at low temperatures ($T \geq 700\,^{\circ}$C), a deep level or impurity transition was found to be dominant [31.465], which can significantly deteriorate the quality of the InGaN material. *Kumakura* et al. [31.466] investigated the electrical properties of Mg-doped InGaN grown by MOCVD with an indium composition smaller than 0.2. The activation energy E_A of the Mg acceptors in InGaN was found to decrease with the increase of the indium content, leading to higher hole concentration at room temperature for higher indium composition within the studied mole fraction range ($x > 0.2$). This phenomenon is consistent with other group III nitride semiconductors, which demonstrated that activation energy increases with energy gap [31.459, 467]. Another report also investigated the p-type doping in $In_xGa_{1-x}N$ alloys grown by MOCVD on semi-insulating *c*-GaN/sapphire templates [31.468]. p-Type layers were achieved for indium composition up to 0.35. The hole concentration was found to continuously increase from 2×10^{17} cm^{-3} for $x = 0$ (GaN) to 5×10^{18} cm^{-3} for $x = 0.22$, while the hole mobility was found to decrease from 15 to 1.8 cm^2/(V s) as x increased from 0 to 0.35. The reduction in hole concentration in p-type $In_xGa_{1-x}N$ with $x > 0.22$ was attributed to the effect of hole compensation by background electrons, which may be due to the defects generated during low-temperature growth, a condition necessary for growing higher indium composition InGaN. The presence of high background electron concentration, most likely due to the low growth temperature, is suggested as the main obstacle for obtaining p-type conductivity in InGaN with indium composition larger than 0.35. The Mg-acceptor level was estimated

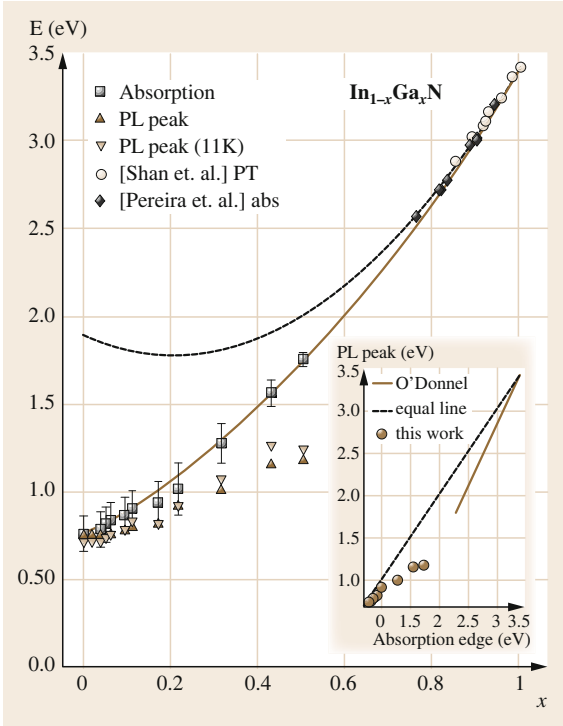

Fig. 31.33 PL peak energy and bandgap determined by optical absorption as a function of composition, including the previously reported data for the Ga-rich end of the ternary, which is not affected by the large InN bandgap previously used. The *solid curve* shows the fit to the bandgap energies using an InN bandgap of 0.77 eV and a bowing parameter of $b = 1.43$ eV. The *dashed line* is the fit to the bandgap energies on the Ga-rich side assuming a bandgap of 1.9 eV for InN. The *inset* shows the PL peak energy plotted against absorption edge energy, where the *solid line* is a least-square fit to experimental data on the Ga-rich side and the *dashed straight line* shows the relationship when the Stokes shift is zero. (After [31.428])

to be about 43 meV for Mg-doped $In_{0.35}Ga_{0.65}N$ alloys, which is roughly four times smaller than that in Mg-doped GaN [31.468]. A room-temperature resistivity as low as 0.4 Ω cm was obtained with a hole concentration of $\approx 5\times10^{18}\,cm^{-3}$ and hole mobility of $\approx 3\,cm^2/(V\,s)$ in Mg-doped $In_{0.22}Ga_{0.78}N$. The PL intensity associated with the Mg-related emission line was found to decrease exponentially with indium composition, which may be related to the incorporation of impurities. As stated above, higher temperature is preferred for growing high-quality InGaN while lower growth temperature is required for growing higher indium composition InGaN; thus it may be concluded that the major challenge for obtaining high-quality InGaN is to find a compromise value for the growth temperature.

The $In_{1-x}Al_xN$ alloy is also an important compound that can be grown lattice-matched to GaN, low-fraction AlGaN and InGaN. Due to their large spontaneous polarization, lattice-matched InAlN/GaN-based HFETs achieve significantly larger two-dimensional electrogas (2DEG) densities and consequently large current densities [31.469]. Owing to the high-index-contrast as well as possible lattice-matching between AlInN and GaN, high-quality AlInN/GaN multipair distributed Bragg reflectors have been achieved [31.470]. The bandgap of AlInN versus the Al composition has been investigated intensively; however, no consensus has been achieved for the bowing parameter due to complexities associated with the precise determination of the composition in AlInN alloys. By adopting a bandgap of ≈ 1.95 eV for InN, which is widely believed to be incorrect, a bowing parameter of 5.4 eV was obtained [31.471]. As mentioned earlier, precise information on the bandgap and alloy composition should be obtained for a fit to determine the bowing parameter. By considering the complications of the band structure of In-rich InAlN, including the Burstein–Moss shift, the nonparabolic conduction band, and the softening of the absorption edge, bandgaps of $In_{1-x}Al_xN$ with $x = 0.017–0.60$ were extracted from optical absorption data [31.472]. As demonstrated in Fig. 31.34, with 0.7 eV for the bandgap of InN, the bowing parameter was calculated to be 4.7 eV, which is reasonably close to the value of 4.96 eV obtained in [31.473]. Also noted is that the value of the bowing parameter is found to be sensitive to the bandgap used for AlN as well as whether the composition is determined from RBS or XRD measurements as a divergence was found between these two measurement techniques [31.450].

Similar to the case of InGaN, the indium incorporation in AlInN strongly depends on the growth temperature [31.474]. In-rich InAlN requires lower growth temperatures; however, lower growth temperatures reduce the AlInN crystalline quality and deteriorate the surface morphology. Transport data for InAlN are extremely scarce. The carrier concentration and the mobility of $In_{1-x}Al_xN$ for $x = 0.04$ were reported as $2\times10^{20}\,cm^{-3}$ and $35\,cm^2/(V\,s)$ respectively, and $8\times10^{19}\,cm^{-3}$ and $2\,cm^2/(V\,s)$ for $x = 0.25$ respectively [31.475]. Room-temperature resistivity and Hall measurements were conducted on In-rich and Al-rich AlInN layers respectively [31.476]. For In-rich AlInN with indium composition of 0.55 and 0.67, the electron concentration n is around 2×10^{19} and $1\times10^{20}\,cm^{-3}$ with associated mobilities around 5 and $7\,cm^2/(V\,s)$ respectively. The Al-rich films showed much higher resistivity, namely $\rho \approx 10^4$ and 10^8 Ω cm for Al composition of 0.66 and 0.72 respectively. These results are consistent with the trend that the mobility decreases substantially with an increasing Al mole fraction and increases with increasing In mole fraction, a close analogy to the parent compounds AlN and InN.

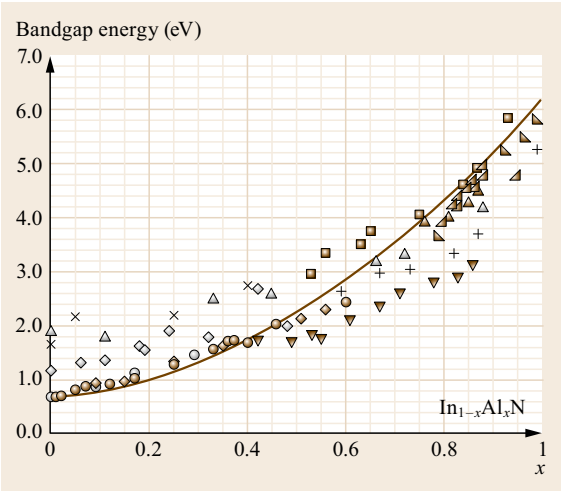

Fig. 31.34 Bandgap energies reported in the literature. A bowing parameter of 4.7 eV was obtained from the fitted *solid curve* with data. (After [31.472], courtesy of Dr. W. Walukiewicz)

By alloying InN with GaN and AlN, the bandgap of the resulting alloy(s) can be expand from the bandgap of InN to that of AlN, which is from 1.9 eV (or ≈ 0.7 eV if we use the recently determined InN bandgap) to a value of 6.0 eV. The benefits of utilizing this quaternary alloy are that: (i) the bandgap of this quaternary can be changed while keeping the lattice constant matched to GaN [31.477, 478]; (ii) an independent control over interface polarization charges and bandgaps is possible, which can result in more uniform carrier distribution among quantum wells while maintaining sufficient electron confinement [31.479, 480]. The InGaN/GaN-based multiquantum wells have been extensively utilized for LED lighting; however, due to the

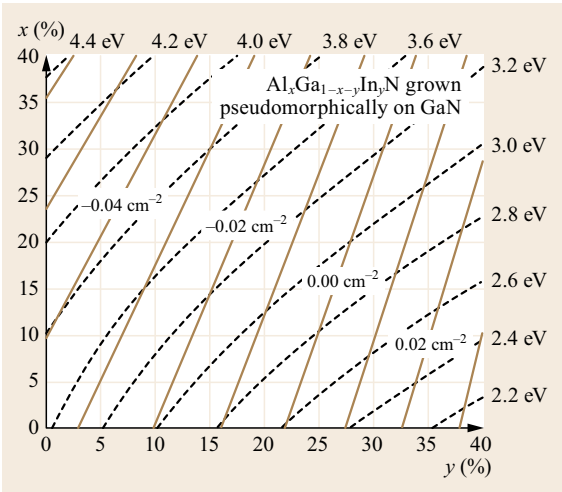

Fig. 31.35 Ga-face polarization charge (*brown*) and bandgap (*black dashed*) contours of quaternary $Al_xGa_{1-x-y}In_yN$ grown pseudomorphically on GaN substrates. (After [31.450], courtesy of Dr. E. Fred Schubert)

polarization charges at the InGaN/GaN interface, the electrons and holes in the quantum wells are separated at two ends of each quantum well due to the polarization charge (mainly of piezoelectric origin) induced electric field, which results in reduced electron-hole overlap and thus radiative recombination. Thus, the radiative recombination would depend on the quantum well width since different well widths result in different electric fields inside the well if all other parameters are fixed, which is the case for InGaN/GaN quantum well structures [31.481]. By utilizing unstrained quantum well layers with quaternary barriers, no emission energy dependence on width was observed due to the elimination of the piezoelectric field. By growing polarization-matched AlGaInN/InGaN LEDs, significant improvements have been achieved in terms of reduced forward voltage, reduced efficiency droop, and improved light-output power at large currents compared to conventional InGaN/GaN LEDs [31.480].

The bandgap and polarization charge versus the In and Al compositions have been calculated for AlGaInN as shown in Fig. 31.35, which clearly demonstrate independent control over the polarization charge and bandgap. However, among other difficulties brought about by the four-component systems, the optimal growth temperature is important to optimize and control, as Al-based compounds generally require higher growth temperatures, while In-based compounds require lower temperatures. Hence, the growth temperature will therefore govern the limits of In and Al incorporation into the AlGaInN quaternary alloy [31.478]. *Ryu* et al. [31.482] reported on optical emission in this quaternary system and AlInGaN/AlInGaN multiple quantum wells grown by pulsed metalorganic chemical-vapor deposition. A strong blueshift with excitation intensity was observed in both the quaternary layers and quantum wells, which was attributed to localization. This would imply that the structures are of inhomogeneous nature and/or presence of band-tail states indicative or early stages of material development and/or serious technological problems.

31.8 Doped GaN

Controlled doping in a broad range of concentrations in wide-bandgap semiconductors is very challenging for p-type varieties, as has been pointed out, for example, by *Walukiewicz* [31.483]. Simple substitution of elements such as C, Si, and Ge on the Ga sites and O, S, and Se on the N sites can potentially form shallow donors in GaN. Simple substitution of elements, such as Be, Mg, Ca, Zn, and Cd on the Ga sites and C, Si, and Ge on the N sites have the potential of forming relatively shallow acceptors in GaN. In practice, however, GaN n-type is achieved by using Si, Ge, and Se, the latter being not that common. On the other hand for p-type GaN only Mg has been successful but the level of hole concentration that can be achieved hit a ceiling of about $10^{18}\,cm^{-3}$.

Electronic and optoelectronic applications require n-type and p-type semiconductors. Even for high-quality GaN, grown by the many different processes (MBE, CVD, and HVPE), is unintentionally n-type doped, a phenomenon that is attributed to native defects (i. e., points defects, dislocation, stacking fault, V_N, antisites) and impurities (i. e., C, O, H) in GaN. Many potential p-type dopants attempted for incorporation into GaN cannot effectively compensate electrons in GaN and lead to p-type GaN. Hence, formation of p-type GaN is not straightforward. On the other hand, n-type doping of GaN is accomplished without major complications. This means that GaN p-type doping is the bottleneck to taking full advantage of the potential of GaN, especially in applications where both n-type GaN and p-type GaN are required, such as in optoelectronics.

The precursors, carrier gas, growth conditions, substrate material, among others, define the incorporation of impurities and imperfections in the crystal that result in the generation of defect-induced free carriers. De-

spite many decades of improvements in GaN technology, the residual electron concentration hovers around $1\times10^{16}\,\mathrm{cm}^{-3}$. Unintentional impurities imply lack of control, which is undesirable. In the following subsections a succinct description of GaN n-type and p-type doping is presented. A detailed treatment of the topic can be found in [31.1].

31.8.1 n-Type Doping

In unintentional GaN samples with a low n-type background, n-type doped GaN with Si is a very well-founded practice for both MBE and MOCVD techniques [31.484]. Controllability of electron concentration $\approx 10^{17}$ to $2\times10^{19}\,\mathrm{cm}^{-3}$ by varying the SiH_4 flow rate in MOCVD growth is possible [31.455]. With GeH_4 an order of magnitude higher electron concentration beyond what is feasible by Si is possible [31.485]. The Si ionization energy level in GaN is about 30 meV (dilution limit) and decreases as the doping level increases due to screening (see, e.g., [31.2, Chap. 5] for details). PL measurements in average-quality GaN yield a binding energy value of 22 meV [31.224]. Measurements on high-quality GaN layers grown on freestanding GaN wafers indicate (as determined by magneto-optical studies [31.486] and detailed analysis of the two-electron satellite transitions [31.487]) a binding energy of 30.18 meV.

Owing to the high solubility of Si ($10^{20}\,\mathrm{cm}^{-3}$) in GaN, Si is suitable for group III nitride doping and it is the most frequently used. Carrier concentrations in Si-doped GaN in the range 10^{17}–$10^{19}\,\mathrm{cm}^{-3}$ were observed, when silane (SiH_4) (used as an Si precursor) molar flow was varied 100 times. Also, Ge doping is well behaved. Ge solubility in GaN is in the range of 10^{17} to $10^{19}\,\mathrm{cm}^{-3}$ when germane (GeH_4) (used as Ge precursor) molar flow was varied 100 times in MOCVD growth. Ge doping has produced materials with electron concentrations of 7×10^{16}–$10^{19}\,\mathrm{cm}^{-3}$. More recently, *Wieneke* et al. [31.488] reported electron concentrations above $10^{20}\,\mathrm{cm}^{-3}$ in nonpolar *a*-plane GaN epilayers grown by MOVPE on *r*-plane sapphire substrates using isobutylgermane (IBGe) as a Ge precursor. A linear electron concentration versus molar flow relationship for both SiH_4 and GeH_4 precursors was observed [31.218, 489]. However, Ge incorporation is less efficient (by one order of magnitude) than Si incorporation.

31.8.2 p-Type Doping

As noted above, p-type doping in wide bandgap semiconductors is challenging and elusive, and nitrides are no exception. p-Type GaN, for the fabrication of p-n junction LEDs, was first achieved by *Akasaki* and *Amano* [31.490] in MOVPE-grown Mg-doped GaN. Doping activation was attained on Mg-doped GaN via low-energy electron-beam irradiation (LEEBI) treatment. The Hall measurement data showed a hole concentration of $\approx 2\times10^{16}\,\mathrm{cm}^{-3}$ with a mobility of $\approx 8\,\mathrm{cm}^2/(\mathrm{V\,s})$ and a resistivity of $\approx 35\,\Omega\,\mathrm{cm}$ at room temperature. *Nakamura* et al., with the same process that Amano used, obtained a hole concentration of $3\times10^{18}\,\mathrm{cm}^3$, a mobility of $9\,\mathrm{cm}^2/(\mathrm{V\,s})$, and a resistivity of $0.2\,\Omega\,\mathrm{cm}$ at room temperature [31.491]. Soon thereafter, *Nakamura* et al. [31.492] developed a doping activation technique based on N_2-ambient thermal annealing at temperatures above 700 °C. After the thermal treatment, the resistivity of Mg-doped GaN films dropped from 1×10^6 to $2\,\Omega\,\mathrm{cm}$ and the hole concentration and mobility were $3\times10^{17}\,\mathrm{cm}^{-3}$ and $10\,\mathrm{cm}^2/(\mathrm{V\,s})$ [31.492]. Nowadays, thermal activation is one of the most widely used techniques to active Mg in GaN. The thermal process is reversible with the GaN reverting to an insulating compensated state when annealed under NH_3, where the decomposed hydrogen from NH_3 was thus considered as the critical compensating agent during the annealing process under the NH_3 atmosphere.

A great deal of effort has been addressed to p-dope GaN and its ternaries by incorporating group II and group IV elements. So far, no other dopant has been as successful as Mg in converting GaN, AlGaN, and InGaN, with low Al and In mole fractions, to p-type materials. Needless to say, p-type doping in GaN and its ternaries remains a topic of interest both in terms of technological aspects and also at the fundamental level. In the case of the chemical vapor phase epitaxy technique [31.493], CCp_2Mg and MCp_2Mg are utilized for the source of Mg. Experimental results indicate CCp_2Mg is less volatile and its incorporation in GaN is more efficient at high temperatures, where a better GaN quality compared with the quality of GaN grown at lower temperatures is attained. Mg concentrations in p-type GaN films may be extremely high: $\approx 1\%$ of the host species. When substitutionally incorporated, only about 1% of the Mg atoms are ionized in GaN.

In Mg-doped GaN grown by MOCVD, the concentration of free holes at room temperature reaches its maximum value of about $10^{18}\,\mathrm{cm}^{-3}$ for a Mg chemical concentration of about $3\times10^{19}\,\mathrm{cm}^{-3}$, and it decreases with further increase of Mg concentration [31.494]. The activation energy of Mg acceptors in GaN and $Al_xGa_{1-x}N$ is in the range of 160–200 meV, which is larger than k_BT at 300 K and increases with Al fraction [31.495–499]. As a result, low conductivity of holes in p-type GaN and p-type $Al_xGa_{1-x}N$ is observed, degrading the performance of light emitters.

Because of the relevance of GaN-based optoelectronic devices, studies conducted to better understand the process and realize highly conductive p-type GaN and AlGaN are in demand, especially for the case of high Al-composition p-type AlGaN. Results on Mg-doped p-type $Al_xGa_{1-x}N$ with low Al content $0 < x < 0.27$ are available in [31.459, 500–502]. An activation energy as high as 310 meV was reported in [31.502] for $x = 0.27$. Demonstration of p-type conductivity in Mg-doped $Al_xGa_{1-x}N$ ($x = 0.35$) epilayers was reported by *Yu* et al. [31.503]. The influence of growth conditions on p-type conductivity was also investigated. The authors found that a proper V/III ratio and a relatively high growth rate were needed to improve the electrical characteristics of the p-type AlGaN epilayers. As a result of optimized growth conditions, a p-type resistivity of 3.5 Ω cm and a hole concentration of $> 5 \times 10^{17}\,\mathrm{cm}^{-3}$ were attained.

Unlike layers grown by MOCVD, MBE-grown p-type GaN layers do not require postgrowth annealing, neither employing activated nitrogen nor employing ammonia as the nitrogen source [31.504]. Mg-doped GaN layers grown by RMBE with ammonia as the nitrogen source exhibit p-type conductivity without any postgrowth treatment [31.496], which is very advantageous. In the case of GaN growth by MBE, Mg incorporation depends on the stoichiometry, the polarity of the growing surface [31.505, 506], the substrate temperature, and the growth rate [31.507–509].

Codoping for Improving p-Type Conductivity

As mentioned above, p-type GaN is challenging and low resistivity is difficult to achieve. One of the reasons is the compensation effect due to the low solubility and the low activation rate owing to the deep energy level of the acceptor. The acceptor energy level is very deep (about a few hundred meV) relative to room temperature (≈ 25 meV), for instance, GaN:Mg (200 meV) and AlN:C (500 meV). A 500 meV-deep acceptor if activated would yield one hole for every 10^6 acceptors at room temperature. To attain low-resistivity in wide bandgap semiconductors, the solubility of dopants should be increased while their compensation avoided. Also, the activation rate of the carriers and their mobility should be increased by reducing the energy level of the acceptors and the scattering rate of the carriers. As a response to mitigate the aforementioned concerns an interesting and promising method called codoping was proposed [31.510]. The codoping method is based on the idea that both n and p-type dopants are provided simultaneously under thermal nonequilibrium crystal growth conditions during MBE or MOCVD. The theoretical foundation of the codoping method was provided by *Reiss* et al. [31.511] [31.512] during the early stages of Si and Ge development using solution theory. Codoping can result in an enhancement of equilibrium solubility of the dopants (problematic for p-type impurities in GaN), low ionization energies, and also might affect the carrier mobility. All the above-mentioned benefits are relevant to GaN. Experimental results on codoping in GaN and in AlGaN are reported in [31.513–517] and [31.513, 518] respectively.

The hole concentration was observed to be enhanced in p-type GaN:Mg codoped with oxygen donors wherein the hole concentration increased linearly from 8×10^{16} to $2 \times 10^{18}\,\mathrm{cm}^{-3}$ with increasing oxygen dopant partial pressure. An increment of 3–5 times in the hole concentration resulted for a fixed oxygen partial pressure during growth of p-type GaN:Mg. Unlike the theoretical predictions, for reduced formation energy/increased solubility, when Si was codoped with GaN:Mg, the hole concentration remained constant [31.510].

Use of Superlattices for Improving p-Type Conductivity

Another promising method to get higher acceptor activation and lower resistivity is by using $Al_xGa_{1-x}N$/GaN doped superlattices [31.519–521]. The idea of using AlGaN/GaN heterojunctions for enhancement of p-type doping has been proposed as a technique to increase the average hole concentration [31.521–523]. Increased hole concentrations at room temperature through the use of AlGaN/GaN superlattices have been reported in the literature [31.524–526]. The mechanism for hole enhancement is the periodic oscillation of the valence band edge. Acceptors are ionized where the band edge is far below the Fermi energy and the resulting holes accumulate where the band edge is close to the Fermi level, forming a confined sheet of carriers. Although the free carriers are separated into parallel sheets, their spatially averaged density will be much higher than in a simple bulk film. High electric fields due to both spontaneous and piezoelectric polarization within the strained AlGaN layers strongly impact the band bending within the superlattice. The fields created by the superlattice/carriers exhibit sawtooth variation in the band diagram. The hole concentration expected from an AlGaN/GaN superlattice was calculated in [31.523].

The spatially averaged measured hole concentration and mobility for the Mg-doped $Al_{0.2}Ga_{0.8}N$/GaN superlattices with equal thickness, L, of the GaN and AlGaN layers (superlattice period $2L$) exhibit approximately constant mobility of $10\,\mathrm{cm}^2/(\mathrm{V\,s})$ for $2\,\mathrm{nm} < L < 14\,\mathrm{nm}$ and an average hole concentration which peaks at $2 \times 10^{18}\,\mathrm{cm}^{-3}$ for $L \approx 8\,\mathrm{nm}$. Further improvements of the p-type conductivity of the lattice were obtained by minimizing the ionized and neutral impurity scattering mechanisms via doping that maximize the separation of

the dopants (ionized scattering centers) from the multiple two-dimensional hole gas (2DHG) sheets.

Samples incorporating modulation-doped (MD) and shifted-modulation-doped (SMD) superlattices have been shown to have superior electrical properties compared to uniformly doped (UD) samples, especially at low temperatures [31.525].

After all the efforts invested to achieve high-p-type doping levels in GaN and AlGaN, the maximum attainable doping level is still a limitation for optoelectronic devices, particularly for shorter wavelength devices such as solar-blind ($\approx 290\,\mathrm{nm}$) detectors, UV LEDs, LDs and even visible LEDs, which need p-type AlGaN with high-Al composition and large hole concentration for efficiency retention. For example, a UV LED using an AlGaN p-n junction with an emission wavelength shorter than 290 nm can only give submilliwatt or milliwatt power [31.527].

31.9 Defects in GaN

Regardless of the degree of perfection of the material, defects are always present in semiconductors, particularly during the early stages of development. In fact, defects in complex semiconductors may never be fully solved [31.528]. By having to be grown on nonnative substrates due to the prohibitively expensive bulk material, GaN layers exhibit a wide variety of defects. Extended defects, such as threading dislocations and staking faults, and intrinsic defects, such as point defects and vacancies, among many others (for an in-depth discussion on defects the reader is encouraged to read [31.2]), may coexist in GaN eptaxial layers. In order to improve the quality of the layers a good deal of effort still is devoted to attaining material perfection via heteroepitaxy. However, after decades of research and investigations, both extended and intrinsic defects are still present to varying degrees. Nevertheless, defect densities have been reduced to a level where the realization of commercial devices based on GaN is feasible.

In what follows we center our discussion on two different kinds of defects. Because of their importance in the determination of electrical properties, we address the intrinsic point defects followed by staking fault defects, which is particularly important in nonpolar GaN for optoelectronic applications.

31.9.1 Points Defects

The importance of intrinsic point defects in nitrides is due to their role in determining the electrical and optical properties of the material, as well as their influence on the material behavior in various processing steps such as ion implantation and thermal annealing. Point defects are created in semiconductor materials during growth, where their formation is governed by thermodynamics and growth kinetics. Because GaN is unintentionally n-type, it is assumed that an acceptor-like defect is ionized and negatively charged as the Fermi level is close to the conduction band. Then, the important question is what is the source of these negative charges? To answer this question we need to take into account two factors in our analysis, namely the effect of incorporated impurities and charged defects. Both entities may behave like n or p donors. In GaN, point defects are identified as nitrogen vacancy (V_N), gallium vacancy (V_{Ga}) and Ga interstitial. A large variety of analysis tools have been used to study point defects and their impact on GaN physical properties. Some of the utilized techniques are photoluminescence (introduced already in Sect. 31.6), deep-level transient spectroscopy, minority carrier lifetime measurements, positron annihilation, electron paramagnetic resonance (EPR), and optically detected magnetic resonance (ODMR).

Deep-level transient spectroscopy (DLTS) [31.529, 530] is a popular method to get insight into electrical characteristics of point defects; both donor- or acceptor-like traps. The drawback of DLTS is its incapability to give local information or the chemical nature of the defect centers. These shortcomings can be alleviated to some extent if DLTS studies are realized in conjunction with systematic studies, such as irradiation damage and measurements in a pressure cell. Even though DTLS is a mature method, the characteristics of defects as analyzed by DLTS for GaN are widely scattered. A large dispersion in the basic reported parameters of the defects in GaN hide their genesis and nature. As many as eight point defects active in DLTS, some of which may be the same due to the aforementioned dispersion, have been reported in n-type GaN, and only one in p-type GaN.

GaN samples prepared by OMVPE on sapphire substrates have been investigated by DLTS by several groups [31.531–533]. Typical defect states are termed as E1, E2, E3, E4, and E5 with energy level in the range of 0.14−0.27, 0.49−0.598, 0.62−0.67, 0.81−0.85, and 1.07−1.44 eV respectively. The concentration of the same defects are in the ranges of 1.6×10^{13}−7.7×10^{14}, 2×10^{13}−1.2×10^{15}, 1.6×10^{14}−3.8×10^{14}, 1.5×10^{14}−2×10^{15}, and 2.4×10^{14}−$3.34\times10^{15}\,\mathrm{cm}^{-3}$ for E1, E2, E3, E4, and E5 traps respectively. An illustration of various defect states detected in DLTS and photoemission tran-

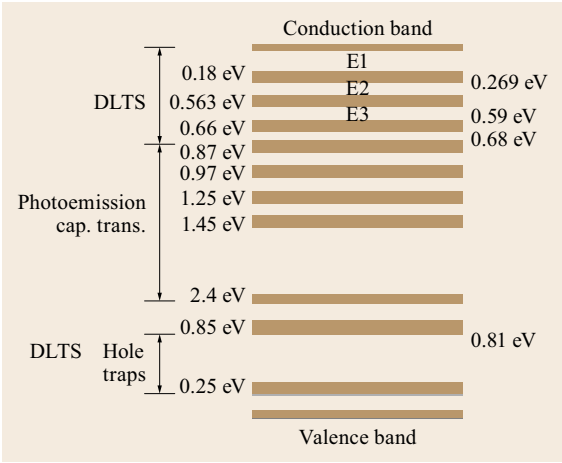

Fig. 31.36 Various deep levels within the gap energy of GaN grown by OMVPE, as observed by DLTS and photoemission transient spectroscopy. The two hole trap energies are with respect to the valence band maximum. (After [31.1])

sient capacitance methods are schematically shown in Fig. 31.36.

Minority carriers are widely trapped by defects, easily reducing their lifetime and diffusion length in the material. Minority carrier lifetime measurements are of importance in the evaluation of device performance and assessment of the material quality. Minority carrier lifetimes, τ, can be estimated using diffusion length L and measured mobility μ, through the expression $L = \sqrt{D\tau}$, where the diffusivity, D, and τ are related via the Einstein relation. The minority hole diffusion length can be derived from the line-scan electron beam-induced current (EBIC) measurements [31.534, 535]. The measurements are carried out at a distance from the material/substrate interface i. e., the GaN/sapphire interface [31.536]. In this kind of measurements the electron beam (positioned perpendicular to the sample edge) is moved from the vertical wall of the Au/n-GaN Schottky barrier toward another Au contact. The diffusion length L, can be obtained from the EBIC current decay versus distance from the edge of the Schottky contact (for distances $> 2L$). The methodology for diffusion length extraction can be found elsewhere [31.534, 535]. TEM and DLTS results clearly indicate that the defect density is reduced away from the GaN/sapphire interface. Then it is reasonable to evaluate the minority carrier lifetime as a function of distance away from the interface. Comparing the depth dependence of the dislocation density with that of the diffusion length, it is observed that the decrease in minority carrier diffusion length toward the GaN/sapphire interface is correlated with an increase in the dislocation density. The minority carrier diffusion length at a certain distance from the interface agrees well with the spacing between two adjacent dislocations, provided that the sample thickness is four times the minority carrier diffusion length. In which case, no sample thickness correction is needed because the sample can be construed as bulk [31.514].

Certain intrinsic defects (point defects/vacancies) can be studied with nondestructive positron annihilation spectroscopy (PAS) [31.537–558], which together with theoretical calculations provides a means to deduce both the nature and the concentration of the vacancies in the material. Parametric measurements with varying temperature provide information on the charge states of the detected vacancies. Positrons impingent onto a sample can get trapped in and localize neutral and negative vacancies due to the missing positive ion core. This positron lifetime and the momentum distribution of the annihilating positron-electron pair (Doppler broadening) represent the observable changes that the method relies on. Positron studies have been performed in nitride semiconductors for decades after the pioneering work of *Saarinen* et al. [31.559], which resulted in the identification of Ga vacancies in bulk GaN crystals. Many others studies were carried out [31.545, 547–549, 551–553, 555, 558]. The following is the most relevant data, regarding vacancies in GaN, InN, and AlN [31.540].

Vacancies in GaN

Most of the average positron lifetimes (τ_{ave}) measured in a variety of thick bulk or quasibulk GaN samples are above the bulk lifetime of 160 ps [31.560] for temperatures below 240 K indicating that positrons are annihilated as they get trapped at vacancy defects. The defects are identified as Ga vacancies by the second lifetime component $\tau_2 = 235 \pm 10$ ps deconvolved (separated) from the lifetime spectra [31.559, 561] as demonstrated in Fig. 31.37 [31.562].

The temperature dependence of τ_{ave} in O-doped and undoped GaN samples grown by HVPE at low temperatures points to an enhanced positron trapping at Ga vacancies, indicating that Ga vacancies are negatively charged. The lifetime, $\tau_{ave,}$ in GaN grown by the high nitrogen pressure (HNP) method indicates that nonopen volume defects, identified as MgGa-acceptors [31.559, 560], act as shallow traps competing with Ga vacancies in positron trapping at low temperatures.

No evidence of, or very low levels of, shallow traps in undoped and O-doped GaN grown by HVPE [31.561, 563, 564] set Ga vacancies as the dominant intrinsic acceptor defects in n-type GaN [31.565] (Fig. 31.37). The above-mentioned assessment is supported by a very good agreement between the vacancy and total acceptor densities, acquired by combining PAS and temperature-

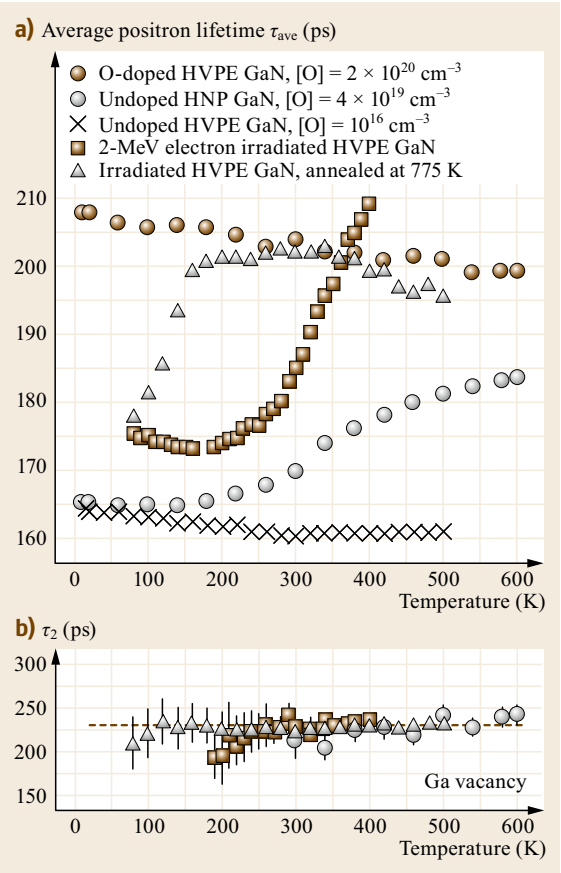

Fig. 31.37 **(a)** Average positron lifetime as a function of temperature. Vacancies are present when the average positron lifetime is above the bulk lifetime of $\tau_B \approx 160$ ps. The temperature dependence of the average positron lifetime evidences the different effects of negative charge of both the vacancies and acceptor-type impurities. **(b)** The second lifetime component extracted from the lifetime spectra, $\tau_2 \approx 235$ ps. This component is attributed to Ga vacancies or Ga-O complexes. (After [31.562], courtesy of Dr. F. Tuomisto)

dependent Hall measurements [31.564]. Experimental data show the Ga vacancy as being the most important compensating acceptor (over four orders of magnitude of the intentional oxygen doping) [31.563]. Ga vacancies in as-grown and highly O-doped GaN were identified as V_{Ga}–O_N pairs [31.563, 566], while isolated Ga vacancies are generated in electron irradiation experiments [31.561, 567]. Second lifetime components (Fig. 31.37b) are similar in grown O-complexed (V_{Ga}–O_N) and in isolated Ga vacancies, in good agreement with theory [31.563].

The τ_{ave} in as-irradiated (2 meV at room temperature) samples exhibit the coexistence of a high-Ga vacancy concentration and irradiation-induced negative ions. Annealed at 775 K, irradiated samples display a change in threshold temperature at which positrons can escape from negative ions (Fig. 31.37a). This can be interpreted as a change of positron-defects binding energy, i. e., change in the charge state of negatives ions, from 2^- to 1^-. Results from electron irradiation experiments [31.561, 567] showed a migration barrier $E_M = 1.8 \pm 0.2$ eV for isolated Ga vacancies. On the other hand, in HVPE GaN samples annealed at high temperatures and high nitrogen pressure, a redistribution of the V_{Ga}-O_N pairs [31.566–569] was observed, giving a way to calculate the binding energy of the pair as $E_B = 1.6 \pm 0.2$ eV, which is in good agreement with theoretical results [31.378, 379]. Studies on the effect of polarity (N-polar, Ga-polar, and nonpolar in both homo- and heteroepitaxy by HVPE) on Ga vacancies provided further understanding of the V_{Ga}–O_N pair formation [31.560, 570–572]. Experimental results indicate that Ga vacancies are created thermally as isolated defects in GaN growth at high temperatures in both HVPE and HNP methods and that the formation of V_{Ga}–O_N complexes is determined by the fraction of Ga vacancies that remain after the cool-down process.

O incorporation and subsequent vacancy depends on GaN growth polarity, owing to the different surface sticking coefficients of oxygen on different polarities. This effect is not observed in Si doping as the binding energy between Si donors and Ga vacancies is weaker, due to a larger distance between a Ga vacancy (acceptor) and substitutional Si (donor) [31.573].The above-mentioned results show that Ga vacancies act as dominant compensating centers in n-type GaN. In p-type GaN, because of its acceptor nature, Ga vacancy formation is energetically unfavorable. Studies of N vacancies (V_N) by PAS are useless owing to the small open volume generated by N vacancies. However, evidence of V_N-Mg_{Ga} complexes was obtained by PAS in Mg-doped (p-type) GaN grown by MOCVD [31.574, 575]. In [31.561] it is reported that N vacancies in p-type GaN samples that are electron irradiated (0.5 meV) behave like isolated neutral vacancies. Vacancies in both n-type and p-type GaN are a few percent of the doping densities. In n-type GaN, vacancies are dominantly compensating centers. On the other hand, in p-type GaN, other defects and impurities, such as hydrogen, play a more relevant role from the point of view of compensating centers.

The effect of growth conditions in thin-film (MBE, MOCVD), and bulk or quasibulk (HVPE)-grown samples were also studied by slow positron beam. Showing that stoichiometry has a very strong impact on Ga vacancy formation, the richer the growth in N and the higher the growth temperature, the higher the Ga va-

cancy concentration. This indicates that Ga vacancy is ruled by the thermodynamics of the reaction, but not necessarily by the growth method. The latter statement is supported by the results obtained from samples grown with various polarities [31.560, 570, 572, 576], where it is observed that the sticking coefficient and density of O on different growing surfaces determine the formation of Ga vacancies.

Vacancies in InN

InN layers of different thicknesses grown on sapphire by MBE [31.577, 578] have also been studied by PSA. The low electron-momentum parameter S and the high electron-momentum parameter W were calculated at room temperature to evaluate the positron annihilation with the valence electrons and the annihilation contribution from the core electrons, respectively [31.579]. In the context of the S parameter, the larger the value the higher the vacancy density in the layer. Regardless of the sample thickness, a value of $S = 0.48$ is registered for all samples for positron implantation energies in the range of (E) 0–1 keV (0–5 nm) (Fig. 31.38). For higher values of E and up to 30 keV, S remains constant. The S value and the extent of E values for which S remains constant is a characteristic of each sample. Note that for thinner InN layers, S decreases when the layer thickness increases. This is an indication of improvement in the quality of InN layer growth. Close to the InN-sapphire interface, the parameter S starts to decrease, approaching a value of 0.41, due to the increasing fraction of positrons annihilating.

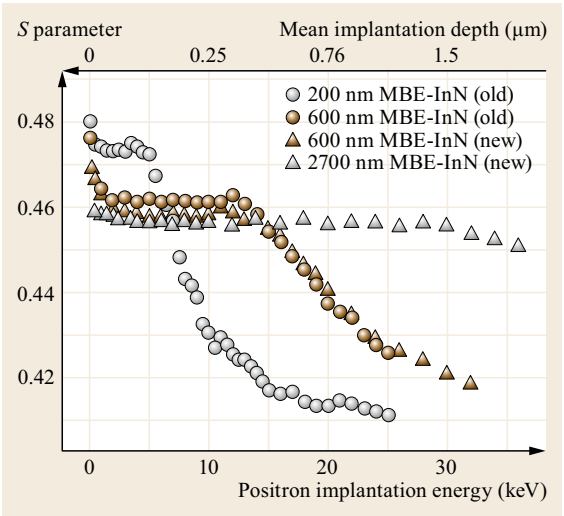

Fig. 31.38 The S parameter measured as a function of positron implantation energy in selected MBE-grown InN layers. *Old* from [31.577], *new* from [31.578]. (After [31.562], courtesy of Dr. F. Tuomisto)

Indium vacancy concentration is typically not sufficient to compensate electron conductivity in n-type InN. Indium vacancies are, as evaluated by electron mobility, effective scattering centers in InN. Improved electron mobility for thicker layers (up to 1 μm) suggest that In vacancy concentration is dramatically reduced [31.577]. An interesting point is that In vacancy formation does not seem to be promoted by the growth stoichiometry in MOVCD grown InN [31.580] and the same has been suggested to hold for MBE growth as well [31.581].

Vacancies in AlN

Average positron lifetime as a function of the temperature was measured in bulk AlN [31.582] grown by physical vapor transport (PVT) [31.172] and in thin layers grown heteropitaxily on various substrates by MBE [31.391] and MOCVD [31.583]. Qualitatively, the temperature dependence of τ_{ave} in AlN is similar to that on GaN. Any deviation in τ_{ave} as function of temperature in GaN and AlN can be interpreted as a competition between the negative ion type defects (shallow traps with no open volume) and vacancy defects for trapping positrons.

Taking an Al vacancy trapping coefficient of $3 \times 10^{15}\,\mathrm{cm^3\,s^{-1}}$ at 300 K and its temperature dependency, a lower limit for Al vacancy concentration is estimated as $1 \times 10^{17}\,\mathrm{cm^{-3}}$ at 600 K. On the other hand, negative ion concentration is $4 \times 10^{18}\,\mathrm{cm^{-3}}$ from data taken below 300 K, which indicates that negative ions are the dominant acceptor centers in AlN. A comparison between impurity and negative ion concentrations suggests that negative ions are related to oxygen incorporation and not to carbon impurity as is usually the case. In contrast with the case in GaN, O in AlN is predicted to behave as a negative charge.

In thin AlN films PAS results are similar to those acquired in GaN and InN thin films. Larger AlN-substrate mismatch and higher growth temperatures lead to higher Al vacancy concentrations. Also the growth stoichiometry effect is more notorious at very high V/III ratios. Measurements as a function of temperature provide valuable information on the charge states of the detected defects. Briefly, group III sublattice vacancies are common defects in all the group III nitrides. They compensate donors either by forming vacancy-impurity complexes or by providing deep states for electrons. Additionally, the presence of N vacancies was observed.

31.9.2 Extended Defects

As mentioned in Sect. 31.7 GaN-based LEDs and lasers rely for their functionality on QWs, which are formed,

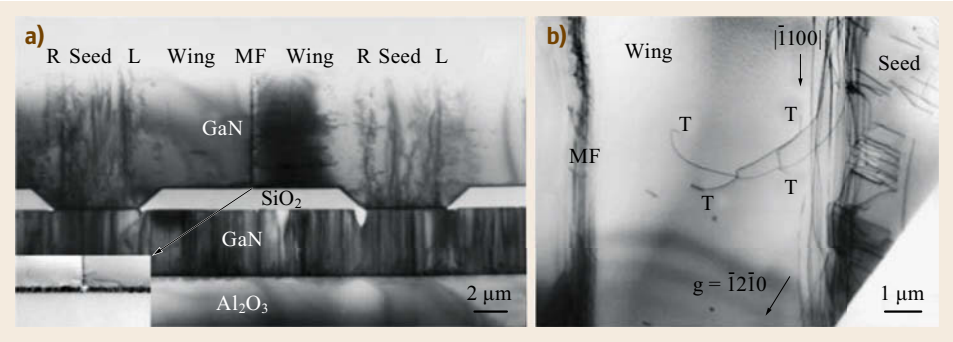

Fig. 31.39 **(a)** Cross-sectional TEM image showing defect distribution in a LEO layer. The seeds, left (L) and right (R) wings, meeting fronts (MF) of two wings, dielectric (SiO_2) layer and original GaN deposited on the Al_2O_3 (seed layer) are indicated. The *inset* shows a formation of a small void where two wings originally meet each other; **(b)** Plan view of the laterally overgrown area showing a meeting front of the two wings (MF) and one wing with a small part of the seed on the *right-hand side* of the image. The indicated threading parts of the dislocation, which originate either at the interface with the substrate or at some obstacles in the seed, are indicated as T. (After [31.584], courtesy of Dr. Zuzanna Liliental-Weber)

basically, by sandwiching a semiconductor material layer (GaN-based active region) with layers of semiconductor material with larger bandgap. On the other hand, because of economical, practical and functional reasons, the material for GaN-based optoelectronic devices is usually grown on SiC (for high-intensity LEDs) and sapphire substrates (note that the improved quality of GaN grown on Si substrates paved the way for high-brightness LEDs, which already made it into the marketplace); the latter is of low cost and light-transparent (from UV to IR). The lattice mismatch between the epitaxial layer and the substrate result in high-strain fields, which in turn lead to a high density of extended defects, i. e., threading dislocations (TD) and staking faults (SFs). Residual strain is also present in epitaxial layers upon cool-down due to the difference in temperature expansion coefficients. In fact the tensile strain when grown on SiC and Si leads to cracking, which must be addressed by strain engineering during growth.

Extended defects do affect device performance. TDs can act as both scattering centers and nonradiative recombination centers lowering either or both carrier mobility [31.585] and quantum efficiency [31.586]. The SFs are linked to high leakage current [31.587]. In short, extended defect density needs to be decreased in order to attain better device performance. A well-known method to decrease the defect density, for GaN growth on *c*-plane, is the epitaxial lateral overgrowth method (ELO) [31.588–590] (Fig. 31.39), which has been developed [31.591–593]. This approach yields a much lower density of defects (SF $\approx 1\times10^4\,cm^{-1}$), especially those that propagate along the growth direction. The ELO technique is also used to grow GaN along the semipolar and nonpolar directions.

When group III nitride samples grown on *c*-plane sapphire are heavily doped to produce n-type GaN, structural defect formation occurs. High-resolution transmission electron microscopy (HRTEM) investigation has revealed that these defects are small dislocation loops (in the range of few nanometers) associated with extrinsic SFs. This problem can be mitigated with the use of Ge doping instead of Si, as discussed below. The demonstrated superiority of Ge doping compared to Si, on GaN layers on *c*-plane sapphire, in terms of achievable free-carrier concentrations (up to $2.9\times10^{20}\,cm^{-3}$), surface smoothness, and reduced layer stress, has been reported in [31.485]. The authors observed a reduction in tensile stress for any Ge doping level, which could lead to a reduction of crystal defect density at high doping levels. On the other hand and in contrast with the structural defects formation in GaN heavily doped with Si, TEM investigations on Si-doped and undoped GaN samples grown by MOVCD on the (11−20) plane of sapphire revealed an improvement of the GaN layer quality with Si doping. For a Si concentration of $3\times10^{18}\,cm^{-3}$ dislocation density decreased from $5\times10^9\,cm^{-2}$ (undoped sample) to $7\times10^8\,cm^{-2}$ [31.594]. Also, a correlation between the Mg doping level and SF concentration in highly Mg-doped *c*-plane homoepitaxial GaN layers was found. As the Mg concentration increased from 2×10^{18} to $5\times10^{19}\,cm^{-3}$, the density of small, 3−10 nm-sized, SFs increased [31.595].

A scheme, which overcomes ELO limitations to a great extent, is the nanoheteroepitaxy (NHE) as shown schematically in Fig. 31.40. NHE has the potential

to eliminate defects more efficiently than conventional ELO. In the NHE technique coalescence would occur at a nanodimension scale reducing subsequent overall strain for minimal defect propagations. The NHE growth process begins with the definition of a two-dimensional array of e.g., 10–300 nm-sized nucleation islands on a substrate. It is then followed by a selectively grown epitaxial material vertically on the islands (in the case of AlN/SiC template, AlN array is generated with lithography followed by etching). What follows is the lateral overgrowth to achieve coalescence as indicated in Fig. 31.40. In contrast to the millimeter scale of patterns in ELO, patterning is in the nanometer scale in NHE, which allows for stress in the NHE sample to decay exponentially away from the heterointerface. The characteristic decay length is proportional to the diameter of the island. According to the NHE theory, a mismatch dislocation formation can be eliminated from materials systems with a lattice mismatch in the range of 0–4%. For a higher mismatch, defects are probably unavoidable, such as the case for GaN on Si (20% lattice mismatch); however, NHE may still result in a significant reduction in the local defect density.

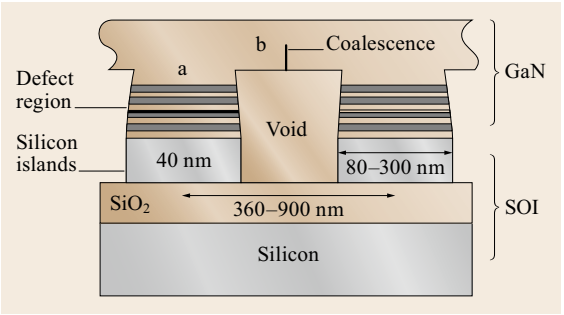

Fig. 31.40 Patterned silicon-on-insulator (SOI) substrate with islands created in the upper Si layer. The selective growth of GaN is also illustrated. A defected region is located at the heterointerface. *Point* a corresponds to selective growth of islands on a patterned substrate. *Point* b corresponds to the case where lateral epitaxy has been performed already. (After [31.596])

31.10 GaN-Based Nanostructures

At the nanometer scale, semiconductor structures exhibit novel electronic and optical properties, primarily owing to the dimensions that are comparable to the length of intrinsic processes (Fig. 31.41). The aforementioned novel properties are observed in GaN devices based on quantum wells [31.597–601], nanowires [31.601–605], or nanodots [31.606, 607]. In addition to the common issues related to conventional semiconductors such as band discontinuity, and dopant and carrier redistribution, polarization effects have to be taken into account in GaN devices. Polarization field effects may be in some cases desirable as in HFETs. But intense polarization fields foster an undesirable effect, the stark effect, which reduces the internal quantum efficiency in quantum confined structures. To mitigate the polarization effect, a quaternary alloy, InGaAlN, is used to neutralize the strain-induced component of the polarization field. Spontaneous polarization can be avoided by growing the heterostructure on $(1\bar{1}00)$ (*m*-plane) or $(11\bar{2}0)$ (*a*-plane), which represent the nonpolar planes.

31.10.1 Quantum Wells

As already discussed, the polarization-induced fields can drastically reduce the oscillator strength (Sect. 31.6.1, *Free Exciton in GaN* and Sect. 31.6.2, *Bound Exciton in GaN* for details on oscillator strength concept) for the ground-state optical transition [31.609–611]. The observed Stokes shift in two-dimensional (2-D) systems such as QWs [31.612, 613] is partly due to polarization effects. In this subsection we focus on the impacts of the piezoelectric effect and how to minimize them by manipulating well size and the crystal orientation. In multiple quantum wells

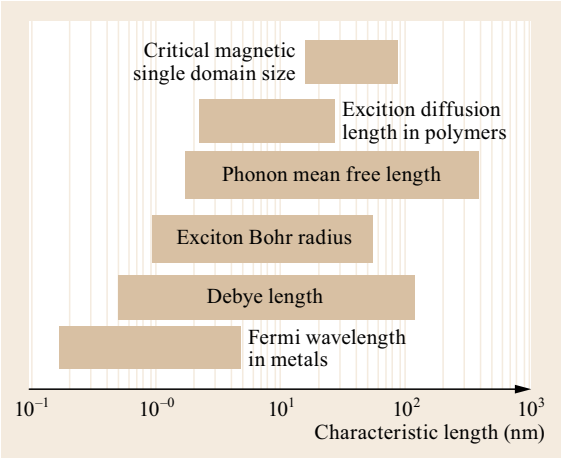

Fig. 31.41 Some of the well-known processes taking place in a semiconductor. Indicated characteristic lengths at 300 K go from tens of nanometers to hundreds of nanometers. The exciton Bohr radius is the most critical parameter in optical processes. (After [31.1])

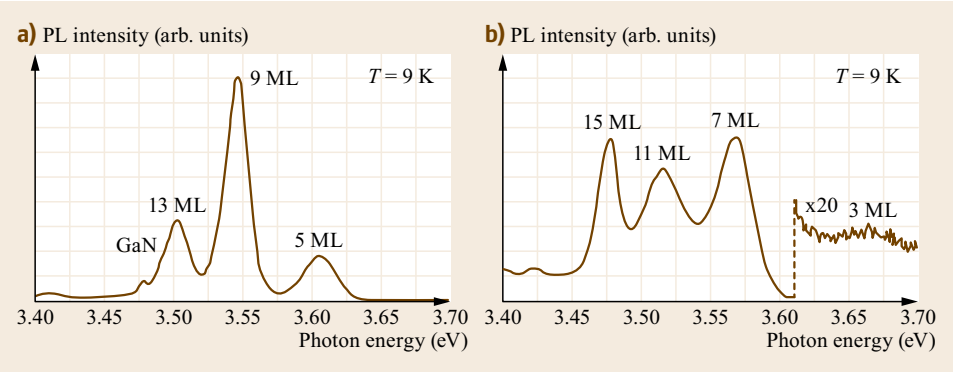

Fig. 31.42a,b Photoluminescence spectra at 9 K of $GaN/Al_{0.11}Ga_{0.89}N$ single QW. **(a)** corresponds to series A, **(b)** corresponds to series B. Note that in **(a)** the GaN buffer layer emission at 3.478 eV. (After [31.608], courtesy of Dr. N. Grandjean)

(MQWs), polarization effects manifest themselves as a redshift excitonic transition peak position [31.614, 615]. The effect can be compensated (blueshifting) by making the well size small enough to induce quantum confinement. The balance between redshift and blueshift is attained at a well thickness of 2 nm or less ($\approx$ 10 monolayers – MLs). The effect of QW thickness on the low-temperature photoluminescence spectra was studied by *Grandjean* et al. [31.608]. A single QW with 50 Å-thick $Al_{0.11}Ga_{0.89}N$ barrier layers grown by ammonia MBE were used. The data were from two samples: sample A consisting of 5, 9, and 13 ML well width, and sample B consisting of 3, 7, 11, and 15 ML width. PL spectra at 9 K are shown in Fig. 31.42.

It is evident from Fig. 31.42b, for the samples therein in particular, that the balance between the blueshift due to the confinement and the redshift, a consequence of the polarization effect, takes place at a QW thickness of 15 ML ($\approx$ 4 nm). The latter is wider than the values reported by other studies where a barrier layer with higher Al content was used. It is not necessarily a discrepancy and it may be because at a higher Al content the polarization effect is larger, which means the larger redshift needs to be compensated by a larger blueshift afforded by thinner QWs. Similar studies on AlGaN/GaN quantum wells grown by MOCVD but with high Al content (50%) in the barrier layer have been reported [31.616]. PL transition energies (not shown here) display a clear dominant transition from a redshift of 100 meV for a 4 nm QW width to a blueshift of 300 and 600 meV for QW widths of 2 and 1 nm respectively. The difference among the QW widths reported for the redshift-blueshift crossover, is mainly due to a larger than expected Al mole fraction in the PL reference samples and the growth technique, which may limit to some extent the heterostructure quality, particularly in terms of different degrees of localizing potentials. In the GaN system, the barrier thickness redistributes the polarization difference between wells and barriers, and thinner barrier layers were found to lead to larger blueshifts [31.600]. A point worth noting is that the trend of the electric field dependence on the barrier layer thickness can be found by using simple electrostatic calculations. However, not only piezoelectric-induced polarization, but also spontaneous polarization should be taken into account.

Nitrides are usually grown heteropitaxially on the basal plane of sapphire and SiC as well as Si substrates. Under normal growth conditions, nitrides assume wurtzite crystal structures, which have a hexagonal symmetry and a polar axis, *c*-axis [0001], along which both piezoelectric and spontaneous polarization are manifested. For optoelectronics, the ideal situation could be to grow nitride layers on nonpolar planes, i. e., $[1\bar{1}00]$ (*m*) and $[11\bar{2}0]$ (*a*) planes, in which case the polarization-induced shift would be eliminated, or at least the effect of the polarization-induced field associated with Stark shift could be suppressed. However, the inconvenience with nonpolar nitrides has to do with their film quality, which is lower than for those grown on *c*-planes. The most intensively investigated nonpolar directions are the $[1\bar{1}00]$ *m*-plane [31.617, 618] and the $[11\bar{2}0]$ *a*-plane [31.619, 620], which are free of polarization-induced internal electric fields along the growth direction.

At the present time, *a*-plane GaN is routinely grown on $(1\bar{1}02)$ or $(10\bar{1}2)$ *r*-plane sapphire by both MBE [31.619, 621] and MOCVD [31.618, 622–624]. However, heterostructures grown on *a*-plane, as well as the other nonpolar orientations, such as the *m*-plane, suffer from large stacking fault densities due to the low formation energy, making the radiative recombination at the desired wavelength relatively weak (this correction is a matter of style). Effects of systematic variation of well width on $GaN/Al_{0.16}Ga_{0.84}N$ quantum wells with a fixed 10 nm-thick barrier layer and 10-period *a*- or *c*-plane MQWs regrown by MBE on MOCVD-grown GaN/*r*-plane sapphire templates was investigated. Because of the absence of a polarization-

induced field, *a*-plane MQWs showed enhanced recombination efficiency as compared with *c*-plane wells, even though the *a*-plane variety presented a higher dislocation density [31.625]. It should be pointed out that this limited comparison does not necessarily hold in general.

31.10.2 Quantum Dots

In semiconductor quantum dots (QDs) electronic states are spatially localized and the energy is fully quantizied for all three directions. The atomic-like density of states near the bandgap is higher than in three-dimensional (3-D) and 2-D systems, leading to relatively high efficiency optical transitions. The latter is of great interest in terms of its potential in light emitting applications and optical sensors. The caveat of course is the carrier transport, which is impeded as well. Another interesting characteristic of the QDs is they are less sensitive to thermal perturbations, due to confinement, which is important for thermal stability of devices. Also, because the carriers are strongly localized their migration toward nonradiative centers such as dislocations outside of the dot region is somewhat inhibited [31.626].

Assuming good uniformity and control over the shape, quantum dots present some advantages as compared with QWs. Among them are a sharp energy level transition leading to reduced lasing thresholds, tunable bandgaps, and additionally reduced defects in nitrides. As in quantum wells, the optical properties of group III nitride QDs are assessed via photoluminescence. There is not an established consensus on the spectra emitted by GaN-based QDs. Published data indicate PL peak energies from 2.15 to 3.9 eV, depending on sample and temperature. QDs exhibit strong, albeit broad, PL intensity peaks with energies ranging from 2.6 to 3.9 eV (Fig. 31.43). The spread in the spectrum is most likely due to the divergence in dot size and shape.

As mentioned already, quantum confinement shifts the effective bandgap to higher energies. The amount of energy shift depends on the size and shape of the QDs, as well as the material optical properties of both the QD and its surrounding matrix. For small dots (disk, cubic, or sphere-like shape) of few nanometers in size, confinement energy is very sensitive to the dot size, becoming lower and less sensitive to the dot size for large-size quantum dots. Depending on the dot shape, confinement energy may change from 20 meV to 1 V for dot size from 2−10 nm [31.627].

Because of the relevance of strain-induced effects on group III nitrides, it should also be taken into account in QDs. In GaN QDs grown on $Al_xGa_{1-x}N$ and $In_xGa_{1-x}N$, which in turn is grown on GaN, strain is compressive, leading to a blueshift in the bandgap. For example, for a fully strained GaN on $Al_xGa_{1-x}N$, assuming the validity of Vergad's law, the bandgap energy shift is of 0.04 x eV, where x is the Al composition. On the other hand, as in the case of QWs, the polarization effect induces a redshift in the bandgap. Both spontaneous and piezoelectic (strain-induced) polarization induce very strong electric fields in nitride-based QDs, affecting significantly their optical properties. It should also be noted that the small dimensions associated with dots reduce the extent of the energy shift induced by polarization effects.

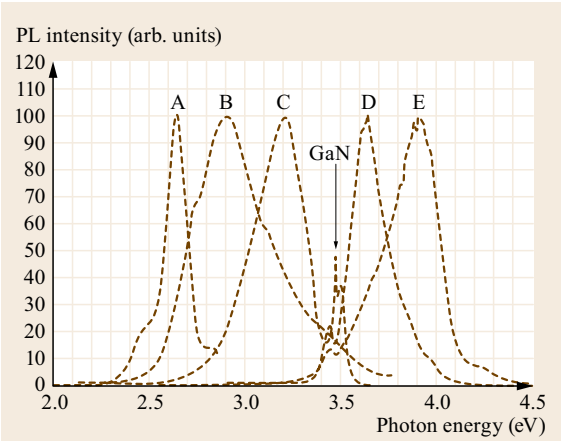

Fig. 31.43 PL spectra of GaN/AlN QD samples grown by MBE on different substrates and under different conditions. Samples A and B were grown on Si substrates; C, D, and E on sapphire substrates. Spectra were taken at 15 K under Ti-sapphire laser excitation (photon energy 5.06 eV). Intensity is normalized with respect to QD maximum signal. Also, for comparison, GaN bulk PL spectrum is displayed at 3.45 eV. (After [31.2])

31.10.3 Vertical Cavities

In terrestrial long-range and high-data-density communication systems based on fiber optics, where data transfer speed is as high as 100 G/s on 10 Tb/s [31.628], zero dispersion at a wavelength 1.3 μm [31.598, 599, 629–644], and lowest attenuation at 1.5 μm [31.597, 645–648] are possible. Then, it is desirable to count with powerful lasers emitting at the mentioned fiber-optic transmission windows. Vertical cavity surface emitting lasers (VCSELs) based on more recently developed dilute nitrides (GaAsN), are touted to satisfy the mentioned requirements (8 W at 1300 nm [31.649] and 12 W at 1120 nm [31.650]), but the quality requirements have not yet been met. A schematic cross-section description of a particular VCSEL design is presented in Fig. 31.44.

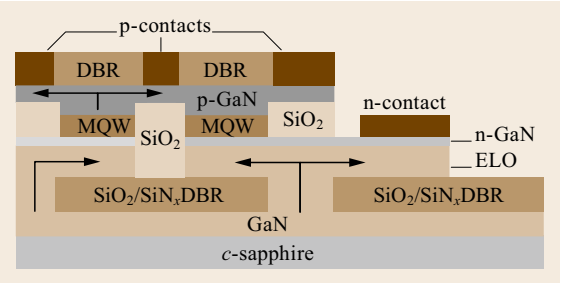

Fig. 31.44 Cross-sectional schematic of VCU's (Virginia Commonwealth University) VCSEL design. The design is meant for current injection. Lateral epitaxial overgrowth allows the implementation of distributed Bragg reflectors (DBR). The ELO growth technique allows all-dielectric DBR implementation. The design exhibits a SiO_2-defined current aperture. Current is injected and distributed via n and p GaN layers (after [31.651])

Aspects fostering the development of VCSELs are its small size ($\approx 10\,\mu m$ diameter), easier packaging and testing, possible fabrication and integration of 2-D arrays, and manufacturability. The smallest lasers available commercially today are vertical-cavity surface-emitting lasers [31.652]. The core part of VCSELs is the microcavity (MC). The constituting parts of a MC are top- and bottom-distributed Bragg reflectors (DBRs), which consist of $\lambda/4$-thick (where λ is the designed wavelength) alternating semiconductor or dielectric layers with low and high refractive index. Located between the DBRs is the active region of the VCSEL formed by multiple quantum wells (MQWs). The higher the refractive index dissimilarity, the contrast, between the alternating layers forming the dielectric stack, the fewer the number of stack pairs needed to attain DBRs with high reflectivity, which should be as close as possible to 100% for low-threshold current density. The cavity thickness should be an integer number of $\lambda/2$ times the length of the active region.

Difficulties arise when we shift from the 850 nm wavelength, either to shorter wavelengths (toward UV) or to longer wavelengths (toward infrared). In the case of short wavelengths, the number of quarter-wavelength DBR mirror pairs required increases considerably, which lowers the thermal conductivity and also increases the electrical contact's resistance. As a result, the heat dissipation problem increases substantially, which limits the VCSEL's thermal operating range.

Reflectors are commonly composed of either heterostructures or dielectric stacks and thus cleaved and/or etched facets are not applicable for vertical cavities. In the case of reflectors based on heterostructures, layers are made of materials with similar crystal structures but with different reflection indices; the larger the difference between their reflection indices the fewer the number of layers and the wider the blocking wavelength band. Due to the epitaxial growth of the active region of the VCSEL, bottom reflector stacks are commonly made of compounds compatible with the active region. Thanks to the development of the epitaxial lateral overgrowth technique (Sect. 31.10.2) for the GaN material system, it is possible to use dielectric stacks (SiN/SiO_2) as reflectors. Dielectrics constituting the stacks offer large reflection index contrast, which is beneficial to obtain a wider blocking band as well as a high reflection coefficient. On the other hand, top reflectors can be made of either semiconductors or dielectrics. Due to the short length of the active region in a vertical cavity, the gain is low. A minimum reflective coefficient for top and bottom DBR of 90% or higher is required, in order to have optical efficiency for lasing. The ideal case could be a reflection of 100% for the bottom DBR while the value for the top one should be slightly lower to allow light extraction, the extent of which depends on the desired output power.

Also in VCSELs based on GaN, AlN/GaN DBRs have been investigated. The main interest in such stacks stems from the fact that they possess the highest refractive index contrast among all the III–V compounds, so that a fewer number of stacks is required to obtain high reflectivity and relatively wide stop bands. But owing to the lattice mismatch between the AlN and GaN, which leads to crack formation (promoted by tensile strained GaN on AlN, and causing generation and propagation of defects), stack thickness is somehow limited. A way to mitigate the mentioned issues is by using AlGaN/GaN DBRs with Al concentration lower than 40% [31.653–657], and also introducing a digital equivalent of lower index materials as opposed to constant composition.

Figure 31.45 shows a stop-band-wide comparison between a 10-pair SiO_2/Si_3N_4 quarter wavelength DBR and a 30-pair $Al_{0.5}Ga_{0.5}N/GaN$ quarter wavelength DBR, both designed for a central frequency of 380 nm. The relevant point here is that even though few stacks were used, dielectric DBR achieves a higher reflectivity and a wider stop band compared with those obtained with semiconductor DBRs. GaN-based VCSELs with semiconductor-dielectric and all-dielectric reflectors were compared by *Okur* et al. [31.651]. The active region of VCSELs was formed by 6× $In_{0.01}Ga_{0.99}N$ (12 nm)/$In_{0.15}Ga_{0.85}N$ (2 nm) QWs. Sample 1 had semiconductor-dielectric DBRs, the top one being composed of 13.5 pairs of SiO_2/SiN_x while the bottom DBR was formed by 29 AlN/GaN pairs on top of a freestanding GaN (*c*-plane) substrate. Sample 2

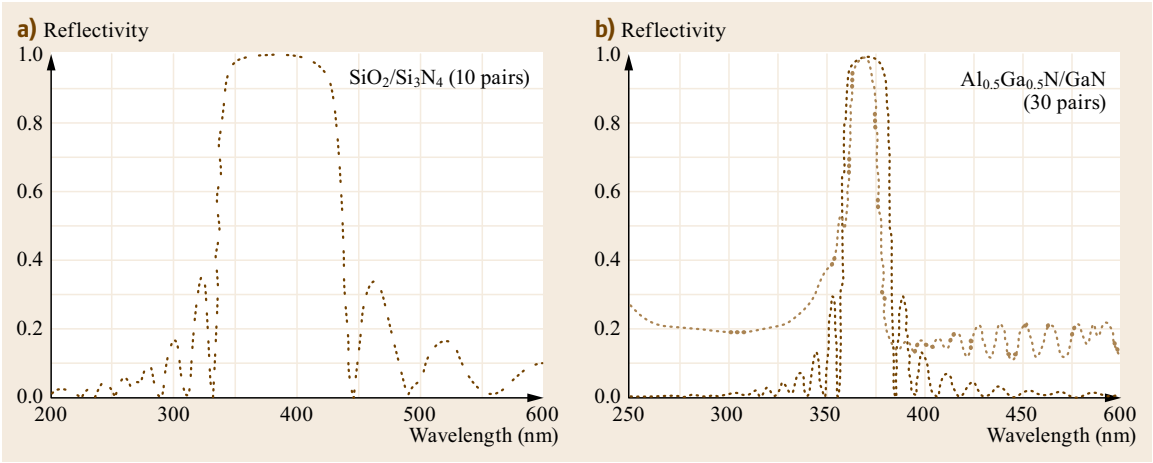

Fig. 31.45a,b Calculated reflection spectra. **(a)** for a 10-pair SiO_2/Si_3N_4 quarter wavelength DBR **(b)** for a 30-pair $Al_{0.5}Ga_{0.5}N/GaN$ quarter wavelength DBR. The *dotted line* is the calculated reflection spectra. Note that even though fewer pair stacks were used, dielectric DRBs exhibit a better reflectivity and wider stop band. (After [31.3])

consisted of all dielectric reflectors, where the top and bottom DBRs consisted of 13.5 pairs of SiO_2/SiN_x. In the latter case the entire structure was grown on a 3 μm GaN layer prepared by the ELO technique on top of a *c*-plane sapphire. Sample 2 exhibited a quality factor of 1200 at high excitation against a quality factor of 800 for sample 1, both at a wavelength of 403 nm. Also, sample 1 demonstrated one order of magnitude lower stimulated emission density ($\approx 5\,\mu J/cm^2$). On the other hand, *Butté* et al. [31.658] reported on VCSELs formed by a $5\lambda/2$ GaN cavity containing three $In_{0.15}Ga_{0.85}N/GaN$ QWs composed of a bottom 50-pair $Al_{0.83}In_{0.17}N/GaN$ DBR and a top 20-pair SiO_2/Si_3N_4 DBR with a quality factor as high as 6400 as determined from PL spectra at a wavelength of 421.1 nm.

Even though VCSELs are advantageous in many respects, some technological aspects delayed the GaN-based VCSEL development. One of those aspects is related to the fabrication of high-Q optical resonators. Another issue is the electrical current injection, which should incorporate lateral current spreading, because of the low conductivity of the p-GaN and its alloys used in the construction of some DBRs. Also, smooth dielectric and semiconductor interfaces are required of VCSELs to a greater extent due to the relatively short wavelengths involved. A roughness of smaller than 2–3 nm for areas of several hundred square micrometers is required. VCSELs based on nonpolar GaN have also been demonstrated by *Holder* et al. [31.659]. Vertical cavities were implemented on *m*-plane freestanding GaN substrates grown by HVPE. The active region, grown by MOCVD, consisted of five $In_{0.1}Ga_{0.9}N$ QWs (7 nm-thick) separated by 5 nm GaN barriers. DBRs were formed by 10-pair SiO_2/Ta_2O_5 (bottom) and 13-pair SiO_2/Ta_2O_5 (top).

Kasahara et al. [31.660] demonstrated current injection stimulated lasing at room temperature in GaN-based VCSELs on GaN substrates. CW operation for blue (8 μm aperture) and under pulsed (pulse width: 1.0 μs; pulse period: 500 μs) current operation (10 μm aperture) was reported. Devices were formed by InGaN/GaN quantum wells in conjunction with dielectric DBRs and a vertical current injection configuration. Blue CW lasing at 451 nm had a threshold current and voltage of 1.5 mA and 3.3 V respectively. Pulsed green lasing (503 nm) was attained at a threshold current of 22 mA and a threshold voltage of 6.3 V. Maximum output power for blue emission was 0.7 mW, while for green light it was 0.8 mW. The authors suggest that the difference in the threshold current, from blue to green emission, is caused by the quantum confinement Stark effect caused by the piezoelectric polarization-induced field, the genesis of which is the strain due to the mismatch between GaN and InGaN and which increases for higher In content. Electrically injected stimulated emission at a wavelength of 411.9 nm and a maximum power output of 19.5 μW in these devices was observed. However, high threshold current and very low forward voltage suggests high leakage current. Laser emission was polarized-locked with an optical electric field oriented parallel to the *a*-plane, in contrast to that which occurs in *c*-plane VCSELs, where the emitted light is randomly polarized. This can be a key characteristic of VCSELs built on m-plane orientations for applications where high-intensity polarized light is desired.

31.10.4 Nitride Nanorods

Nanorods, also known as nanowires (NWs) and whiskers, can be synthesized with a 5−500 nm diameters, and be dozens of micrometers long given the opportunity, as mentioned in the introduction of this section, to explore the realm of the mesoscopic phenomena. Some of the potential and interesting applications are nanowire light-emitting diodes (NW LEDs) in all visible spectra [31.606, 661–664], white light generation [31.11], nanowire lasers (NW lasers) [31.665–668] with emission wavelengths from the deep ultraviolet (UV) [31.669] to the near-infrared [31.670–672] spectral range, and photodetectors [31.673–676]. However, for successful insertion of nitride nanowires into the actual market, electrical injection, ultralow-threshold, and continuous wave (CW) operation at room temperature are crucial. In this vein some obstacles need to be overcome first, such as the carrier loss to defect-related nonradiative and surface recombination processes [31.602], electron overflow [31.677, 678], and poor hole transport [31.679]. In order to enhance group III nitride NW performance, thermal management in NW lasers, which plays a principal role, also needs to be addressed.

Because of the reduced diameter of the NWs, thermal conductivity is also lower compared with that of the bulk. Thermal conductivity of single-GaN NWs for different diameters has been reported [31.680–682]. Thermal conductivities as low as 0.13−0.19 $\mathrm{Wcm^{-1}K^{-1}}$ at 300 K (while for bulk Si, GaN and 4HSiC is 1.5, 2.3, 4.5 $\mathrm{W\,cm^{-1}\,K^{-1}}$ respectively) were reported. NW doping, for both n and p-type materials, still remains a challenging problem, especially the p-type variety, which makes electrical injection difficult to attain. n-ype NWs doped with Si have been demonstrated [31.683, 684], while p-type doping, as in the case of planar structures, is a main concern, especially for InGaN and InAlN with high Al and In compositions. Generally, lasing in NW lasers is demonstrated via optical pumping, while electrical injection in group III nitride NW lasers remains elusive. At this time there is no report on electrically pumped group III nitride NW lasers.

One-dimensional nanostructures are usually grown by a variety of techniques. Among them are vapor phase, laser ablation, chemical vapor deposition [31.685, 686], chemical vapor transport methods, molecular beam epitaxy [31.687], sputtering [31.688–692], vapor-liquid-solid (VLS) [31.693–697], inclusive of self-catalytic and vapor phase varieties, vapor-solid (VS) growth [31.698, 699], confined chemical reaction [31.700–702] such as that utilized for carbon nanotube preparation, and anodized Al membrane confined reactions [31.703, 704]. No matter what growth techniques is used, it must have attributes such as reproducibility, uniformity, scalability, cost-effectiveness, and a well understood growth process. Nanorods are typically grown by patterning techniques as an integral part of the growth process. For instance, high-quality InGaN NWs have been grown by many methods including CVD [31.603, 705], MBE [31.603, 705–708], and hydride vapor phase epitaxy [31.709, 710] to produce a diverse class of heterostructures: core-shell [31.604, 705], core-multishell [31.604], well/disk-in-a-wire [31.711, 712], and dot-in-a-wire [31.606, 706]. Also, InN nanostructures have been grown in many different shapes: nanocrystals [31.713], nanocolumns [31.714], nanorods [31.715], NWs [31.684], nanotubes [31.716], and nanobelts [31.602, 717]. For more details on group III nitride nanorods, the reader may wish to see reviews [31.667, 718–723].

As in the case of layers grown by heteroepitaxy, the material perfection is highly coveted, and in order to master the growth process, an in-depth understanding of the kinetics and thermodynamics of reactions applied to a wide variety of material systems is necessary [31.724]. Note that for group III nitride nanowires there are no affordable lattice-matched substrates available. The small base area, however, together with the large surface/volume ratio leads to relaxed nanowires without extended defects on nonnative substrates. As a result, nearly structural defect-free nanorods are possible to attain. A relaxed material is beneficial in terms of minimization of the strain-induced polarization effects in the polar direction, which is advantageous for heterojunction systems, such as green LDs based on InGaN in a GaN matrix.

For optoelectronic applications, sapphire and Si are of most interest. The optical window of sapphire is consistent with UV, visible, and near-infrared applications. Even though the Si transmission window begins at the far-deep-infrared spectrum, the main interest in Si wafers lies in their relatively low cost and possibility to integrate light emitters with electronics in cases where the performance of the emitter does not rely on substrate transparency i. e., VCSELs, NWs Fabry–Pérot cavities and longitudinal heterostructures. The cost issue alone has been driving the LED industry to migrate to Si substrates along with processes that are already in place for substrate removal.

As noted already, nanowire growth in a variety of cross-sectional shapes (hexagonal, triangular, circular, and rectangular) has been achieved. The triangular cross-section is to some extent related to the growth method and growth conditions employed. Hexagonal or triangular cross-section NWs are attained commonly by MOCVD [31.605, 725]. Nearly extended defect-free wurtzite single-crystal GaN nanocolumns grown

by plasma-assisted molecular beam epitaxy with a diameter in the range of 20–40 nm were grown along the [0001] *c*-direction on Si substrates with (001) and (111) surfaces [31.726]. This represents another piece of evidence that, when not bounded by the substrate, the wurzite phase is the preferential polytype with dominant growth parallel to the polar direction. Vertically aligned [0001] GaN nanorods on sapphire were grown by MBE using an RF source for reactive nitrogen [31.687]. Nanorod growth that took place under GaN growth conditions deviated from that used for standard growth (planar growth). In other words, the growth takes place at relatively high temperatures (> 800 °C), some 200 °C higher than that used to obtain uniform layers under Ga-rich conditions, and under very high nitrogen fluxes. This approach exploits the very high sticking coefficient of nitrogen and the high evaporation rate of Ga at high temperatures.

Because high-quality devices based on heterostructures are commonly produced by MOCVD and to a lesser extent by MBE, these methods could facilitate a smooth integration of nanowire growth with compositional and doping modulation in the growth direction. In practical applications, more precisely those based on electrical injection, a p-type semiconductor is crucial. The p-type doping in GaN systems for functional device structures was reported in [31.727]. The authors used a chemical vapor transport vapor-solid process to introduce Cp_2Mg to accomplish p-type doping. In another report [31.601], the authors used the vapor-liquid-solid (VLS) method to grow nanowires. The tuned incorporation of Mg during synthesis resulted in 35 nm-diameter nanowires with rectifying p-n junction properties. GaN nanowires synthesized by a catalytic chemical vapor deposition, with hexagonal single-crystalline structure and diameters of 10–50 nm and lengths of tens of micrometers, exhibited UV bands at 3.481 and 3.285 eV in low-temperature PL measurements associated with donor-bound excitons and donor-acceptor pairs respectively [31.728]. The observed blueshift of UV bands was attributed to quantum confinement effects in thin GaN nanowires with diameters of about 11 nm. The turn-on field emission of nanowires was 8.5 V mm^{-1} and the current density was about 0.2 mA cm^{-2} at 17.5 V mm^{-1}, which is sufficient for field emission display applications and vacuum microelectronic devices. Also, GaN nanowires formed via the VLS mechanism with gold, iron, or nickel as catalysts, exhibited orientations predominantly along directions [001] and [101]. The NWs with growth orientation [210] featured a triangular cross-section with an n-type character and a mobility of 65 cm^2 V^{-1}s^{-1} [31.729].

In an attempt to accomplish highly efficiency light emission, *Qian* et al. [31.604] prepared core multishell nanowire (CMS) radial heterostructures by MOVPE having triangular cross-sections, which allowed synthetically tunable multicolor light emitting diodes. Structures consisted of n-GaN cores surrounded by $In_xGa_{(1-x)}N$/GaN/p-AlGaN/p-GaN shells. Electrical carrier injection was achieved by forming metal contacts on the p-type outer shell and n-type cores at the ends of individual nanowires. I–V curves exhibited p-n diode characteristics with a knee voltage of around 3.5 V. CMS nanowires display electroluminescence spectra with emission peaks at 367, 412, 459, 510, and 577 nm, consistent with $In_xGa_{1-x}N$ band edge emissions for In compositions of 1, 10, 20, 25, and 35%, respectively. Estimation of quantum efficiencies (QEs) for these CMS nanowire LEDs gave a value of 5.8% at 440 nm and 3.9% at 540 nm, both of which are several times better than the QEs reported for nanoscale LEDs and approach InGaN-based SQW thin-film LEDs at similar emission wavelengths. InGaN/GaN multiple quantum disk (MQD) nanocolumn LEDs are fabricated on n-type Si(111) substrates [31.730] as well. The columnar growth was preceded by the deposition of GaN dots. The latter was obtained by exposing the surface of the wafer to a Ga beam and RF plasma excited nitrogen at 530 °C. In order to attain p-type GaN, growth conditions were changed to those suitable for GaN-Mg doping. Resulting nanocolumn LEDs exhibited diode I–V characteristics with a typical turn-on voltage of 2.5–3 V at room temperature [31.711]. With this process, functional LEDs emitting in the entire visible spectrum were demonstrated.

Regardless of the growth direction of the NWs, the junction area between InGaN and GaN is reduced. Therefore, strain along the direction perpendicular to the growth is relaxed. Then a lower density of defects and weaker piezoelectric polarization-induced fields are expected, which is an advantage in comparison with InGaN-GaN quantum wells in planar structures where strain degrades the internal quantum efficiency (IQE) of the LED. In contrast, and in addition to a higher extraction efficiency (because of the NW aspect ratio), NWs exhibit an improved IQE. By way of background, white LEDs are commonly achieved by blue LED pumping a yellow phosphor-dye and leaking through it [31.731], a technique where a blue LED chip is packaged with a precise phosphor arrangement. As a result, blue light is converted to white light. *Nguyen* et al. [31.606, 732] obtained phosphor-free nanowire white light LEDs by the incorporation of different In content levels in stacked InGaN/GaN QWs and the use of an p-doped AlGaN electron blocking layer between the active region and the uppermost NW layer, the p-GaN layer. The authors attained stable white light emission, which was attributed to the large variation of QW In composition,

uniform carrier distribution in the LED active region, and reduced quantum confinement stark effect [31.733]. Also, the authors claim a negligible degradation up to $\approx 2200\,\mathrm{A/cm^2}$.

Lasers have also been attained in NWs, albeit with optical pumping at this stage. The possibility to grow NWs on Si wafers paves the way for their integration with very-large-scale integration circuits (VLSIs) if suitable applications can be visualized. Along these lines, recent investigations have focused on making NW lasers compatible with VLSI circuits. The integration of optics and digital electronics in the same chip is of great interest in high-speed communication systems, fiber optic communication, and in all the relevant potential applications where optoelectronic at the nanometer scale is required. The reduction of laser dimensions is associated with some beneficial features, such as low-threshold, high efficiency, and low power consumption, all of which are difficult to achieve with VCSELs. It should be noted that group III nitride NW lasers under electrical injection at room temperature and continuous wave face considerable challenges. Carrier loss mechanisms (nonradiative centers), electron overflow, poor hole transport, thermal management, and poor ohmic contact to the p-GaN layer all need to be overcome in order to fully exploit the potential of group III nitride NW lasers.

Among the studied micro- and nanocavities are Fabry–Pérot [31.665, 669, 717, 734–738], nanoplasmonics [31.739, 740], photonic crystals [31.741], micro stadium lasers [31.666], and ring cavities [31.742]. The Fabry–Pérot (FP) cavity, the simplest one, has been very widely investigated. The NW lasers based on FP cavities consist of two crystalline facets at the ends of the NWs. The optical field propagates along the longitudinal direction of the NW, being amplified and absorbed inside the active region and reflected back by the crystalline facets. Lasing threshold conditions in NWs result from the balance of the round-trip losses and the round-trip gains in the cavity. For details on NW Fabry–Pérot lasers see [31.668].

Optoelectronic devices based on nitrides, such as LEDs and lasers, although commercially available, are still far from being fully exploited from the viewpoint of what GaN has to offer. This is mainly because the material quality, in spite of continual improvement, is still far from being nearly defect-free. In addition, limitations imposed by p-type doping make it difficult to obtain good contacts and provide a sufficient number of holes to match that of electrons in optical devices. As a result, electrical carrier injection is limited. Optically pumped nanolasers have been demonstrated by many groups around the world. However, electrical carrier injection in group III nitride NW lasers is still lacking. To succeed in practice, nitride-based NW lasers need to be electrically driven, and therefore they should feature good electric contacts. Also their manipulation should be well controlled.

31.11 Summary and Conclusions

Group III nitride semiconductors continue to attract a good deal of interest due to their numerous industrial applications. To begin with, AlN exhibits many useful mechanical, electronic, and thermal properties, for example, hardness, resistance to high temperature and caustic chemicals, and high thermal conductivity in crystalline shape, and so on. The wide bandgap is also the reason AlN is touted as an insulating material in semiconductor device applications, for example, AlN has been attempted as surface passivation layer in AlGaN/GaN-based heterojunction field effect transistors (HFETs) with the benefit of better heat dissipation compared to other common passivation materials. Piezoelectric properties also make AlN suitable for surface-acoustic-wave devices and sensor applications. However, the majority of interest in this semiconductor, in the context of electronic and optoelectronic devices, stems from its ability to form alloys with GaN and InN to tune the bandgap, polarization charge, and lattice constant. A few usages of AlGaN alloy are as a barrier layer in AlGaN/GaN HFETs, as an electron blocking layer in InGaN-based LEDs, as buffer layers in AlGaN/GaN HFETs to reduce the buffer leakages, and in deep UV LEDs, and so on. AlN also forms a crucial component of the nitride-based AlInGaN quaternary, which allows tuning of the bandgap independently of the composition over a reasonably wide range of bandgaps. Currently, AlN crystals up to 2 in in diameter are available; however, many challenges still remain that need to be addressed to further exploit its usage in electronic and optoelectronic applications.

Although GaN has been studied far more extensively than the other group III nitrides, there is still a great need for further investigations to approach the level of understanding of technologically important materials such as Si and GaAs. GaN growth still suffers from the insufficient control of impurity levels, defects and dislocations. Although native substrates are commercially available, which can alleviate the above-mentioned challenges to a certain extent, these issues

may remain for a fairly long time when foreign substrates such as sapphire and silicon are used for cost reduction as well as other considerations. These, together with the difficulties in obtaining high-quality p-type doping layers, will certainly slow down the process of further improvements in the performance of GaN-based electronic and optoelectronic devices.

Oddly enough, InN received much of the early attention compared to the other nitride binaries. However it is still difficult to grow high-quality crystalline InN layers. Although InN can be alloyed with GaN, which enables the tuning of the bandgap from $\approx$ 0.7 to ≈ 3.4 eV, the high-In composition InGaN has to be grown at low temperatures, rendering rather low-quality layers. Thus, small-bandgap InN does not escape competition by the existing alternatives: well-characterized/developed semiconductors such as AlGaAs and In (Ga, Al)AsP. Consequently, practical applications of InN may be restricted to its alloys with GaN and AlN, especially low-indium composition alloys, in addition to tandem solar cells, which are very unlikely to be successful. The growth of high-quality InN/high-indium-composition alloys and the enumeration of their fundamental physical properties remain, for the present, a scientific enterprise.

32. Electron Transport Within III-V Nitride Semiconductors

Stephen K. O'Leary, Poppy Siddiqua, Walid A. Hadi, Brian E. Foutz, Michael S. Shur, Lester F. Eastman†

The III-V nitride semiconductors, gallium nitride, aluminum nitride, and indium nitride, have been recognized as promising materials for novel electronic and optoelectronic device applications for some time now. Since informed device design requires a firm grasp of the material properties of the underlying electronic materials, the electron transport that occurs within these III–V nitride semiconductors has been the focus of considerable study over the years. In an effort to provide some perspective on this rapidly evolving field, in this paper we review analyses of the electron transport within these III–V nitride semiconductors. In particular, we discuss the evolution of the field, compare and contrast results obtained by different researchers, and survey the more recent literature. In order to narrow the scope of this chapter, we will primarily focus on the electron transport within bulk wurtzite gallium nitride, aluminum nitride, and indium nitride for the purposes of this review. Most of our discussion will focus on results obtained from our ensemble semi-classical three-valley Monte Carlo simulations of the electron transport within these materials, our results conforming with state-of-the-art III–V nitride semiconductor orthodoxy. Steady-state and transient electron transport results are presented. We conclude our discussion by presenting some recent developments on the electron transport within these materials.

The III–V nitride semiconductors, gallium nitride (GaN), aluminum nitride (AlN), and indium nitride (InN), have been known as promising materials for novel electronic and optoelectronic device applications for some time now [32.1–4]. In terms of electronics, their wide energy gaps, large breakdown fields, high thermal conductivities, and favorable electron transport characteristics, make GaN, AlN, and InN, and alloys of these materials, ideally suited for novel high-power and high-frequency electron device applications. On the optoelectronics front, the direct nature of the energy gaps associated with GaN, AlN, and InN, make this family of materials, and its alloys, well suited for novel optoelectronic device applications in the visible and ultraviolet frequency range. While initial efforts to study these materials were hindered by growth diffi-

culties, recent improvements in material quality have made the realization of a number of III–V nitride semiconductor-based electronic [32.5–9] and optoelectronic [32.9–12] devices possible. These developments have fuelled considerable interest in these III–V nitride semiconductors.

In order to analyze and improve the design of III–V nitride semiconductor-based devices, an understanding of the electron transport that occurs within these materials is necessary. Electron transport within bulk GaN, AlN, and InN has been examined extensively over the years [32.13–32]. Unfortunately, uncertainty in the material parameters associated with GaN, AlN, and InN remains a key source of ambiguity in the analysis of the electron transport within these materials [32.32]. In addition, some experimental [32.33] and theoretical [32.34] developments have cast doubt upon the validity of widely accepted notions upon which our understanding of the electron transport mechanisms within the III–V nitride semiconductors, GaN, AlN, and InN, has evolved. Another confounding matter is the sheer volume of research activity being performed on the electron transport within these materials, presenting the researcher with a dizzying array of seemingly disparate approaches and results. Clearly, at this critical juncture at least, our understanding of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, remains in a state of flux.

In order to provide some perspective on this rapidly evolving field, we aim to review analyses of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, within this chapter. In particular, we will discuss the evolution of the field and survey the more recent literature. In order to narrow the scope of this review, we will primarily focus on the electron transport within bulk wurtzite GaN, AlN, and InN for the purposes of this chapter. Most of our discussion will focus upon results obtained from our ensemble semi-classical three-valley Monte Carlo simulations of the electron transport within these materials, our results conforming with state-of-the-art III–V nitride semiconductor orthodoxy. We hope that researchers in the field will find this review useful and informative.

We begin our review with the Boltzmann transport equation, which underlies most analyses of the electron transport within semiconductors. The ensemble semi-classical three-valley Monte Carlo simulation approach that we employ in order to solve this Boltzmann transport equation is then discussed. The material parameters corresponding to bulk wurtzite GaN, AlN, and InN are then presented. We then use these material parameter selections and our ensemble semi-classical three-valley Monte Carlo simulation approach to determine the nature of the steady-state and transient electron transport within the III–V nitride semiconductors. Finally, we present some developments on the electron transport within these materials.

This chapter is organized in the following manner. In Sect. 32.1, we present the Boltzmann transport equation and our ensemble semi-classical three-valley Monte Carlo simulation approach that we employ in order to solve this equation for the III–V nitride semiconductors, GaN, AlN, and InN. The material parameters, corresponding to bulk wurtzite GaN, AlN, and InN, are also presented in Sect. 32.1, these material parameters being updated for the specific case of wurtzite InN. Then, in Sect. 32.2, using results obtained from our ensemble semi-classical three-valley Monte Carlo simulations of the electron transport within these III–V nitride semiconductors, we study the nature of the steady-state electron transport that occurs within these materials. Transient electron transport within the III–V nitride semiconductors is also discussed in Sect. 32.2. A review of the III–V nitride semiconductor electron transport literature, in which the evolution of the field is discussed and a survey of the more recent literature is presented, is then featured in Sect. 32.3. Finally, conclusions are provided in Sect. 32.4.

32.1 Electron Transport Within Semiconductors and the Monte Carlo Simulation Approach

The electrons within a semiconductor are in a perpetual state of motion. In the absence of an applied electric field, this motion arises as a result of the thermal energy that is present, and is referred to as thermal motion. From the perspective of an individual electron, thermal motion may be viewed as a series of trajectories, interrupted by a series of random scattering events. Scattering may arise as a result of interactions with the lattice atoms, impurities, other electrons, and defects. As these interactions lead to electron trajectories in all possible directions, i. e., there is no preferred direction, while individual electrons will move from one location to another, when taken as an ensemble, and assuming that the electrons are in thermal equilibrium, the overall electron distribution will remain static. Accordingly, no net current flow occurs.

With the application of an applied electric field $\boldsymbol{E}$ each electron in the ensemble will experience a force,

$-q\boldsymbol{E}$, where q denotes the magnitude of the electron charge. While this force may have a negligible impact upon the motion of any given individual electron, taken as an ensemble, the application of such a force will lead to a net aggregate motion of the electron distribution. Accordingly, a net current flow will occur, and the overall electron ensemble will no longer be in thermal equilibrium. This movement of the electron ensemble in response to an applied electric field, in essence, represents the fundamental issue at stake when we study the electron transport within a semiconductor.

In this section, we provide a brief tutorial on the issues at stake in our analysis of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN. We begin our analysis with an introduction to the Boltzmann transport equation. This equation describes how the electron distribution function evolves under the action of an applied electric field, and underlies the electron transport within bulk semiconductors. We then introduce the Monte Carlo simulation approach to solving this Boltzmann transport equation, focusing on the ensemble semi-classical three-valley Monte Carlo simulation approach used in our simulations of the electron transport within the III–V nitride semiconductors. Finally, we present the material parameters corresponding to bulk wurtzite GaN, AlN, and InN.

This section is organized in the following manner. In Sect. 32.1.1, the Boltzmann transport equation is introduced. Then, in Sect. 32.1.2, our ensemble semi-classical three-valley Monte Carlo simulation approach to solving this Boltzmann transport equation is presented. Finally, in Sect. 32.1.3, our material parameter selections, corresponding to bulk wurtzite GaN, AlN, and InN, are presented.

32.1.1 The Boltzmann Transport Equation

An electron ensemble may be characterized by its distribution function $f(\boldsymbol{r},\boldsymbol{p},t)$, where $\boldsymbol{r}$ denotes the position, $\boldsymbol{p}$ represents the momentum, and t indicates time. The response of this distribution function to an applied electric field $\boldsymbol{E}$ is the issue at stake when one investigates the electron transport within a semiconductor. When the dimensions of the semiconductor are large, and quantum effects are negligible, the ensemble of electrons may be treated as a continuum, so the corpuscular nature of the individual electrons within the ensemble, and the attendant complications which arise, may be neglected. In such a circumstance, the evolution of the distribution function $f(\boldsymbol{r},\boldsymbol{p},t)$ may be determined using the Boltzmann transport equation. In contrast, when the dimensions of the semiconductor are small, and quantum effects are significant, then the Boltzmann transport equation, and its continuum description of the electron ensemble, is no longer valid. In such a case, it is necessary to adopt quantum transport methods in order to study the electron transport within the semiconductor [32.35].

For the purposes of this analysis, we will focus on the electron transport within bulk semiconductors, i. e., semiconductors of sufficient dimensions so that the Boltzmann transport equation is valid. *Ashcroft* and *Mermin* [32.36] demonstrated that this equation can be expressed as

$$\frac{\partial f}{\partial t} = -\dot{\boldsymbol{p}}\cdot\nabla_{\mathrm{p}} f - \dot{\boldsymbol{r}}\cdot\nabla_{\mathrm{r}} f + \left.\frac{\partial f}{\partial t}\right|_{\mathrm{scat}} . \tag{32.1}$$

The first term on the right-hand side of (32.1) represents the change in the distribution function due to external forces applied to the system. The second term on the right-hand side of (32.1) accounts for the electron diffusion which occurs. The final term on the right-hand side of (32.1) describes the effects of scattering.

Owing to its fundamental importance in the analysis of the electron transport within semiconductors, a number of techniques have been developed over the years in order to solve the Boltzmann transport equation. Approximate solutions to the Boltzmann transport equation, such as the displaced Maxwellian distribution function approach of *Ferry* [32.14] and *Das* and *Ferry* [32.15] and the nonstationary charge transport analysis of *Sandborn* et al. [32.37], have proven useful. Low-field approximate solutions have also proven elementary and insightful [32.17, 20, 38]. A number of these techniques have been applied to the analysis of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN [32.14, 15, 17, 20, 38, 39]. Alternatively, more sophisticated techniques have been developed which solve the Boltzmann transport equation directly. These techniques, while allowing for a rigorous solution of the Boltzmann transport equation, are rather involved, and require intense numerical analysis. They are further discussed by *Nag* [32.40].

For studies of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, by far the most common approach to solving the Boltzmann transport equation has been the ensemble semi-classical Monte Carlo simulation approach. Of the III–V nitride semiconductors, the electron transport within GaN has been studied the most extensively using this ensemble Monte Carlo simulation approach [32.13, 16, 18, 19, 21, 22, 27, 29, 32], with AlN [32.24, 25, 29] and InN [32.23, 28, 29, 31] less so. The Monte Carlo simulation approach has also been used to study the electron transport within the two-dimensional electron gas of the AlGaN/GaN interface which occurs in high electron

mobility AlGaN/GaN field-effect transistors [32.41, 42].

At this point, it should be noted that the complete solution of the Boltzmann transport equation requires the resolution of both steady-state and transient responses. Steady-state electron transport refers to the electron transport that occurs long after the application of an applied electric field, i. e., once the electron ensemble has settled to a new equilibrium state (we are not necessarily referring to thermal equilibrium here, since thermal equilibrium is only achieved in the absence of an applied electric field). As the distribution function is difficult to visualize quantitatively, researchers typically study the dependence of the electron drift velocity (the average electron velocity determined by statistically averaging over the entire electron ensemble) on the applied electric field in the analysis of steady-state electron transport; in other words, they determine the velocity–field characteristic. Transient electron transport, by way of contrast, refers to the transport that occurs while the electron ensemble is evolving into its new equilibrium state. Typically, it is characterized by studying the dependence of the electron drift velocity on the time elapsed, or the distance displaced, since the electric field was initially applied. Both steady-state and transient electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, are reviewed within this chapter.

32.1.2 Our Ensemble Semi-Classical Monte Carlo Simulation Approach

For the purposes of our analysis of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, we employ ensemble semi-classical Monte Carlo simulations. A three-valley model for the conduction band is employed. Nonparabolicity is considered in the lowest conduction band valley, this nonparabolicity being treated through the application of the Kane model [32.43].

In the Kane model, the energy band of the Γ valley is assumed to be nonparabolic, spherical, and of the form

$$\frac{\hbar^2 k^2}{2m^*} = E\,(1+\alpha E)\,, \tag{32.2}$$

where $\hbar k$ denotes the magnitude of the crystal momentum, E represents the energy above the minimum, m^* is the effective mass, and the nonparabolicity coefficient α is given by

$$\alpha = \frac{1}{E_g}\left(1-\frac{m^*}{m_e}\right)^2\,, \tag{32.3}$$

where m_e and E_g denote the free electron mass and the energy gap, respectively [32.43].

The scattering mechanisms considered in our analysis are:

1. Ionized impurity
2. Polar optical phonon
3. Piezoelectric [32.44, 45]
4. Acoustic deformation potential.

Intervalley scattering is also considered. Piezoelectric scattering is treated using the well established zinc blende scattering rates, and so a suitably transformed piezoelectric constant, e_{14}, must be selected. This may be achieved through the transformation suggested by *Bykhovski* et al. [32.44, 45]. We also assume that all donors are ionized and that the free electron concentration is equal to the dopant concentration. The motion of three thousand electrons is examined in our steady-state electron transport simulations, while the motion of ten thousand electrons is considered in our transient electron transport simulations. The crystal temperature is set to 300 K and the doping concentration is set to $10^{17}\,\mathrm{cm}^{-3}$ in all cases, unless otherwise specified. Electron degeneracy effects are accounted for by means of the rejection technique of *Lugli* and *Ferry* [32.46]. Electron screening is also accounted for following the Brooks–Herring method [32.47]. Further details of our approach are discussed in the literature [32.16, 21–24, 29, 32, 48].

32.1.3 Parameter Selections for Bulk Wurtzite GaN, AlN, and InN

The material parameter selections, used for our simulations of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, are tabulated in Table 32.1. These parameter selections are the same as those employed by *Foutz* et al. [32.29], with the exception of the case of InN, whose material parameters have been updated [32.49, 50]; following the lead of *Polyakov* et al. [32.50], the parameters corresponding to InN are as set by *Hadi* et al. [32.49]. While the band structures corresponding to bulk wurtzite GaN, AlN, and InN are still not agreed upon, the band structures of *Lambrecht* and *Segall* [32.51] are adopted for the purposes of this analysis except for the case of InN; for the case of InN, following the lead of *Polyakov* et al. [32.50], the band structure is as set by *Hadi* et al. [32.49]. For the case of bulk wurtzite GaN, the analysis of *Lambrecht* and *Segall* [32.51] suggests that the lowest point in the conduction band is located at the center of the Brillouin zone, at the Γ point, the first upper conduction band valley minimum also occurring at the Γ point, 1.9 eV above the lowest point

Table 32.1 The material parameter selections corresponding to bulk wurtzite GaN, AlN, and InN. (These parameter selections are from *Foutz* et al. [32.29] and *Hadi* et al. [32.49])

Parameter	GaN	AlN	InN
Mass density (g/cm^3)	6.15	3.23	6.81
Longitudinal sound velocity (cm/s)	6.56×10^5	9.06×10^5	6.24×10^5
Transverse sound velocity (cm/s)	2.68×10^5	3.70×10^5	2.55×10^5
Acoustic deformation potential (eV)	8.3	9.5	7.1
Static dielectric constant	8.9	8.5	15.3
High-frequency dielectric constant	5.35	4.77	8.4
Effective mass (Γ_1 valley)	$0.20\,m_e$	$0.48\,m_e$	$0.04\,m_e$
Piezoelectric constant, e_{14} (C/cm^2)	3.75×10^{-5}	9.2×10^{-5}	3.75×10^{-5}
Direct energy gap (eV)	3.39	6.2	0.7
Optical phonon energy (meV)	91.2	99.2	73.0
Intervalley deformation potentials (eV/cm)	10^9	10^9	10^9
Intervalley phonon energies (meV)	91.2	99.2	73.0

Table 32.2 The band structure parameter selections corresponding to bulk wurtzite GaN, AlN, and InN. (These parameter selections are from *Foutz* et al. [32.29] and *Hadi* et al. [32.49]. These parameters were originally determined from the band structural calculations of *Polyakov* et al. [32.50] and *Lambrecht* and *Segall* [32.51])

		Valley number		
		1	2	3
GaN	Valley location	Γ_1	Γ_2	L–M
	Valley degeneracy	1	1	6
	Effective mass	$0.2\,m_e$	m_e	m_e
	Intervalley energy separation (eV)	–	1.9	2.1
	Energy gap (eV)	3.39	5.29	5.49
	Nonparabolicity (eV^{-1})	0.189	0.0	0.0
AlN	Valley location	Γ_1	L-M	K
	Valley degeneracy	1	6	2
	Effective mass	$0.48\,m_e$	m_e	m_e
	Intervalley energy separation (eV)	–	0.7	1.0
	Energy gap (eV)	6.2	6.9	7.2
	Nonparabolicity (eV^{-1})	0.044	0.0	0.0
InN	Valley location	Γ_1	Γ_2	L–M
	Valley degeneracy	1	1	6
	Effective mass	$0.04\,m_e$	$0.25\,m_e$	m_e
	Intervalley energy separation (eV)	–	1.775	2.709
	Energy gap (eV)	0.7	2.475	3.409
	Nonparabolicity (eV^{-1})	1.43	0.0	0.0

in the conduction band, the second upper conduction band valley minima occurring along the symmetry lines between the L and M points, 2.1 eV above the lowest point in the conduction band; see Table 32.2. The other materials considered in this analysis have suitably modified band structures, as described in Table 32.2. We ascribe an effective mass equal to the free electron mass m_e to all of the upper conduction band valleys, with the exception of the case of InN, the values suggested by *Polyakov* et al. [32.50] and *Hadi* et al. [32.49] being employed for the specific case of this material. The nonparabolicity coefficient α corresponding to each upper conduction band valley is set to zero, so the upper conduction band valleys are assumed to be completely parabolic. For our simulations of the electron transport within gallium arsenide (GaAs), the material parameters employed are mostly from *Littlejohn* et al. [32.52], although it should be noted that the mass density, the energy gap, and the sound velocities are from *Blakemore* [32.53].

It should be noted that the energy gap associated with InN has been the subject of some controversy since 2002. The pioneering experimental results of *Tansley* and *Foley* [32.54], reported in 1986, suggested that InN has an energy gap of 1.89 eV. This value has been used extensively in Monte Carlo simulations of the electron transport within this material since that time [32.23, 28, 29, 31]; typically, the influence of the energy gap on the electron transport occurs through its impact on the nonparabolicity coefficient α. In 2002,

Davydov et al. [32.55], *Wu* et al. [32.56], and *Matsuoka* et al. [32.57], presented experimental evidence which instead suggests a considerably smaller energy gap for InN, around 0.7 eV. For the purposes of this analysis, the revised value for the InN energy gap is employed; the sensitivity of the velocity–field characteristic associated with bulk wurtzite GaN to variations in the nonparabolicity coefficient α has been explored, in detail, by *O'Leary* et al. [32.32].

The band structure associated with bulk wurtzite GaN has also been the focus of some controversy. In particular, *Brazel* et al. [32.58] employed ballistic electron emission microscopy measurements in order to demonstrate that the first upper conduction band valley occurs only 340 meV above the lowest point in the conduction band for this material. This contrasts rather dramatically with more traditional results, such as the calculation of *Lambrecht* and *Segall* [32.51], which instead suggest that the first upper conduction band valley minimum within wurtzite GaN occurs about 2 eV above the lowest point in the conduction band. Clearly, this will have a significant impact upon the results. While the results of *Brazel* et al. [32.58] were reported in 1997, electron transport simulations adopted the more traditional intervalley energy separation of about 2 eV until relatively recently. Accordingly, we have adopted the more traditional intervalley energy separation for the purposes of our present analysis. The sensitivity of the velocity–field characteristic associated with bulk wurtzite GaN to variations in the intervalley energy separation has been explored, in detail, by *O'Leary* et al. [32.32].

32.2 Steady-State and Transient Electron Transport Within Bulk Wurtzite GaN, AlN, and InN

The current interest in the III–V nitride semiconductors, GaN, AlN, and InN, is primarily being fuelled by the tremendous potential of these materials for novel electronic and optoelectronic device applications. With the recognition that informed electronic and optoelectronic device design requires a firm understanding of the nature of the electron transport within these materials, electron transport within the III–V nitride semiconductors has been the focus of intensive investigation over the years. The literature abounds with studies on steady-state and transient electron transport within these materials [32.13–34, 38, 39, 41, 42, 48]. As a result of this intense flurry of research activity, novel III–V nitride semiconductor-based devices are starting to be deployed in today's commercial products. Future developments in the III–V nitride semiconductor field will undoubtedly require an even deeper understanding of the electron transport mechanisms within these materials.

In the previous section, we presented details of the Monte Carlo simulation approach that we employ for the analysis of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN. In this section, an overview of the steady-state and transient electron transport results we obtained from these Monte Carlo simulations is provided. In the first part of this section, we focus upon bulk wurtzite GaN. In particular, the velocity–field characteristic associated with this material will be examined in detail. Then, an overview of our steady-state electron transport results, corresponding to the three III–V nitride semiconductors under consideration in this analysis, i. e., GaN, AlN, and InN, will be given, and a comparison with the more conventional III–V compound semiconductor, GaAs, will be presented. A comparison between the temperature dependence of the velocity–field characteristics associated with GaN and GaAs will then be provided, and our Monte Carlo results will be used to account for the differences in behavior. A similar analysis will be presented for the doping dependence. Next, detailed simulation results for AlN and InN will be presented. Finally, the transient electron transport that occurs within the III–V nitride semiconductors, GaN, AlN, and InN, is determined and compared with that in GaAs.

This section is organized in the following manner. In Sect. 32.2.1, the velocity–field characteristic associated with bulk wurtzite GaN is presented and analyzed. Then, in Sect. 32.2.2, the velocity-field characteristics associated with the III–V nitride semiconductors under consideration in this analysis will be compared and contrasted with that of GaAs. The sensitivity of the velocity–field characteristic associated with bulk wurtzite GaN to variations in the crystal temperature will then be examined in Sect. 32.2.3, and a comparison with that corresponding to GaAs presented. In Sect. 32.2.4, the sensitivity of the velocity–field characteristic associated with bulk wurtzite GaN to variations in the doping concentration level will be explored, and a comparison with that corresponding to GaAs presented. The velocity–field characteristics associated with AlN and InN will then be examined in

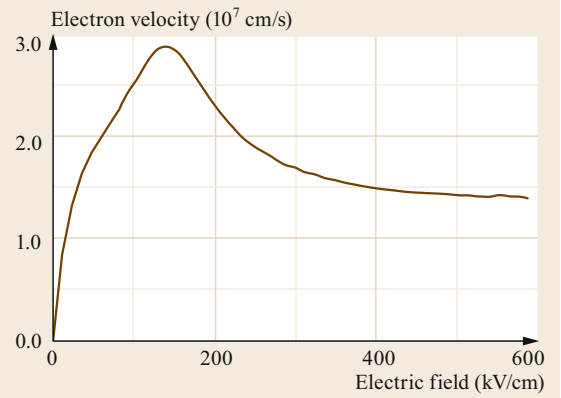

Fig. 32.1 The velocity–field characteristic associated with bulk wurtzite GaN. Like many other compound semiconductors, the electron drift velocity reaches a peak, and at higher applied electric fields it decreases until it saturates

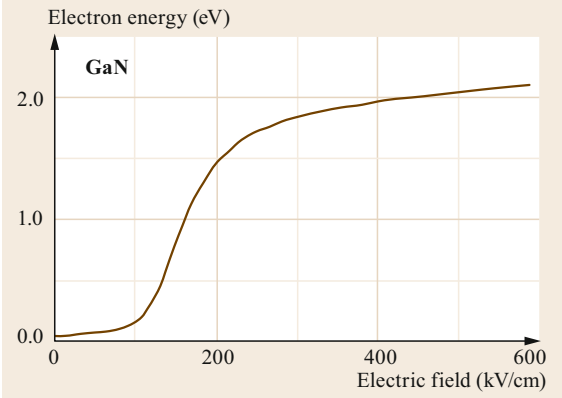

Fig. 32.2 The average electron energy as a function of the applied electric field for bulk wurtzite GaN. Initially, the average electron energy remains low, only slightly higher than the thermal energy, $\frac{3}{2}k_{\mathrm{B}}T$. At 100 kV/cm, however, the average electron energy increases dramatically. This increase is due to the fact that the polar optical phonon scattering mechanism can no longer absorb all of the energy gained from the applied electric field

Sect. 32.2.5 and Sect. 32.2.6, respectively. Our transient electron transport analysis results are then presented in Sect. 32.2.7. Finally, the conclusions of this electron transport analysis are summarized in Sect. 32.2.8.

32.2.1 Steady-State Electron Transport Within Bulk Wurtzite GaN

Our examination of results begins with GaN, the most commonly studied III–V nitride semiconductor. The velocity–field characteristic associated with this material is presented in Fig. 32.1. This result was obtained through our Monte Carlo simulations of the electron transport within this material for the bulk wurtzite GaN parameter selections specified in Table 32.1 and Table 32.2; the crystal temperature was set to 300 K and the doping concentration to $10^{17}\,\mathrm{cm}^{-3}$. We see that for applied electric fields in excess of 140 kV/cm, the electron drift velocity decreases, eventually saturating at 1.4×10^7 cm/s for high applied electric fields. By examining the results of our Monte Carlo simulation further, an understanding of this result becomes clear.

First, we discuss the results at low applied electric fields, i. e., applied electric fields of less than 30 kV/cm. This is referred to as the linear regime of electron transport as the electron drift velocity is well characterized by the low-field electron drift mobility μ in this regime, i. e., a linear low-field electron drift velocity dependence on the applied electric field, i. e., $v_{\mathrm{d}} = \mu \boldsymbol{E}$, applies in this regime. Examining the distribution function for this regime, we find that it is very similar to the zero-field distribution function with a slight shift in the direction opposite to the applied electric field. In this regime, the average electron energy remains relatively low, with most of the energy gained from the applied electric field being transferred into the lattice through polar optical phonon scattering.

If we examine the average electron energy as a function of the applied electric field, shown in Fig. 32.2, we see that there is a sudden increase at around 100 kV/cm. In order to understand why this increase occurs, we note that the dominant energy loss mechanism for many of the III–V compound semiconductors, including GaN, is polar optical phonon scattering. When the applied electric field is less than 100 kV/cm, all of the energy that the electrons gain from the applied electric field is lost through polar optical phonon scattering. The other scattering mechanisms, i. e., ionized impurity scattering, piezoelectric scattering, and acoustic deformation potential scattering, do not remove energy from the electron ensemble: they are elastic scattering mechanisms. However, beyond a certain critical applied electric field strength, the polar optical phonon scattering mechanism can no longer remove all of the energy gained from the applied electric field. Other scattering mechanisms must start to play a role if the electron ensemble is to remain in equilibrium. The average electron energy increases until intervalley scattering begins and an energy balance is re-established.

As the applied electric field is increased beyond 100 kV/cm, the average electron energy increases un-

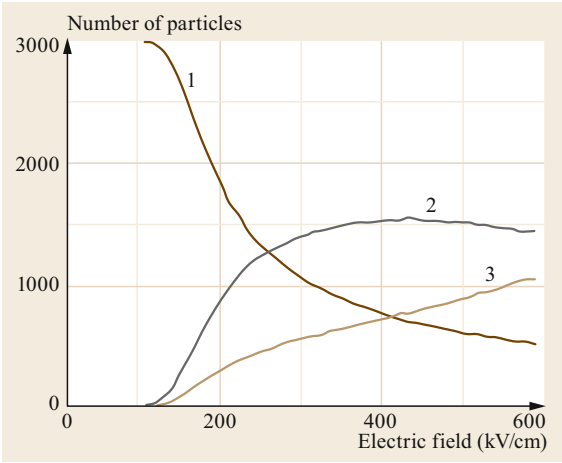

Fig. 32.3 The valley occupancy as a function of the applied electric field for the case of bulk wurtzite GaN. Soon after the average electron energy increases, electrons begin to transfer to the upper valleys of the conduction band. Three thousand electrons were employed for this simulation. The valleys are labeled 1, 2, and 3, in accordance with their energy minima; the lowest energy valley is valley 1, the next higher energy valley is valley 2, and the highest energy valley is valley 3

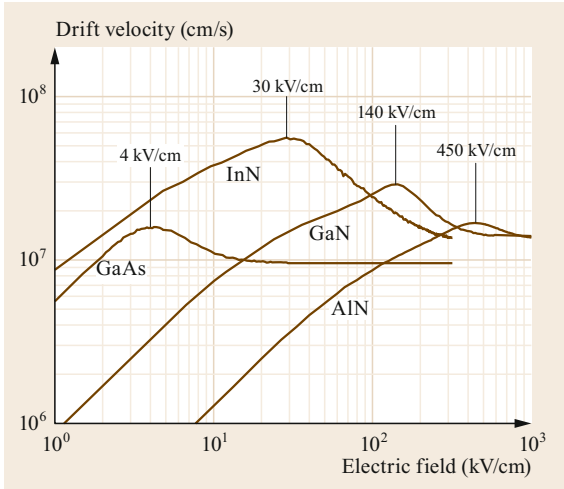

Fig. 32.4 A comparison of the velocity–field characteristics associated with the III–V nitride semiconductors, GaN, AlN, and InN, with that associated with GaAs. (After [32.29], with permission from AIP)

til a substantial fraction of the electrons have acquired enough energy in order to transfer into the upper valleys. As the effective mass of the electrons in the upper valleys is greater than that in the lowest valley, the electrons in the upper valleys will be slower. As more electrons transfer to the upper valleys (Fig. 32.3), the electron drift velocity decreases. This accounts for the negative differential mobility observed in the velocity–field characteristic depicted in Fig. 32.1.

Finally, at high applied electric fields, the number of electrons in each valley saturates. It can be shown that in the high-field limit the number of electrons in each valley is proportional to the product of the density of states of that particular valley and the corresponding valley degeneracy. At this point, the electron drift velocity stops decreasing and achieves saturation.

Thus far, electron transport results corresponding to bulk wurtzite GaN have been presented and discussed qualitatively. It should be noted, however, that the same phenomenon that occurs in the velocity–field characteristic associated with GaN also occurs for the other III–V nitride semiconductors, AlN and InN. The importance of polar optical phonon scattering when determining the nature of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, will become even more apparent later, as it will be used to account for much of the electron transport behavior within these materials.

32.2.2 Steady-State Electron Transport: A Comparison of the III–V Nitride Semiconductors with GaAs

Setting the crystal temperature to 300 K and the level of doping to $10^{17}\,\mathrm{cm}^{-3}$, the velocity–field characteristics associated with the III–V nitride semiconductors under consideration in this analysis – GaN, AlN, and InN – are contrasted with that of GaAs in Fig. 32.4. We see that each of these III–V compound semiconductors achieves a peak in its velocity–field characteristic. InN achieves the highest steady-state peak electron drift velocity, $5.6\times10^7\,\mathrm{cm/s}$ at an applied electric field of 30 kV/cm. This contrasts with the case of GaN, $2.9\times10^7\,\mathrm{cm/s}$ at 140 kV/cm, and that of AlN, $1.7\times10^7\,\mathrm{cm/s}$ at 450 kV/cm. For GaAs, the peak electron drift velocity of $1.6\times10^7\,\mathrm{cm/s}$ occurs at a much lower applied electric field than that for the III–V nitride semiconductors (only 4 kV/cm).

32.2.3 Influence of Temperature on the Electron Drift Velocities Within GaN and GaAs

The temperature dependence of the velocity–field characteristic associated with bulk wurtzite GaN is now examined. Figure 32.5a shows how the velocity–field characteristic associated with bulk wurtzite GaN varies as the crystal temperature is increased from 100 to 700 K, in increments of 200 K. The upper limit, 700 K, is chosen as it is the highest operating temperature that may be expected for AlGaN/GaN power devices. To

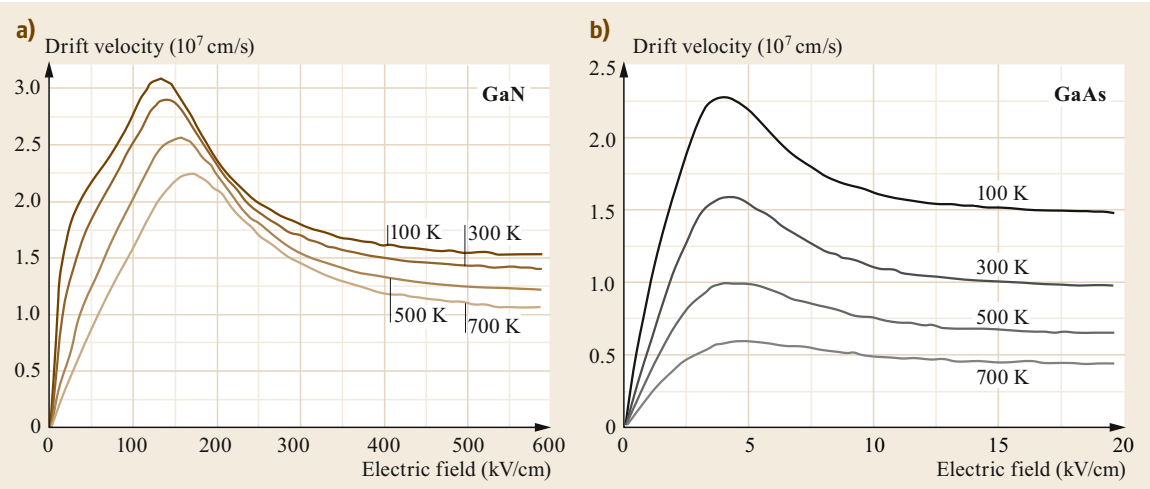

Fig. 32.5a,b A comparison of the temperature dependence of the velocity–field characteristics associated with **(a)** GaN and **(b)** GaAs. GaN maintains a higher electron drift velocity with increased temperatures than GaAs does

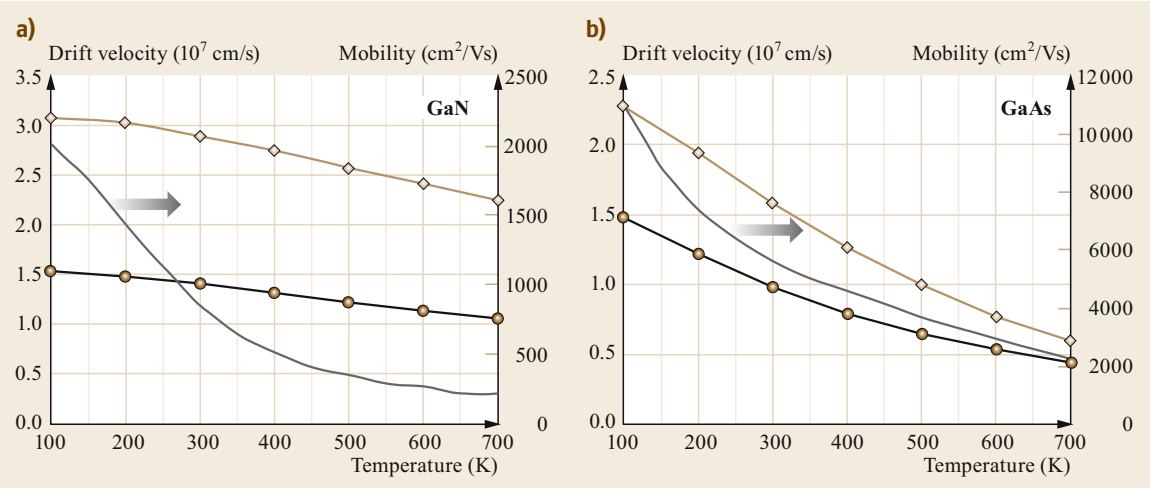

Fig. 32.6a,b A comparison of the temperature dependence of the low-field electron drift mobility (*solid lines*), the peak electron drift velocity (*diamonds*), and the saturation electron drift velocity (*solid points*) for **(a)** GaN and **(b)** GaAs. The low-field electron drift mobility of GaN drops quickly with increasing temperature, but its peak and saturation electron drift velocities are less sensitive to increases in temperature than GaAs

highlight the difference between the III–V nitride semiconductors with more conventional III–V compound semiconductors, such as GaAs, Monte Carlo simulations of the electron transport within GaAs have also been performed under the same conditions as GaN. Figure 32.5b shows the results of these simulations. Note that the electron drift velocity for the case of GaN is much less sensitive to changes in temperature than that associated with GaAs.

To quantify this dependence further, the low-field electron drift mobility, the peak electron drift velocity, and the saturation electron drift velocity are plotted as a function of the crystal temperature in Fig. 32.6, these results being determined from our Monte Carlo simulations of the electron transport within these materials. For both GaN and GaAs, it is found that all of these electron transport metrics diminish as the crystal temperature is increased. As may be seen through an inspection of Fig. 32.5, the peak and saturation electron drift velocities do not drop as much in GaN as they do in GaAs in response to increases in the crystal temperature. The low-field electron drift mobility in GaN, however, is seen to fall quite rapidly with temperature, this drop being particularly severe for tem-

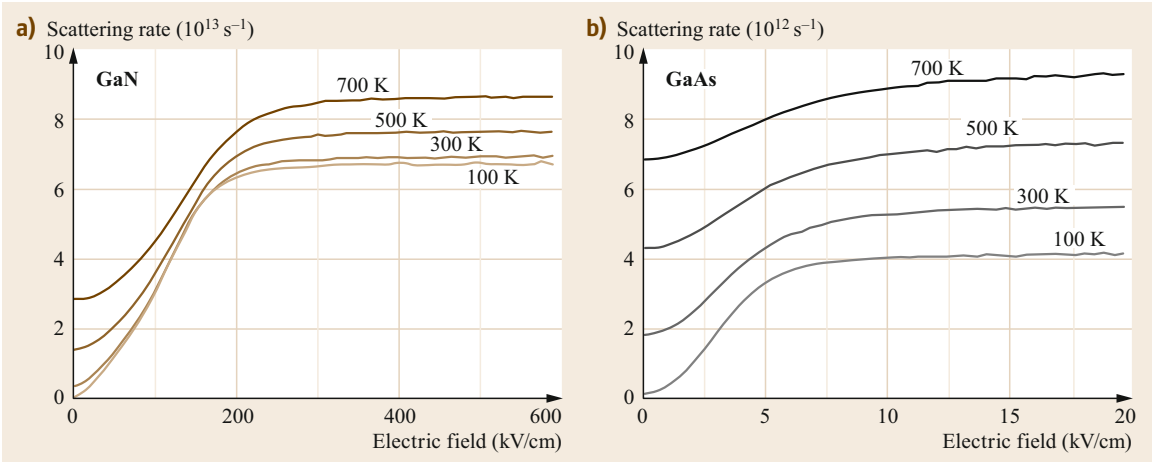

Fig. 32.7a,b A comparison of the polar optical phonon scattering rates as a function of the applied electric field strength for various crystal temperatures for **(a)** GaN and **(b)** GaAs. Polar optical phonon scattering is seen to increase much more quickly with temperature in GaAs

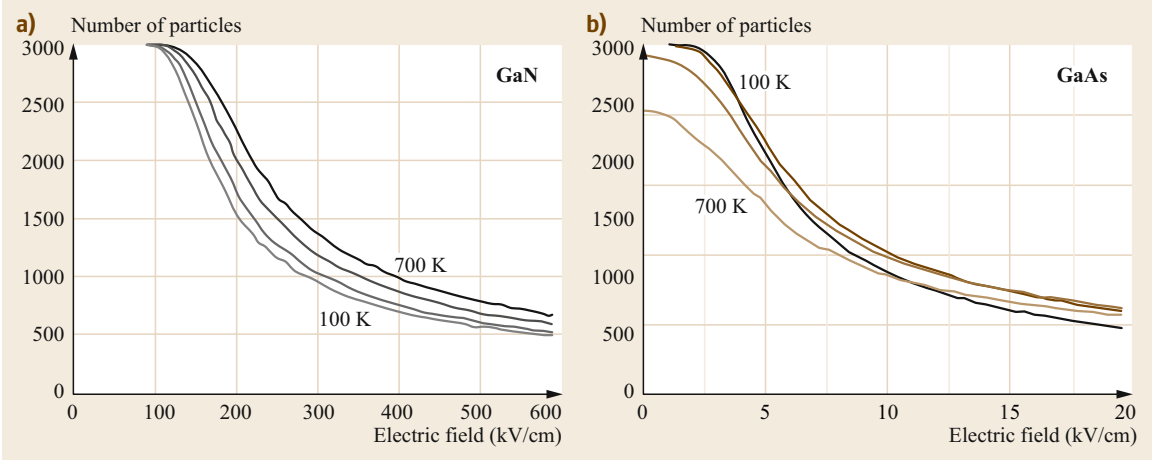

Fig. 32.8a,b A comparison of the number of particles in the lowest energy valley of the conduction band, the Γ valley, as a function of the applied electric field for various crystal temperatures, for the cases of **(a)** GaN and **(b)** GaAs. In GaAs, the electrons begin to occupy the upper valleys much more quickly, causing the electron drift velocity to drop as the crystal temperature is increased. Three thousand electrons were employed for these steady-state electron transport simulations

peratures at and below room temperature. This property will likely have an impact on high-power device performance.

Delving deeper into our Monte Carlo results yields clues into the reason for this variation in temperature dependence. First, we examine the polar optical phonon scattering rate as a function of the applied electric field strength. Figure 32.7 shows that the scattering rate only increases slightly with temperature for the case of GaN, from $6.7\times10^{13}\,\mathrm{s}^{-1}$ at 100 K to $8.6\times10^{13}\,\mathrm{s}^{-1}$ at 700 K, for high applied electric field strengths. Contrast this with the case of GaAs, where the rate increases from $4.0\times10^{12}\,\mathrm{s}^{-1}$ at 100 K to more than twice that amount at 700 K, $9.2\times10^{12}\,\mathrm{s}^{-1}$, at high applied electric field strengths. This large increase in the polar optical phonon scattering rate for the case of GaAs is one reason for the large drop in the electron drift velocity with increasing temperature for the case of GaAs.

A second reason for the variation in temperature dependence of the two materials is the occupancy of the upper valleys, shown in Fig. 32.8. In the case of GaN, the upper valleys begin to become occupied at roughly

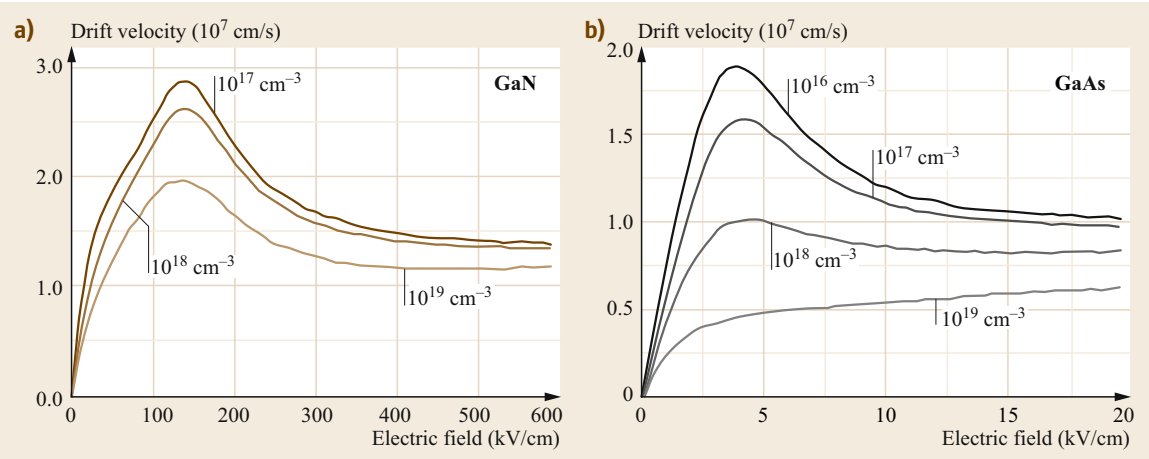

Fig. 32.9a,b A comparison of the dependence of the velocity–field characteristics associated with **(a)** GaN and **(b)** GaAs on the doping concentration. GaN maintains a higher electron drift velocity with increased doping levels than GaAs does

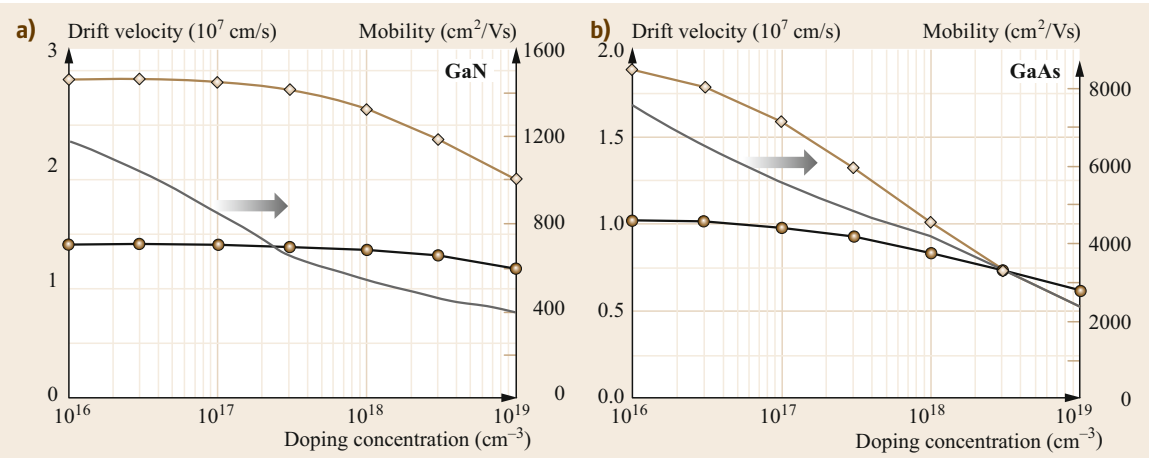

Fig. 32.10a,b A comparison of the low-field electron drift mobility (*solid lines*), the peak electron drift velocity (*diamonds*), and the saturation electron drift velocity (*solid points*) for **(a)** GaN and **(b)** GaAs as a function of the doping concentration. These parameters are more insensitive to increases in doping in GaN than in GaAs

the same applied electric field strength, 100 kV/cm, independent of temperature. For the case of GaAs, however, the upper valleys are at a much lower energy than those in GaN. In particular, while the first upper conduction band valley minimum is 1.9 eV above the lowest point in the conduction band in GaN, the first upper conduction band valley is only 290 meV above the bottom of the conduction band in GaAs [32.53]. As the upper conduction band valleys are so close to the bottom of the conduction band for the case of GaAs, the thermal energy (at 700 K, $k_B T \cong 60$ meV) is enough in order to allow for a small fraction of the electrons to transfer into the upper valleys even before an electric field is applied. When electrons occupy the upper valleys, intervalley scattering and the upper valleys' larger effective masses reduce the overall electron drift velocity. This is another reason why the velocity–field characteristic associated with GaAs is more sensitive to variations in crystal temperature than that associated with GaN.

32.2.4 Influence of Doping on the Electron Drift Velocities Within GaN and GaAs

One parameter that can be readily controlled during the fabrication of semiconductor devices is the doping concentration. Understanding the effect of doping on the resultant electron transport is also important.

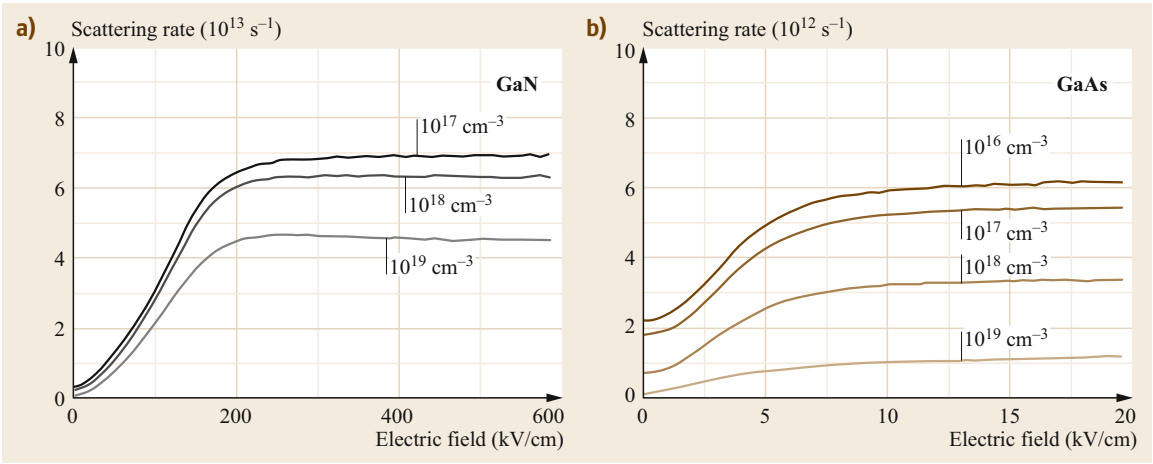

Fig. 32.11a,b A comparison of the polar optical phonon scattering rates as a function of the applied electric field, for both **(a)** GaN and **(b)** GaAs, for various doping concentrations

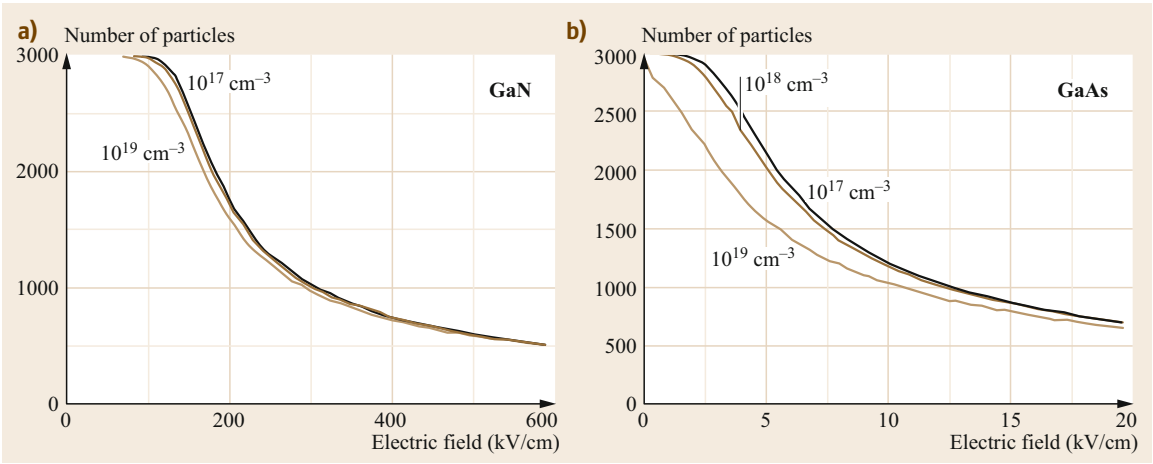

Fig. 32.12a,b A comparison of the number of particles in the lowest valley of the conduction band, the Γ valley, as a function of the applied electric field, for both **(a)** GaN and **(b)** GaAs, for various doping concentration levels. Three thousand electrons were employed for these steady-state electron transport simulations

In Fig. 32.9, the velocity–field characteristic associated with GaN is presented for a number of different doping concentration levels. Once again, three important electron transport metrics are influenced by the doping concentration level: the low-field electron drift mobility, the peak electron drift velocity, and the saturation electron drift velocity; see Fig. 32.10. Our simulation results suggest that for doping concentrations of less than $10^{17}\,\mathrm{cm}^{-3}$, there is very little effect on the velocity–field characteristic for the case of GaN. However, for doping concentrations above $10^{17}\,\mathrm{cm}^{-3}$, the peak electron drift velocity diminishes considerably, from $2.9\times10^{7}\,\mathrm{cm/s}$ for the case of $10^{17}\,\mathrm{cm}^{-3}$ doping to $2.0\times10^{7}\,\mathrm{cm/s}$ for the case of $10^{19}\,\mathrm{cm}^{-3}$ doping. The saturation electron drift velocity within GaN is found to only decrease slightly in response to increases in the doping concentration. The effect of doping on the low-field electron drift mobility is also shown. It is seen that this mobility drops significantly in response to increases in the doping concentration level, from $1200\,\mathrm{cm}^2/(\mathrm{V\,s})$ at $10^{16}\,\mathrm{cm}^{-3}$ doping to $400\,\mathrm{cm}^2/(\mathrm{V\,s})$ at $10^{19}\,\mathrm{cm}^{-3}$ doping.

As we did for temperature, we compare the sensitivity of the velocity-field characteristic associated with GaN to doping with that associated with GaAs. Figure 32.10 shows this comparison. For the case of GaAs, it is seen that the electron drift velocities decrease much more with increased doping than those associated with GaN. In particular, for the case of GaAs, the peak electron drift velocity decreases from

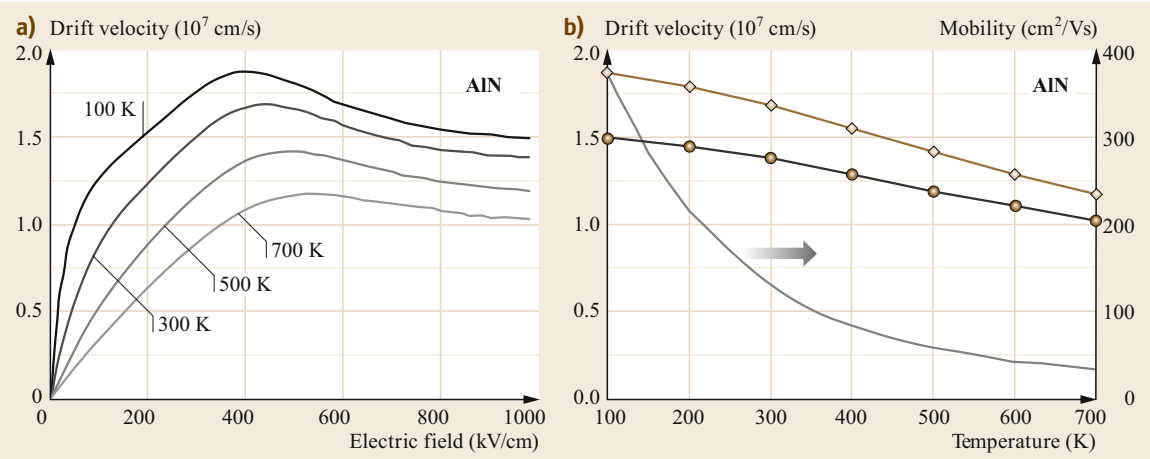

Fig. 32.13 The velocity–field characteristic associated with AlN **(a)** for various crystal temperatures. The trends in the low-field mobility (*solid line*), the peak electron drift velocity (*diamonds*), and the saturation electron drift velocity (*solid points*), are also shown. AlN exhibits its peak electron drift velocity at very high applied electric fields. AlN has the lowest peak electron drift velocity and the lowest low-field electron drift mobility of the III–V nitride semiconductors considered in this analysis **(b)**

1.8×10^7 cm/s at 10^{16} cm^{-3} doping to 0.6×10^7 cm/s at 10^{19} cm^{-3} doping. For GaAs, at the higher doping levels, the peak in the velocity-field characteristic disappears completely for sufficiently high doping concentrations. The saturation electron drift velocity decreases from 1.0×10^7 cm/s at 10^{16} cm^{-3} doping to 0.6×10^7 cm/s at 10^{19} cm^{-3} doping. The low-field electron drift mobility also diminishes dramatically with increased doping, dropping from 7800 cm^2/(V s) at 10^{16} cm^{-3} doping to 2200 cm^2/(V s) at 10^{19} cm^{-3} doping; see Fig. 32.10.

Once again, it is interesting to determine why the doping dependence in GaAs is so much more pronounced than it is in GaN. Again, we examine the polar optical phonon scattering rate and the occupancy of the upper valleys. Figure 32.11 shows the polar optical phonon scattering rates as a function of the applied electric field, for both GaN and GaAs. In this case, however, due to screening effects, the rate drops when the doping concentration is increased. The decrease, however, is much more pronounced for the case of GaAs than for GaN. It is believed that this drop in the polar optical phonon scattering rate allows for upper valley occupancy to occur more quickly in GaAs rather than in GaN (Fig. 32.12). For GaN, electrons begin to occupy the upper valleys at roughly the same applied electric field strength, independent of the doping level. However, for the case of GaAs, the upper valleys are occupied more quickly with greater doping. When the upper valleys are occupied, the electron drift velocity decreases due to intervalley scattering and the larger effective mass of the electrons within the upper valleys.

32.2.5 Electron Transport in AlN

AlN has the largest effective mass of the III–V nitride semiconductors considered in this analysis. Accordingly, it is not surprising that this material exhibits the lowest electron drift velocity and the lowest low-field electron drift mobility. The sensitivity of the velocity–field characteristic associated with AlN to variations in the crystal temperature may be examined by considering Fig. 32.13. As with the case of GaN, the velocity–field characteristic associated with AlN is extremely robust to variations in the crystal temperature. In particular, its peak electron drift velocity, which is 1.8×10^7 cm/s at 100 K, only decreases to 1.2×10^7 cm/s at 700 K. Similarly, its saturation electron drift velocity, which is 1.5×10^7 cm/s at 100 K, only decreases to 1.0×10^7 cm/s at 700 K. The low-field electron drift mobility associated with AlN also diminishes in response to increases in the crystal temperature, from 375 cm^2/(V s) at 100 K to 40 cm^2/(V s) at 700 K.

The sensitivity of the velocity–field characteristic associated with AlN to variations in the doping concentration may be examined by considering Fig. 32.14. It is noted that the variations in the velocity–field characteristic associated with AlN in response to variations in the doping concentration are not as pronounced as those which occur in response to variations in the crystal temperature. Quantitatively, the peak electron drift velocity drops from 1.7×10^7 cm/s at 10^{17} cm^{-3} doping to 1.3×10^7 cm/s at 10^{19} cm^{-3} doping. Similarly, its saturation electron drift velocity drops from 1.4×10^7 cm/s at 10^{17} cm^{-3} doping to 1.2×10^7 cm/s

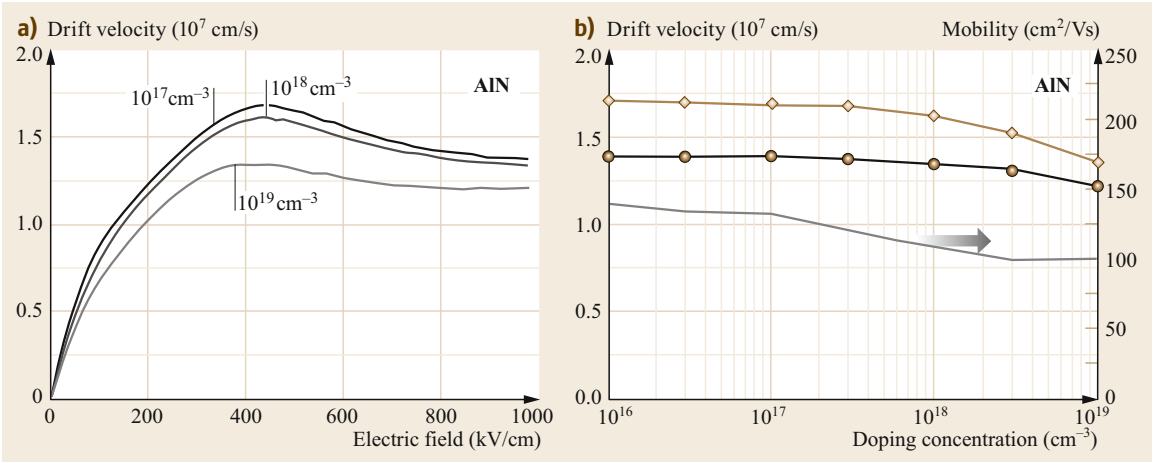

Fig. 32.14 The velocity–field characteristic associated with AlN for various doping concentrations **(a)**. The trends in the low-field electron drift mobility (*solid line*), the peak electron drift velocity (*diamonds*), and the saturation electron drift velocity (*solid points*), are also shown **(b)**

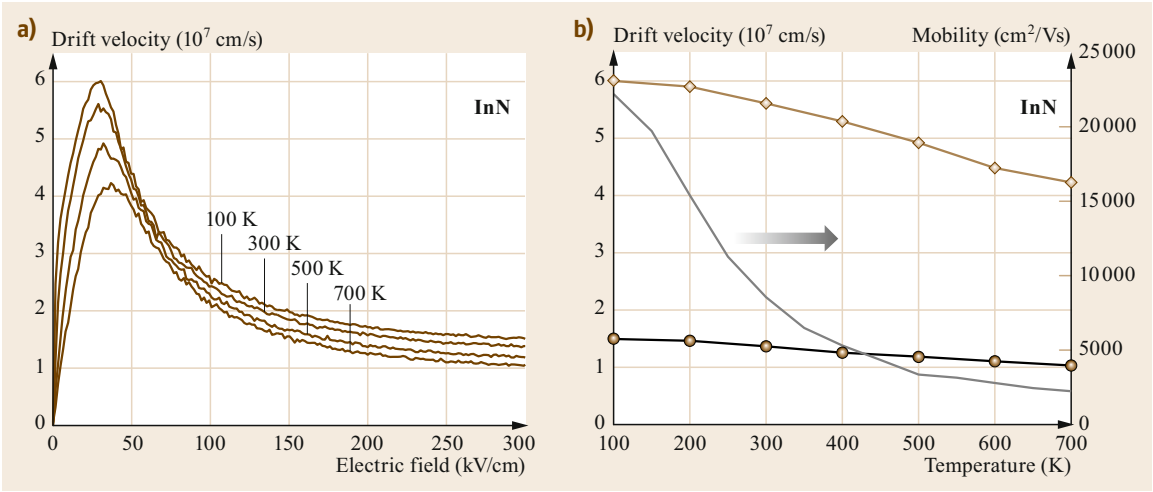

Fig. 32.15 The velocity–field characteristic associated with InN for various crystal temperatures **(a)**. The trends in the low-field electron drift mobility (*solid line*), the peak electron drift velocity (*diamonds*), and the saturation electron drift velocity (*solid points*), are also shown **(b)**. InN has the highest peak electron drift velocity and the highest low-field electron drift mobility of the III–V nitride semiconductors considered in this analysis

at $10^{19}\,\mathrm{cm}^{-3}$ doping. The influence of doping on the low-field electron drift mobility associated with AlN is also observed to be not as pronounced as for the case of crystal temperature. Figure 32.14b shows that the low-field electron drift mobility associated with AlN decreases from $140\,\mathrm{cm}^2/(\mathrm{V\,s})$ at $10^{16}\,\mathrm{cm}^{-3}$ doping to $100\,\mathrm{cm}^2/(\mathrm{V\,s})$ at $10^{19}\,\mathrm{cm}^{-3}$ doping.

32.2.6 Electron Transport in InN

InN has the smallest effective mass of the three III–V nitride semiconductors considered in this analysis. Accordingly, it is not surprising that it exhibits the highest electron drift velocity and the highest low-field electron drift mobility. The sensitivity of the velocity-field characteristic associated with InN to variations in the crystal temperature may be examined by considering Fig. 32.15. As with the cases of GaN and AlN, the velocity–field characteristic associated with InN is extremely robust to increases in the crystal temperature. In particular, its peak electron drift velocity, which is 6.0×10^7 cm/s at 100 K, only decreases to 4.2×10^7 cm/s at 700 K. Similarly, its saturation electron drift velocity, which is 1.5×10^7 cm/s at 100 K, only decreases to

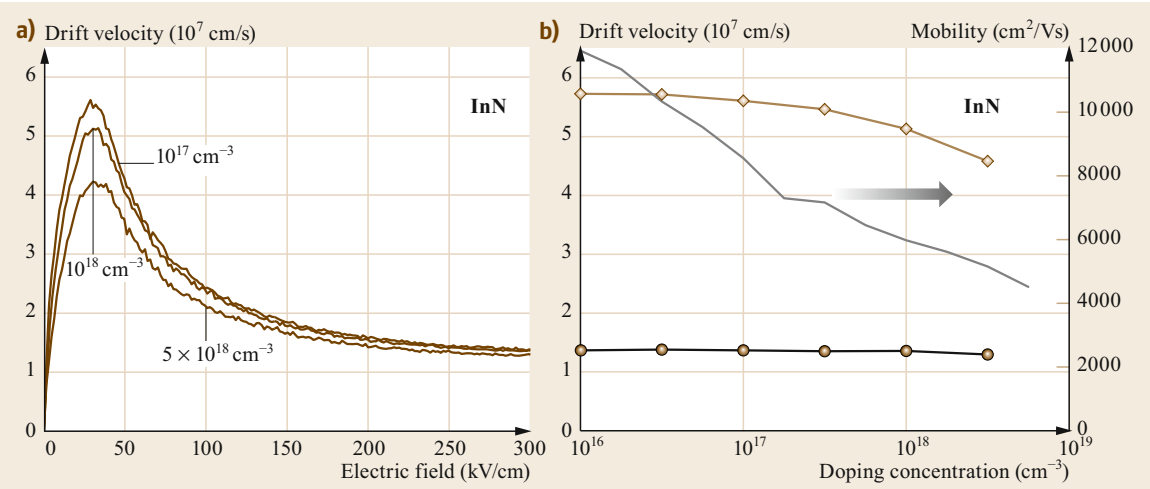

Fig. 32.16 The velocity–field characteristic associated with InN for various doping concentrations **(a)**. The trends in the low-field electron drift mobility (*solid line*), the peak electron drift velocity (*diamonds*), and the saturation electron drift velocity (*solid points*), are also shown **(b)**

1.0×10^7 cm/s at 700 K. The low-field electron drift mobility associated with InN also diminishes in response to increases in the crystal temperature, from about 22 000 cm^2/(V s) at 100 K to below 2300 cm^2/(V s) at 700 K.

The sensitivity of the velocity–field characteristic associated with InN to variations in the doping concentration may be examined by considering Fig. 32.16. These results suggest a similar robustness to the doping concentration for the case of InN. In particular, it is noted that for doping concentrations below 10^{17} cm^{-3}, the velocity–field characteristic associated with InN exhibits very little dependence on the doping concentration. When the doping concentration is increased above 10^{17} cm^{-3}, however, the peak electron drift velocity diminishes. Quantitatively, the peak electron drift velocity decreases from 5.6×10^7 cm/s at 10^{17} cm^{-3} doping to 4.2×10^7 cm/s at 5×10^{18} cm^{-3} doping; a numerical instability occurs for the case of InN at large doping concentrations, owing to its small electron effective mass, and this prevented the determination of a 10^{19} cm^{-3} doping concentration result. The saturation electron drift velocity only drops slightly, however, from 1.4×10^7 cm/s at 10^{17} cm^{-3} doping to 1.3×10^7 cm/s at 5×10^{18} cm^{-3} doping. The low-field electron drift mobility, however, drops significantly with doping, from 12 000 cm^2/(V s) at 10^{16} cm^{-3} doping to 4900 cm^2/(V s) at 5×10^{18} cm^{-3} doping.

32.2.7 Transient Electron Transport

Steady-state electron transport is the dominant electron transport mechanism in devices with larger dimensions. For devices with smaller dimensions, however, transient electron transport must also be considered when evaluating device performance. *Ruch* [32.59] demonstrated, for both silicon and GaAs, that the transient electron drift velocity may exceed the corresponding steady-state electron drift velocity by a considerable margin for appropriate selections of the applied electric field. *Shur* and *Eastman* [32.60] explored the device implications of transient electron transport, and demonstrated that substantial improvements in the device performance can be achieved as a consequence. *Heiblum* et al. [32.61] made the first direct experimental observation of transient electron transport within GaAs. Since then there have been a number of experimental investigations into the transient electron transport within the III–V compound semiconductors [32.62–64].

Thus far, very little research has been invested into the study of transient electron transport within the III–V nitride semiconductors, GaN, AlN, and InN. *Foutz* et al. [32.21] examined transient electron transport within both the wurtzite and zinc blende phases of GaN. In particular, they examined how electrons, initially in thermal equilibrium, respond to the sudden application of a constant electric field. In devices with dimensions greater than 0.2 μm, they found that steady-state electron transport is expected to dominate device performance. For devices with smaller dimensions, however, upon the application of a sufficiently high electric field, they found that the transient electron drift velocity can considerably overshoot the corresponding steady-state electron drift velocity. This velocity overshoot was found to be comparable with that which occurs within GaAs.

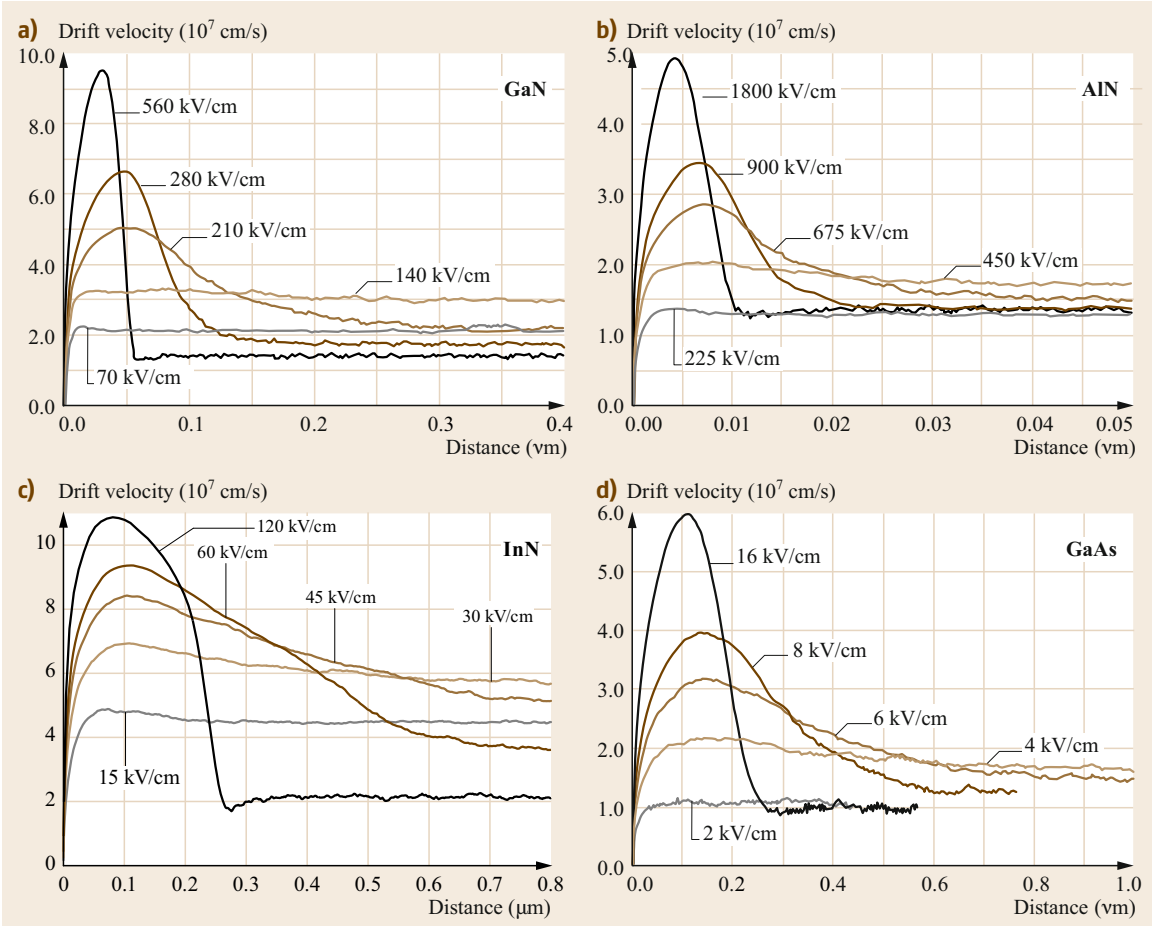

Fig. 32.17a–d The electron drift velocity as a function of the distance displaced since the application of the electric field for various applied electric field strengths, for the cases of **(a)** GaN, **(b)** AlN, **(c)** InN, and **(d)** GaAs. In all cases, we have assumed an initial zero field electron distribution, a crystal temperature of 300 K, and a doping concentration of 10^{17} cm^{-3}. (After [32.29] with permission, copyright AIP)

Foutz et al. [32.29] performed a subsequent analysis in which the transient electron transport within all of the III–V nitride semiconductors under consideration in this analysis were compared with that which occurs within GaAs. In particular, following the approach of *Foutz* et al. [32.21], they examined how electrons, initially in thermal equilibrium, respond to the sudden application of a constant electric field. A key result of this study, presented in Fig. 32.17, plots the transient electron drift velocity as a function of the distance displaced since the electric field was initially applied for a number of applied electric field strengths and for each of the materials considered in this analysis. The InN results have been updated owing to the revisions in the material parameter selections corresponding to this particular material; see Figure 32.17c.

Focusing initially on the case of GaN (Fig. 32.17a), we note that the electron drift velocity for the applied electric field strengths 70 kV/cm and 140 kV/cm reaches steady-state very quickly, with little or no velocity overshoot. In contrast, for applied electric field strengths above 140 kV/cm, significant velocity overshoot occurs. This result suggests that in GaN, 140 kV/cm is a critical field for the onset of velocity overshoot effects. As mentioned in Sect. 32.2.2, 140 kV/cm also corresponds to the peak in the velocity-field characteristic associated with GaN; recall Fig. 32.4. Steady-state Monte Carlo simulations suggest that this is the point at which significant upper valley occupation begins to occur; recall Fig. 32.3. This suggests that velocity overshoot is related to the transfer of electrons to the upper valleys. Similar results are

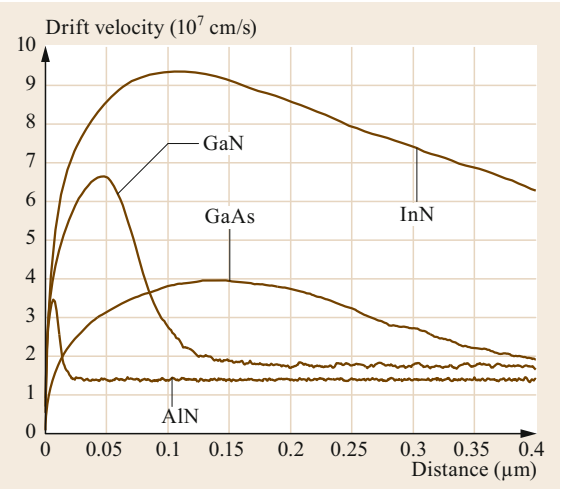

Fig. 32.18 A comparison of the velocity overshoot amongst the III–V nitride semiconductors and GaAs. The applied electric field strength chosen corresponds to twice the critical applied electric field strength at which the peak in the steady-state velocity–field characteristic occurs (Fig. 32.4), i. e., 280 kV/cm for the case of GaN, 900 kV/cm for the case of AlN, 60 kV/cm for the case of InN, and 8 kV/cm for the case of GaAs. (After [32.29] with permission, copyright AIP)

found for the other III–V nitride semiconductors, AlN and InN, and GaAs; see Figs. 32.17b–d.

We now compare the transient electron transport characteristics for the materials. From Fig. 32.17, it is clear that certain materials exhibit higher peak overshoot velocities and longer overshoot relaxation times. It is not possible to fairly compare these different semiconductors by applying the same applied electric field strength to each of the materials, as the transient effects occur over such a disparate range of applied electric field strengths in each material. In order to facilitate such a comparison, we choose a field strength equal to twice the critical applied electric field strength for each material. Figure 32.18 shows a comparison of the velocity overshoot effects amongst the four materials considered in this analysis, i. e., GaN, AlN, InN, and GaAs. It is clear that among the three III–V nitride semiconductors considered, InN exhibits superior transient electron transport characteristics. In particular, InN has the largest overshoot velocity and the distance over which this overshoot occurs, 0.6 μm, is longer than in either GaN or AlN. GaAs exhibits a longer overshoot relaxation distance, approximately 0.7 μm, but the electron drift velocity exhibited by InN is greater than that of GaAs for all distances.

32.2.8 Electron Transport: Conclusions

In this section, steady-state and transient electron transport results, corresponding to the III–V nitride semiconductors, GaN, AlN, and InN, were presented, these results being obtained from our Monte Carlo simulations of the electron transport within these materials. Steady-state electron transport was the dominant theme of our analysis. In order to aid in the understanding of these electron transport characteristics, a comparison was made between GaN and GaAs. Our simulations showed that GaN is more robust to variations in crystal temperature and doping concentration than GaAs, and an analysis of our Monte Carlo simulation results showed that polar optical phonon scattering plays the dominant role in accounting for these differences in behavior. This analysis was also performed for the other III–V nitride semiconductors considered in this analysis – AlN and InN – and similar results were obtained. Finally, we presented some key transient electron transport results. These results indicated that the transient electron transport that occurs within InN is the most pronounced of all of the materials under consideration in this review (GaN, AlN, InN, and GaAs).

32.3 Electron Transport Within III–V Nitride Semiconductors: A Review

Pioneering investigations into the material properties of the III–V nitride semiconductors, GaN, AlN, and InN, were performed during the earlier half of the 20th Century [32.65–67]. The III–V nitride semiconductor materials available at the time, small crystals and powders, were of poor quality, and completely unsuitable for device applications. Thus, it was not until the late 1960s, when *Maruska* and *Tietjen* [32.68] employed chemical vapor deposition to fabricate GaN, that interest in the III–V nitride semiconductors experienced a renaissance. Since that time, interest in the III–V nitride semiconductors has been growing, the material properties of these semiconductors improving considerably over the years. As a result of this research effort, there are currently a number of commercial devices available that employ the III–V nitride semiconductors. More III–V nitride semiconductor-based device applications are currently under development, and these should become available in the near future.

In this section, we present a brief overview of the III–V nitride semiconductor electron transport field. We start with a survey describing the evolution of the field. In particular, the sequence of critical developments that have occurred that contribute to our current understanding of the electron transport mechanisms within the III–V nitride semiconductors, GaN, AlN, and InN, is chronicled. Then, some of the more recent literature related to the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, is presented, with particular emphasis being placed on the most recent developments in the field that have occurred in the 21st Century, and how such developments have shaped our understanding of the electron transport mechanisms within these materials. Finally, frontiers for further research and investigation are presented.

This section is organized in the following manner. In Sect. 32.3.1, we present a brief survey describing the evolution of the field. Then, in Sect. 32.3.2, the developments that have occurred in the 21st Century are discussed. Finally, frontiers for further research and investigation are presented in Sect. 32.3.3.

32.3.1 Evolution of the Field

The favorable electron transport characteristics of the III–V nitride semiconductors, GaN, AlN, and InN, have long been recognized. As early as the 1970s, *Littlejohn* et al. [32.13] pointed out that the large polar optical phonon energy characteristic of GaN, in conjunction with its large intervalley energy separation, suggests a high saturation electron drift velocity for this material. As high-frequency electron device performance is, to a large degree, determined by this saturation electron drift velocity [32.14], the recognition of this fact ignited enhanced interest in this material and its III–V nitride semiconductor compatriots, AlN and InN. This enhanced interest, and the developments which have transpired as a result of it, are responsible for the III–V nitride semiconductor industry of today.

In 1975, *Littlejohn* et al. [32.13] were the first to report results obtained from semi-classical Monte Carlo simulations of the steady-state electron transport within bulk wurtzite GaN. A one-valley model for the conduction band was adopted in their analysis. Steady-state electron transport, for both parabolic and nonparabolic band structures, was considered in their analysis, nonparabolicity being treated through the application of the Kane model [32.43]. The primary focus of their investigation was the determination of the velocity-field characteristic associated with GaN. All donors were assumed to be ionized, and the free electron concentration was taken to be equal to the dopant concentration. The scattering mechanisms considered were:

1. Ionized impurity
2. Polar optical phonon
3. Piezoelectric
4. Acoustic deformation potential.

For the case of the parabolic band, in the absence of ionized impurities, they found that the electron drift velocity monotonically increases with the applied electric field strength, saturating at a value of about $2.5\times10^7\,\mathrm{cm/s}$ for the case of high applied electric fields. In contrast, for the case of the nonparabolic band, and in the absence of ionized impurities, a region of negative differential mobility was found, the electron drift velocity achieving a maximum of about $2\times10^7\,\mathrm{cm/s}$ at an applied electric field strength of about $100\,\mathrm{kV/cm}$, with further increases in the applied electric field strength resulting in a slight decrease in the corresponding electron drift velocity. The role of ionized impurity scattering was also investigated by *Littlejohn* et al. [32.13].

In 1993, *Gelmont* et al. [32.16] reported on ensemble semi-classical two-valley Monte Carlo simulations of the electron transport within bulk wurtzite GaN, this analysis improving upon the analysis of *Littlejohn* et al. [32.13] by incorporating intervalley scattering into the simulations. They found that the negative differential mobility found in bulk wurtzite GaN is much more pronounced than that found by *Littlejohn* et al. [32.13], and that intervalley transitions are responsible for this. For a doping concentration of $10^{17}\,\mathrm{cm^{-3}}$, *Gelmont* et al. [32.16] demonstrated that the electron drift velocity achieves a peak value of about $2.8\times10^7\,\mathrm{cm/s}$ at an applied electric field of about $140\,\mathrm{kV/cm}$. The impact of intervalley transitions on the electron distribution function was also determined and shown to be significant. The impact of doping and compensation on the velocity-field characteristic associated with bulk wurtzite GaN was also examined.

Since these pioneering investigations, ensemble Monte Carlo simulations of the electron transport within GaN have been performed numerous times. In particular, in 1995 *Mansour* et al. [32.18] reported the use of such an approach in order to determine how the crystal temperature influences the velocity-field characteristic associated with bulk wurtzite GaN. Later that year, *Kolník* et al. [32.19] reported on employing full-band Monte Carlo simulations of the electron transport within bulk wurtzite GaN and bulk zinc blende GaN, finding that bulk zinc blende GaN exhibits a much higher low-field electron drift mobility than bulk wurtzite GaN. The peak electron drift velocity corresponding to bulk zinc blende GaN was found to be only marginally greater than that exhibited by bulk wurtzite GaN, however. In 1997, *Bhapkar* and

Shur [32.22] reported on employing ensemble semi-classical three-valley Monte Carlo simulations of the electron transport within bulk and confined wurtzite GaN. Their simulations demonstrated that the two-dimensional electron gas within a confined wurtzite GaN structure will exhibit a higher low-field electron drift mobility than bulk wurtzite GaN, by almost an order of magnitude, this being in agreement with experiment. In 1998, *Albrecht* et al. [32.27] reported on employing ensemble semi-classical five-valley Monte Carlo simulations of the electron transport within bulk wurtzite GaN, with the aim of determining elementary analytical expressions for a number of electron transport metrics corresponding to bulk wurtzite GaN, for the purposes of device modeling.

Electron transport within the other III–V nitride semiconductors, AlN and InN, has also been studied using ensemble semi-classical Monte Carlo simulations of the electron transport. In particular, by employing ensemble semi-classical three-valley Monte Carlo simulations, the velocity–field characteristic associated with bulk wurtzite AlN was studied and reported by *O'Leary* et al. [32.24] in 1998. They found that AlN exhibits the lowest peak and saturation electron drift velocities of the III–V nitride semiconductors considered in this analysis. Similar simulations of the electron transport within bulk wurtzite AlN were also reported by *Albrecht* et al. [32.25] in 1998. The results of *O'Leary* et al. [32.24] and *Albrecht* et al. [32.25] were found to be quite similar. The first known simulation of the electron transport within bulk wurtzite InN was the semi-classical three-valley Monte Carlo simulation of *O'Leary* et al. [32.23], reported in 1998. InN was demonstrated to have the highest peak and saturation electron drift velocities of the III–V nitride semiconductors. The subsequent ensemble full-band Monte Carlo simulations of *Bellotti* et al. [32.28], reported in 1999, produced results similar to those of *O'Leary* et al. [32.23].

The first known study of transient electron transport within the III–V nitride semiconductors was that performed by *Foutz* et al. [32.21], reported in 1997. In this study, ensemble semi-classical three-valley Monte Carlo simulations were employed in order to determine how the electrons within wurtzite and zinc blende GaN, initially in thermal equilibrium, respond to the sudden application of a constant electric field. The velocity overshoot that occurs within these materials was examined. It was found that the electron drift velocities that occur within the zinc blende phase of GaN are slightly greater than those exhibited by the wurtzite phase owing to the slightly the smaller effective mass of the electrons within the zinc blende phase of this material. A comparison with the transient electron transport that occurs within GaAs was made. Using the results from this analysis, a determination of the minimum transit time as a function of the distance displaced since the application of the applied electric field was performed for all three materials considered in this study: wurtzite GaN, zinc blende GaN, and GaAs. For distances in excess of 0.1 μm, both phases of GaN were shown to exhibit superior performance (reduced transit time) when contrasted with that associated with GaAs.

A more general analysis, in which transient electron transport within GaN, AlN, and InN was studied, was performed by *Foutz* et al. [32.29], and reported in 1999. As with their previous study, *Foutz* et al. [32.29] determined how electrons, initially in thermal equilibrium, respond to the sudden application of a constant electric field. For GaN, AlN, InN, and GaAs, it was found that the electron drift velocity overshoot only occurs when the applied electric field exceeds a certain critical applied electric field strength unique to each material. The critical applied electric field strengths, 140 kV/cm for the case of wurtzite GaN, 450 kV/cm for the case of AlN, 65 kV/cm for the case of InN (this was the critical applied electric field strength corresponding to our previous InN parameter selections [32.29]), and 4 kV/cm for the case of GaAs, were shown to correspond to the peak electron drift velocity in the velocity-field characteristic associated with each of these materials; recall Fig. 32.4. It was found that InN exhibits the highest peak overshoot velocity, and that this overshoot lasts over prolonged distances compared with AlN, InN, and GaAs. A comparison with the results of experiment was performed.

In addition to Monte Carlo simulations of the electron transport within these materials, a number of other types of electron transport studies have been performed. In 1975, for example, *Ferry* [32.14] reported on the determination of the velocity-field characteristic associated with wurtzite GaN using a displaced Maxwellian distribution function approach. For high applied electric fields, *Ferry* [32.14] found that the electron drift velocity associated with GaN monotonically increases with the applied electric field strength (it does not saturate), reaching a value of about 2.5×10^7 cm/s at an applied electric field strength of 300 kV/cm. The device implications of this result were further explored by *Das* and *Ferry* [32.15]. In 1994, *Chin* et al. [32.17] reported on a detailed study of the dependence of the low-field electron drift mobilities associated with the III–V nitride semiconductors, GaN, AlN, and InN, on crystal temperature and doping concentration. An analytical expression for the low-field electron drift mobility μ determined using a variational principle, was used for the purposes of this analysis. The results obtained were contrasted with those

from experiment. A subsequent mobility study was reported in 1997 by *Look* et al. [32.38]. Then, in 1998, *Weimann* et al. [32.26] reported on a model for determining how the scattering of electrons by the threading dislocations within bulk wurtzite GaN influence the low-field electron drift mobility. They demonstrated why the experimentally measured low-field electron drift mobility associated with this material is much lower than that predicted from Monte Carlo analyses: threading dislocations were not taken into account in the Monte Carlo simulations of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN.

While the negative differential mobility exhibited by the velocity-field characteristics associated with the III–V nitride semiconductors, GaN, AlN, and InN, is widely attributed to intervalley transitions, and while direct experimental evidence confirming this has been presented [32.69], *Krishnamurthy* et al. [32.34] suggest that the inflection points in the bands located in the vicinity of the Γ valley are primarily responsible for the negative differential mobility exhibited by wurtzite GaN instead. The relative importance of these two mechanisms (intervalley transitions and inflection point considerations) were evaluated by *Krishnamurthy* et al. [32.34], for both bulk wurtzite GaN and an AlGaN alloy.

32.3.2 Developments in the 21st Century

Thus far, the electron transport results that have been presented have focused on developments in our understanding of the nature of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN that were acquired in the latter part of the 20th Century. There have been a number of interesting more recent developments in the study of the electron transport within the III–V nitride semiconductors which have influenced the direction of thought in this field. On the experimental front, in 2000 *Wraback* et al. [32.33] reported on the use of a femtosecond optically detected time-of-flight experimental technique in order to experimentally determine the velocity–field characteristic associated with bulk wurtzite GaN. They found that the peak electron drift velocity, 1.9×10^7 cm/s, is achieved at an applied electric field strength of 225 kV/cm. No discernible negative differential mobility was observed. *Wraback* et al. [32.33] suggested that the large defect density characteristic of the GaN samples they employed, which were not taken into account in Monte Carlo simulations of the electron transport within this material, accounts for the difference between this experimental result and that obtained using simulation. They also suggested that decreasing the intervalley energy separation from about 2 eV to 340 meV, as suggested by the experimental results of *Brazel* et al. [32.58], may also account for these observations.

The determination of the electron drift velocity from experimental measurements of the unity gain cutoff frequency f_t has been pursued by a number of researchers. The key challenge in these analyses is the de-embedding of the parasitics from the experimental measurements so that the true intrinsic saturation electron drift velocity may be obtained. *Eastman* et al. [32.70] present experimental evidence which suggests that the saturation electron drift velocity within bulk wurtzite GaN is about 1.2×10^7–1.3×10^7 cm/s. A more recent report, by *Oxley* and *Uren* [32.71], suggests a value of 1.1×10^7 cm/s. The role of self-heating was also probed by *Oxley* and *Uren* [32.71] and shown to be relatively insignificant. A completely satisfactory explanation for the discrepancy between these results and those from the Monte Carlo simulations has yet to be provided.

Wraback et al. [32.72] performed a subsequent study on the transient electron transport within wurtzite GaN. In particular, using their femtosecond optically detected time-of-flight experimental technique in order to experimentally determine the velocity overshoot that occurs within bulk wurtzite GaN, they observed substantial velocity overshoot within this material. In particular, a peak transient electron drift velocity of 7.25×10^7cm/s was observed within the first 200 fs after photoexcitation for an applied electric field strength of 320 kV/cm. These experimental results were shown to be consistent with the theoretical predictions of *Foutz* et al. [32.29].

On the theoretical front, there have been a number of recent developments. In 2001, *O'Leary* et al. [32.30] presented an elementary, one-dimensional analytical model for the electron transport within the III–V compound semiconductors, and applied it to the cases of wurtzite GaN and GaAs. The predictions of this analytical model were compared with those of Monte Carlo simulations and were found to be in satisfactory agreement. Hot-electron energy relaxation times within the III–V nitride semiconductors were studied by *Matulionis* et al. [32.73] and reported in 2002. *Bulutay* et al. [32.74] studied the electron momentum and energy relaxation times within the III–V nitride semiconductors and reported the results of this study in 2003. It is particularly interesting to note that their arguments add considerable credence to the earlier inflection point argument of *Krishnamurthy* et al. [32.34]. In 2004, *Brazis* and *Raguotis* [32.75] reported on the results of a Monte Carlo study involving additional phonon modes and a smaller intervalley energy separation for bulk wurtzite GaN. Their results were found to

be much closer to the experimental results of *Wraback* et al. [32.33] than those found previously.

The influence of hot-phonons on the electron transport mechanisms within the III–V nitride semiconductors, GaN, AlN, and InN, has been the focus of considerable investigation. In particular, in 2004 *Silva* and *Nascimento* [32.76], *Gökden* [32.77], and *Ridley* et al. [32.78], to name just three, presented results related to this research focus. These results suggest that hot-phonon effects play a significant role in influencing the nature of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN. In particular, *Ridley* et al. [32.78] point out that the saturation electron drift velocity and the applied electric field strength at which the peak in the velocity–field characteristic occurs are both influenced by hot-phonon effects. The role that hot-phonons play in influencing device performance was studied by *Matulionis* and *Liberis* [32.79]. Research into the role that hot-phonons play in influencing the electron transport mechanisms within the III–V nitride semiconductors, GaN, AlN, and InN, seems likely to continue into the foreseeable future.

Over the past few years, there have been a number of developments that have occurred that have further enriched our understanding of electron transport within GaN. In 2011, *Ilgaz* et al. [32.80] studied the energy relaxation of hot electrons within AlGaN/GaN/GaN heterostructures. Then, in 2012, *Naylor* et al. [32.81] examined the steady-state and transient electron transport that occurs within bulk wurtzite GaN using an analytical band structure that more accurately reflects the nature of the actual bandstructure. In 2012, *Naylor* et al. [32.82] also examined the electron transport that occurs within dilute GaN_xAs_{1-x} samples. In 2013, *Bellotti* et al. [32.83] employed a full-band model in order to determine the velocity-field characteristics associated with AlGaN alloys. Also in 2013, *Dasgupta* et al. [32.84] estimated the hot electron relaxation time associated with wurtzite GaN using a series of electrical measurements. In 2013, *Zhang* et al. [32.85] determined the hot-electron relaxation time within lattice-matched InAlN/AlN/GaN heterostructures. The potential for electron device structures was then explored. Clearly, the study of electron transport within wurtzite GaN remains an area of active inquiry. The same situation applies for the cases of AlN and InN, and alloys of these materials [32.50, 86–95]. Further information, regarding our current understanding of the nature of the electron transport within these materials, may be found in the recently published review articles of *Hadi* et al. [32.96] and *Siddiqua* et al. [32.97].

32.3.3 Future Perspectives

It is clear that our understanding of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, is, at present at least, in a state of flux. A complete understanding of the electron transport mechanisms within these materials has yet to be achieved, and is the subject of intense current research. Most troubling is the discrepancy between the results of experiment and those of simulation. There are a two principal sources of uncertainty in our analysis of the electron transport mechanisms within these materials: (1) uncertainty in the material properties, and (2) uncertainty in the underlying physics. We discuss each of these subsequently.

Uncertainty in the material parameters associated with the III–V nitride semiconductors, GaN, AlN, and InN, remains a key source of ambiguity in the analysis of the electron transport with these materials [32.32]. Even for bulk wurtzite GaN, the most studied of the III–V nitride semiconductors considered in this analysis, uncertainty in the band structure remains an issue [32.58]. The energy gap associated with InN and the effective mass associated with this material continue to fuel debate; see, for example, *Davydov* et al. [32.55], *Wu* et al. [32.56], and *Matsuoka* et al. [32.57]. Variations in the experimentally determined energy gap associated with InN, observed from sample to sample, further confound matters. *Shubina* et al. [32.98], for example, suggested that nonstoichiometry within InN may be responsible for these variations in the energy gap. Further research will have to be performed in order to confirm this. Given this uncertainty in the band structures associated with the III–V nitride semiconductors, it is clear that new simulations of the electron transport will have to be performed once researchers have settled on the appropriate band structures. We thus view our present results as a baseline, the sensitivity analysis of *O'Leary* et al. [32.32] providing some insights into how variations in the band structures will impact upon the results.

Uncertainty in the underlying physics is considerable. The source of the negative differential mobility remains a matter to be resolved. The presence of hot-phonons within these materials, and how such phonons impact upon the electron transport mechanisms within these materials, remains another point of contention. It is clear that a deeper understanding of these electron transport mechanisms will have to be achieved in order for the next generation of III–V nitride semiconductor-based devices to be properly designed.

32.4 Conclusions

In this chapter, we reviewed analyses of the electron transport within the III–V nitride semiconductors GaN, AlN, and InN. In particular, we have discussed the evolution of the field, surveyed the more recent literature, and presented frontiers for further investigation and analysis. In order to narrow the scope of this review, we focused on the electron transport within bulk wurtzite GaN, AlN, and InN for the purposes of this paper. Most of our discussion focused upon results obtained from our ensemble semi-classical three-valley Monte Carlo simulations of the electron transport within these materials, our results conforming with state-of-the-art III–V nitride semiconductor orthodoxy.

We began our review with the Boltzmann transport equation, since this equation underlies most analyses of the electron transport within semiconductors. A brief description of our ensemble semi-classical three-valley Monte Carlo simulation approach to solving the Boltzmann transport equation was then provided. The material parameters, corresponding to bulk wurtzite GaN, AlN, and InN, were then presented. We then used these material parameter selections, and our ensemble semi-classical three-valley Monte Carlo simulation approach, to determine the nature of the steady-state and transient electron transport within the III–V nitride semiconductors. Finally, we presented some recent developments on the electron transport within these materials, and pointed to fertile frontiers for further research and investigation.

33. II–IV Semiconductors for Optoelectronics: CdS, CdSe, CdTe

Minoru Isshiki, Jifeng Wang

Owing to their suitable band gaps and high absorption coefficients, Cd-based compounds such as CdTe and CdS are the most promising photovoltaic materials available for low-cost high-efficiency solar cells. Additionally, because of their large atomic number, Cd-based compounds such as CdTe and CdZnTe, have been applied to radiation detectors. For these reasons, preparation techniques for these materials in the polycrystalline films and bulk single crystals demanded by these devices have advanced significantly in recent decades, and practical applications have been realized in optoelectronic devices. This chapter mainly describes the application of these materials in solar cells and radiation detectors and introduces recent progress.

33.1 Background

Cd-based compounds are very important semiconductor materials in the II–VI family. The attraction of Cd-based binary and ternary compounds arises from their promising applications as solar cells, γ- and x-ray detectors etc. These devices made from Cd-based materials are being widely applied in many fields.

33.2 Solar Cells

With the development of human society, energy sources in the earth are being slowly exhausted and we are faced with a serious problem. The solar cell is one substitute for fossil fuels and is being realized throughout the world. For this reason, solar-cell technologies have been developed since work was started by *Becquerel* in 1839 [33.1]. The solar cell has now been applied to daily life, industry, agriculture, space exploration, military affairs etc.

Solar cells have many advantages. Firstly, sunlight as an energy source for power generation is not only limitless but can be used freely. Secondly, since light is directly converted to electricity, the conversion process is clean, noise-free and not harmful to the environment, unlike a mechanical power generator. Thirdly, solar cells need little maintenance.

33.2.1 Basic Description of Solar Cells

A solar cell is a semiconductor device that directly converts light energy into electrical energy through the photovoltaic process. The basic structure of a solar cell is shown in Fig. 33.1. A typical solar cell consists of a junction formed between an n-type and a p-type semiconductor, of the same (homojunction) or different materials (heterojunction), an antireflection coating and Ohmic collecting electrodes. When the light irradiates the surface of a solar cell, photons with an energy

© Springer International Publishing AG 2017
S. Kasap, P. Capper (Eds.), *Springer Handbook of Electronic and Photonic Materials*, DOI 10.1007/978-3-319-48933-9_33

greater than the band gap of the semiconductor are absorbed by the semiconductor material. This absorption activates electron transitions from the valence to the conduction band, so that electron–hole pairs are generated. If these carriers can diffuse into the depletion region before they recombine, they can be separated by the applied electric field. At the p–n junction, the negative electrons diffuse into the n-type region and the positive holes diffuse into the p-type region. They are then collected by electrodes, resulting in a voltage difference between the two electrodes. When an external load is connected, electric current flows through the load. This is the origin of the solar cell's photocurrent.

Three parameters can be used to describe the performance of a solar cell: the short-circuit current density (J_{SC}), the open-circuit voltage (V_{OC}) and the fill factor (FF).

The short-circuit current density J_{SC} is the photocurrent output from a solar cell when the output terminals are short-circuited. In the ideal case, this is equal to the current density generated by the light J_L and is proportional to the incident photon flux. J_{SC} is determined by the spectral response of the device, the junction depth, and the series (internal) resistance, R_s. The open-circuit voltage V_{OC} is the voltage appearing across the output terminals of the cell when there is no load present, i. e., when $J = 0$. The relationship between V_{OC} and J_{SC} can be described by the diode equation, i. e.,

$$V_{OC} = \frac{nk_BT}{e} \ln\left(\frac{J_{SC}}{J_0} + 1\right), \tag{33.1}$$

where e, n, J_0, k_B and T are the charge on an electron, the diode ideality factor, the reverse saturation-current density, the Boltzmann constant and the absolute temperature, respectively. The fill factor (FF) is the ratio of the maximum electrical power available from the cell (i. e., at the operating point J_m, V_m) in Fig. 33.2) to the product ofV_{OC} and J_{SC}. It describes the rectangularity of the photovoltaic output characteristic.

$$FF = \frac{V_mJ_m}{V_{oc}J_{sc}} = \frac{P_m}{V_{oc}J_{sc}}. \tag{33.2}$$

The conversion efficiency (η) of a solar cell is determined as

$$\eta = \frac{P_m}{P_s} = \frac{V_{oc}J_{sc}FF}{P_s}. \tag{33.3}$$

Where P_s is the incident illumination power and P_m is the output electricity power, both being per unit area. The relationship between the short-circuit current density J_{SC} and the open-circuit voltage V_{OC} is shown in Fig. 33.2.

33.2.2 Design of Cd-Based Solar Cells

Solar cells can be made from silicon (Si), III–V compounds such as GaAs, or II–VI compounds such as Zn-based and Cd-based compound semiconductors. Of these materials, CdTe is the most attractive because of a number of advantages. CdTe is a direct-band-gap material with a band gap of 1.54 eV at room temperature. This is very close to the theoretically calculated optimum value for solar cells. CdTe has a high absorption coefficient (above 10^5 cm^{-1} at a wavelength of 700 nm), so that approximately 90% of the incident light is absorbed by a layer thickness of only 2 μm (compared with around 10 μm for Si), cutting down the quantity of semiconductor required. Therefore, CdTe is one of the most promising photovoltaic materials available for use in low-cost high-efficiency solar cells.

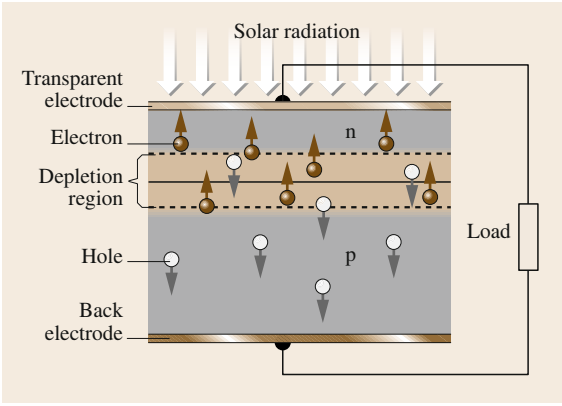

Fig. 33.1 The principle of photovoltaic devices

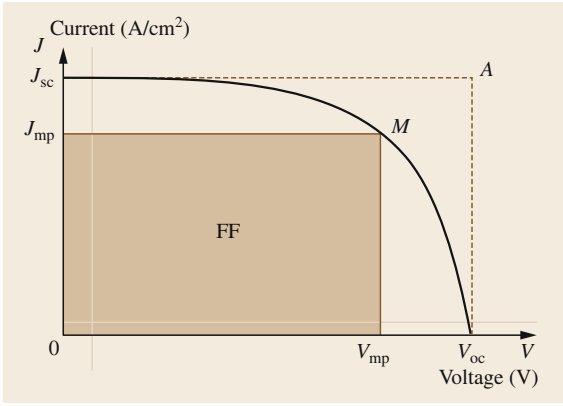

Fig. 33.2 Photovoltaic output characteristics of a solar cell

CdTe is the only material in which both n- and p-type conductivity can be easily controlled by doping acceptor or donor impurities in II–VI compound semiconductors. Furthermore, due to its high absorption coefficient and small carrier diffusion length, the junction must be formed closed to the surface, which reduces the carrier lifetime through surface recombination. In spite of this, the conversion efficiency has been gradually enhanced from 4% [33.2] to 16% [33.3] since the first CdTe-based solar cell was fabricated. CdTe solar cells can be made from polycrystalline or single-crystal material. However, it was found that this p–n homojuction structure is unstable due to the aging behavior of dopants in CdTe films and bulk single crystals [33.4]. Furthermore, it is also difficult to fabricate shallow p–n junctions with highly conducting surface layers, and high surface recombination velocities led to substantial losses that could not easily be avoided. For this reason, the CdS/CdTe heterojunction solar cell was proposed.

It has been proved that CdS/CdTe is a high-efficiency heterojunction solar cell. The theoretical calculation shows that this cell has a conversion efficiency of as high as 29% [33.5], and it is considered a promising alternative to the more widely used silicon devices. The typical structure of a CdS/CdTe solar cell is glass/indium tin oxide (ITO)/CdS/CdTe/back electrode, as seen in Fig. 33.3. The CdS/CdTe solar cell is based on the heterojunction formed between n-type CdS (only n-CdS is available) and p-type CdTe and is fabricated in a superstrate configuration where the incident light passes through the glass substrate, which has a thickness of 2−4 mm. This window glass is transparent, strong and cheap. This glass substrate also protects the active layers from the environment, and it provides the mechanical strength of the device. The outer face of the panel often has an antireflection coating to enhance absorption efficiency. A transparent conducting oxide (TCO) layer, usually tin oxide or indium tin oxide (ITO), acts as the front contact to the device. This is needed to reduce the series resistance of the device, which would otherwise arise from the thinness of the CdS layer. Usually, the polycrystalline n-type CdS layer is deposited onto the TCO. Due to its wide band gap ($E_g \approx 2.4$ eV at 300 K) it is transparent down to wavelengths of around 516 nm. The thickness of this layer is typically 100−300 nm. The CdTe layer is p-type-doped and its thickness is typically around 10 μm. Generally, the carrier concentration in CdS layer is 2–3 orders greater than that of the CdTe layer. As a result, the potential is applied mostly to the CdTe absorber layer, i. e., the depletion region is mostly within the CdTe layer. Therefore, the photogenerated carriers can be effectively separated in this active region.

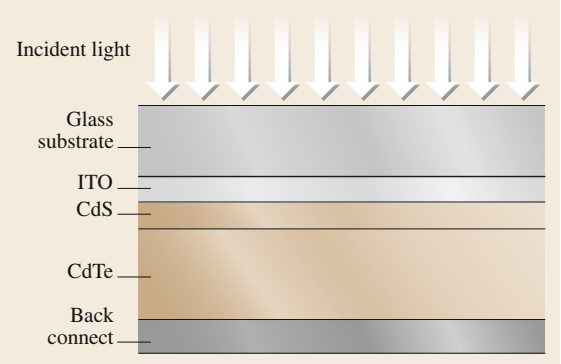

Fig. 33.3 A typical CdS/CdTe solar cell

The electrode preparation is very important in obtaining Ohmic contact or minimal series resistivity. Since there are no metals with a work function higher than the hole affinity of p-type CdTe (−5.78 eV) [33.6], it is difficult to produce a complete Ohmic contact on p-type CdTe surface. Many methods have been tried to fabricate Ohmic contact to p-type CdTe. Different metals or alloy and compounds such as Au, Al, and ZnTe/Cu etc. have also been used to serve as electrode materials. Although significant effort has been applied to this issue, the junction still inevitably displays some Schottky-diode characteristics. This is a problem that will be continuously studied.

33.2.3 Development of CdS/CdTe Solar Cells

The layers of CdS and CdTe for solar cells can be prepared using various techniques, which are summarized in Table 33.1. In these techniques, evaporation, close-space sublimation (CSS), screen printing and electrodeposition (ED) have been demonstrated to be very effective for fabricating high-efficiency large-area CdS/CdTe solar cells.

Study of solar cells based on CdTe single crystals and polycrystalline films were started as early as 1963 [33.14]. The cells were prepared with a p-type copper-telluride surface film as an integral part of the photovoltaic junction. The junction was thought to be a heterojunction between the p-type copper telluride and the n-type CdTe, with the transition region extending well into the CdTe side. A similar structure was reported for single-crystal cells. A conversion efficiency of up to 6% was obtained in the film cells, and 7.5% for single-crystal cells.

Dutton and *Muller* [33.15] fabricated CdS/CdTe solar cells by standard vapor-deposition procedures with a very thin CdTe layer. The existence of the

Table 33.1 Some fabrication techniques and conversion efficiency of CdS/CdTe solar cells

Fabrication techniques of CdS and CdTe	Conversion		Reference
	Efficiency (%)	Area (cm^2)	
Evaporation: physical vapor deposition (PVD), and chemical vapor deposition (CVD)	11.8	0.3	[33.7]
Close-spaced sublimation (CSS)	16	1.0	[33.3]
	8.4	7200	[33.8]

Sputtering deposition (SD)	14	0.09	[33.13]

interfacial layer was confirmed using x-ray diffraction studies, and substantiated by diode photocurrent measurements. The results showed a threshold photon energy that corresponds to the band gap of CdTe. The thin CdTe layer resulted in excellent rectification ratios and high reverse breakdown voltages. The observed photoresponse, *I–V* (current versus voltage), and *C–V* (capacitance versus voltage) characteristics were consistence with those predicted by a semiconductor heterojunction model of the CdS–CdTe interface. *Mitchell* et al. [33.16] prepared a variety of CdS/CdTe heterojunction solar cells with an ITO coating and a glycerol antireflection coating by vacuum evaporation of n-CdS films onto single-crystal p-CdTe substrates. Comparisons were made between cells prepared using different substrate resistivity, substrate surface preparations, and CdS film resistivity. The mechanisms of controlling the dark junction current, photocarrier collection, and photovoltaic properties were modeled, taking account of the interface states of the junction. A conversion efficiency of 7.9% was obtained under 85 mW/cm^2 of solar simulator illumination.

At the end of the 1970s, a new process, screen printing and sintering, was developed for fabricating CdS/CdTe polycrystal solar cells by *Matsushita* and coworkers [33.10, 17–20]. This technique proved to be a very effective method for fabricating large-area CdS/CdTe

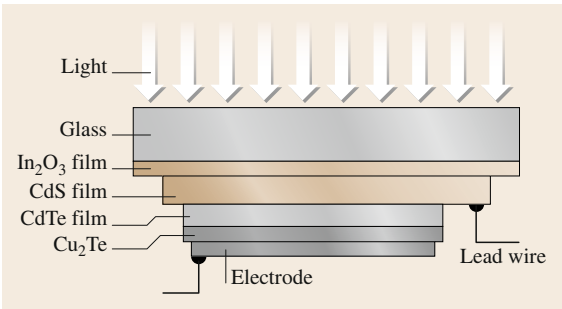

Fig. 33.4 Cross section of a ceramic thin-film CdTe solar cell

film solar cells. There are several important parameters in the screen-printing technique: the viscosity of the paste, the mesh number of the screen, the snap-off distance between the screen and the substrate and the pressure and speed of the squeegee. As cadmium chloride ($CdCl_2$) has a low melting point ($T_m = 568\,°C$), and forms a eutectic with both CdS and CdTe at low temperature, and the vapor pressure at 600 °C is high enough to allow complete volatilization of $CdCl_2$ after the sintering process, $CdCl_2$ is used as an ideal flux for sintering both CdS and CdTe.

Nakayama et al. [33.18] prepared the first thin-film CdS/CdTe solar cells using the screen-printing technique (Fig. 33.4). A glass plate, which was coated successively with In_2O_3 film and CdS ceramic thin film, was used as a transparent Ohmic contact substrate. The n-type CdS film with a thickness of about 20 μm and a resistivity of 0.2 Ω cm was prepared on this substrate by the screen-printing method. The CdTe paste was printed onto the CdS layer using the same technique and then heat-treated in an N_2 atmosphere at temperatures of 500–800 °C. As a result, the p-type CdTe layer with a thickness of 10 μm showed a resistivity of 0.1–1 Ω cm. A silver (Ag) paste electrode was applied to the p-type layer and an In–Ga alloy was applied to the CdS layer. The cell, with an active area of 0.36 cm^2, showed an intrinsic solar conversion efficiency of 8.1% under an illumination of 140 mW/cm^2 solar simulator (AM0). Subsequently, this group continued to work on improving CdS/CdTe solar cells [33.10, 19, 20]. From the practical point of view, a modular solar cell is necessary. For this purpose, thin-film CdS/CdTe solar cells with an efficiency of 6.3% were prepared on a borosilicate-glass substrate of $4 \times 4\,cm^2$ by successively screen printing and heating (sintering) of each paste of CdS, CdTe and carbon [33.19]. Although they fabricated some structures, including dividing the CdTe film on one substrate into five small cells, to prevent increases in the series resistivity, a 1 W module only showed an efficiency of 2.9% from 25 elemental cells with a $4 \times 4\,cm^2$ substrate. A main reason for this

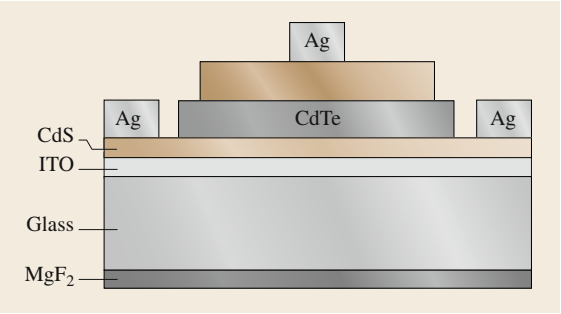

Fig. 33.5 The cross-sectional structure of a CdS/CdTe solar cell fabricating by the screen-printing method

low efficiency was thought to be the high series resistivity.

In order to decrease the resistivity of the carbon electrode further, this group changed the heating conditions of the carbon electrodes for CdTe and examined the effect of impurities in the carbon paste on the characteristics of solar cells [33.10]. They found that the series resistance (R_s) and the conversion efficiency (η) of solar cells exhibited strong dependence on the oxygen (O_2) partial pressure during the heating process. The results showed that the addition of Cu to the carbon paste causes R_s and the diode factor (n) to decrease, resulting in a remarkable improvement in η. Using a low-resistance contact electrode, which was made from 50 ppm added Cu carbon paste, a cell with an active area of 0.78 cm^2 displayed $V_{oc} = 0.754$ V, $I_{sc} = 0.022$ A, FF= 0.606 and $\eta = 12.8\%$.

Britt and *Ferekides* [33.21] reported the fabrication and characteristics of high-efficiency thin-film CdS/CdTe heterojunction solar cells. CdS films with 0.07–0.10 μm in thickness were deposited on a 0.5-μm SnO_2:F transparent conducting oxide layer by chemical-bath deposition and p-CdTe films with a thickness of 5 μm were deposited on the CdS layer by using the CSS method. Prior to the deposition of CdTe, CdS/SnO_2:F/glass was annealed in a H_2 atmosphere at temperatures of 350–425 °C for 5–20 min. The characteristics of the CdS/CdTe solar cell were $V_{oc} = 843$ mV, $J_{sc} = 25.1$ mA/cm^2, FF = 74.5%, corresponding to a total area greater than 1 cm^2 with an air mass 1.5 (AM1.5) conversion efficiency of 15.8%.

With modern growth techniques, high-efficiency CdS/CdTe solar cells have been developed using ultrathin CdS films having a thickness of 50 nm [33.3]. Figure 33.5 shows the cross-sectional structure of a CdS/CdTe solar cell. CdS films were deposited on an ITO glass substrates by the metal organic chemical vapor deposition (MOCVD) technique, and CdTe films were subsequently deposited by the CSS technique (see Fig. 33.6) for the fabrication of CdS/CdTe solar cells.

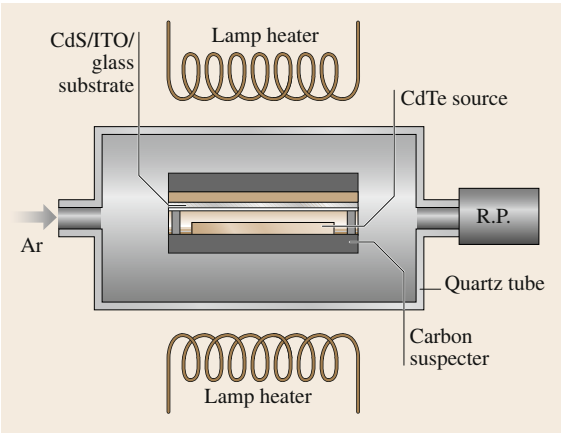

Fig. 33.6 Schematic of the close-spaced sublimation apparatus used for depositing CdTe films

A thin-film CdS/CdTe solar cell with an area of 1.0 cm^2 under AM1.5 conditions showed $V_{oc} = 840$ mV, $J_{sc} = 26.08$ mA/cm^2 and FF = 73%. As a result, a high conversion efficiency of 16.0% was achieved. Furthermore, they made developments in improving the uniformity of thickness and film qualities of CdS in order to obtain more efficient solar cells and to realize film deposition on large-area substrates of 30 × 60 cm or more [33.22]. They found clear differences in the electrical and optical properties between high- and low-quality CdS films. A photovoltaic conversion efficiency of 10.5% was achieved by a solar module with an area of 1376 cm^2 under AM1.5 measurement conditions.

In addition to dry processes such as screen printing, close-spaced sublimation etc., electrodeposition [33.23–26] has been also investigated for preparing polycrystalline CdTe layers for solar cells. *Awakura* and coworkers [33.24–26] reported the cathodic deposition behavior of CdTe thin layers under irradiation by visible light using ammoniacal basic aqueous solution as an electrolytic bath. Both deposition current density and current efficiency for the CdTe deposition were enhanced by irradiation. The deposited rate was over 10 times high than nonphotoassisted electrodeposition. This was believed to represent significant progress in reducing the cost of Cd-based solar cells.

To date, solar cells with an n-CdS/p-CdTe heterojunction have been reported with efficiencies as high as 16% [33.3]. Recently, it was reported that thin-layered n-CdS/p-CdTe heterojunction solar cells have already been manufactured industrially [33.27]. n-CdS film with a thickness range of 500–1000 Å was deposited from an aqueous solution directly onto a transparent conductive oxide (TCO) substrate. After the CdS film was annealed for densification and grain growing, p-CdTe layer was formed by electrochemical deposition.

The CdTe film was then annealed in air at 450 °C. Subsequently, monolithic TCO/CdS/CdTe was cut into discrete cells using an infrared laser. After other preparing process, a maximum efficiency of 10.6% for a CdTe 0.94 m^2 module with a power of 91.5 W was fabricated. The test results showed good stability. For practical applications, a 10-MW CdTe solar-cell manufacturing plant has been constructed [33.27].

33.2.4 CdZnTe Solar Cells

The ternary compound cadmium zinc telluride (CdZnTe, CZT) has potential for the preparation of high-efficiency tandem solar cell since its band gap can be tuned from 1.45 to 2.26 eV [33.28, 29]. *McCandless* et al. [33.28] deposited $Cd_{1-x}Zn_xTe$ films using the physical vapor deposition (PVD) and vapor transport deposition (VTD) techniques. The film composition was between 0.35 and 0.6, corresponding to a band gap from 1.7 to 1.9 eV. Post-deposition treatment of CdZnTe films in $ZnCl_2$ vapor at 400 °C resulted in no change to the alloy composition and caused recrystallization. Solar cells made from $Cd_{1-x}Zn_xTe$ films with $x \approx 0.35$ exhibited $V_{oc} = 0.78$ V and $J_{sc} < 10\,mA/cm^2$. These results were similar to those obtained from CdS window layers. Analysis of the spectral response indicated that $Cd_{1-x}Zn_xTe$ with $x \approx 0.35$ has a band gap of about 1.7 eV. *Gidiputti* et al. [33.29] used two deposition technologies, cosputtering from CdTe and ZnTe targets and coclose-spaced sublimation (CCSS) from CdTe and ZnTe powders, to prepare CdZnTe films. A structure similar to the CdTe superstrate configuration was initially utilized for cell fabrication: glass/ITO/CdS/CZT/graphite. Typical solar cell parameters obtained for CdZnTe/CdS (when $E_g(CdZnTe) = 1.72$ eV) solar cells were $V_{oc} = 720$ mV, and $J_{sc} = 2\,mA/cm^2$. However, the spectral response indicated increasing loss of photocurrent at longer wavelengths. In order to improve the collection efficiency, CdZnTe devices were annealed in a H_2 atmosphere. This postprocessing treatment showed that J_{sc} increased to over $10\,mA/cm^2$. Study of CdZnTe solar cells is being carried out in various directions.

33.2.5 The Future of Cd-Based Solar Cells

From the development process of Cd-based solar cells, the study on the laboratory scale is being transfered to large-scale deposition and cell fabrication. Modules are being developed throughout the world, using the screen printing, evaporative deposition and close-space sublimation [33.30–32]

In order to make a commercial Cd-based photovoltaic cell with its full potential, a large-scale high-throughput manufacturing process is required. The process must possess excellent yields and produce high-efficiency devices with good long-term stability. In order to progress towards these goals, a pilot system for continuous, inline processing of CdS/CdTe devices has been developed [33.33–35]. High-quality low-cost thin-film CdTe modules with an average total area efficiency of 8% and cascaded production-line yield of > 70% have been manufactured, and technology-development programs will further increase production-line module efficiency to 13% within five years [33.35].

33.3 Radiation Detectors

A radiation detector is a device that converts a radiation ray into electrical signal. They can be divided into gas-filled detectors, scintillation detectors and semiconductor detectors. Since semiconductor radiation detectors have a high spectrometric performance, and can be made portable, they have been applied in nuclear safeguards, medical physics and imaging diagnosis, industrial safety, nondestructive analysis, security and monitoring, nonproliferation and astrophysics [33.36, 37]. Meanwhile, they are also being gradually improved.

33.3.1 Basic Description of Semiconductor Radiation Detectors

The principle of operation of a semiconductor radiation detector is shown in Fig. 33.7. When high-energy photons (x- or γ-rays) radiate the detector, they lose the energy to induce electron–hole pairs in the semiconductor through photoelectric or Compton interactions, thereby increasing the conductivity of the material. In order to detect the change in conductivity, a bias voltage is required. An externally applied electric field separates the electron–hole pairs before they recombine, and electrons drift towards the anode, holes to the cathode. The charges are then collected by the electrodes. The collected charges produce a current pulse, whose integral equals the total charge generated by the incident photons, indicating the radiation intensity. The read-out goes through a charge-sensitive preamplifier, followed by a shaping amplifier. The multichannel analyzer is used for spectroscopic measurements of the radiation ray. This type of detector can produce both

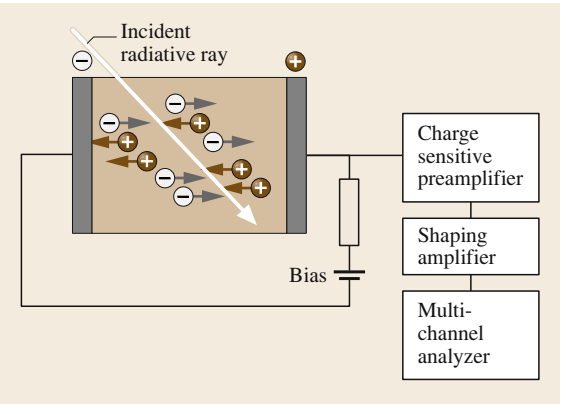

Fig. 33.7 The principle of operation of a semiconductor detector

count and energy information. Typically, detectors are manufactured in a square or rectangular configuration to maintain a uniform bias-current distribution throughout the active region. The wavelength of the peak response depends on the material's band-gap energy.

There are several important parameters to describe a detector performance. Detection efficiency is defined as the percentage of radiation incident on a detector system that is actually detected. Detector efficiency depends on the detector size and shape (larger areas and volumes are more sensitive), radiation type, material density (atomic number), and the depth of the detection medium. Energy resolution is one of the most important characteristics of semiconductor detectors. It is usually defined as the full-width at half-maximum (FWHM) of a single-energy peak at a specific energy. High resolution enables the system to more clearly resolve the peaks within a spectrum. So the reliability of the detector is also high. Detector sensitivity implies minimal detectable counts. It is defined as the number of counts that can be distinguished from the background. The relative detector response factor expresses the sensitivity of a detector relative to a standard substance. If the relative detector response factor is expressed on an equal-mass (-weight) basis, the determined sensitivity values can be substituted for the peak area.

33.3.2 CdTe and CdZnTe Radiation Detectors

Semiconductor radiation detectors are fabricated from a variety of materials including: germanium (Ge), silicon (Si), mercuric iodide (HgI_2), CdTe, CdZnTe etc. Typical detectors for a given application depend on several factors. Table 33.2 shows the features of some semiconductor detectors. From Table 33.2, Ge detectors have the best resolution, but require liquid-nitrogen cooling, which makes them impractical for portable applications. Si detectors also need cooling, and are inefficient in detecting photons with energies greater than a few tens of keV. CdTe and CdZnTe detectors possess their own advantages.

Single crystals of CdTe and CdZnTe are very important materials for the development of x- and γ-ray detectors. Currently Ge and Si detectors have to be used at liquid-nitrogen temperatures, and suffer from poor detection efficiency. Since the compound semiconductors CdTe and CdZnTe with high atomic number ($Z_{Cd} = 48, Z_{Zn} = 30, Z_{Te} = 52$) have a significantly higher photoelectric absorption efficiency in the $-100-500$ keV range, they can be fabricated into detectors that provide two advantages for use in portable instrumentation: (1) the large band-gap energy ($E_g > 1.54$ eV at room temperature) results in extremely small leakage current of a few nanoamps at room temperature. Therefore, these detectors have the potential to serve as useful detectors for radiation spectroscopy without the need for cryogenic cooling as required for more conventional silicon and hyper-pure germanium detectors; (2) the high density of the crystal provides excellent stopping power over a wide range of energies. The ability to operate at room temperature without the need for liquid-nitrogen cooling allows the construction of compact devices. CdTe and CdZnTe detectors can be fabricated into a variety of shapes and sizes, which makes it possible to produce detectors capable of meeting the requirements of a wide assortment of applications that are unsupported by other detector types. Their small size and relatively simple electronics allow them to open new areas of detector application. In many instances, CdTe and CdZnTe detectors can be substituted for other detector types in existing applications.

Table 33.2 The features of some semiconductor detectors

	NaI	Si	Ge	CdTe	$Cd_{0.9}Zn_{0.2}Te$
Bandgap (eV) at 300 K	–	1.14	0.67	1.54	1.58
Density (g/cm^3)	3.67	2.33	5.35	6.2	5.78
Energy per e–h pair (eV)	–	3.61	2.96	4.43	4.64
Detection/absorption	High	Low	Medium	High	High
Operation at room temp.	Yes	Yes	No	Yes	Yes
Spectrometic performance	Medium	High	Very high	High	High

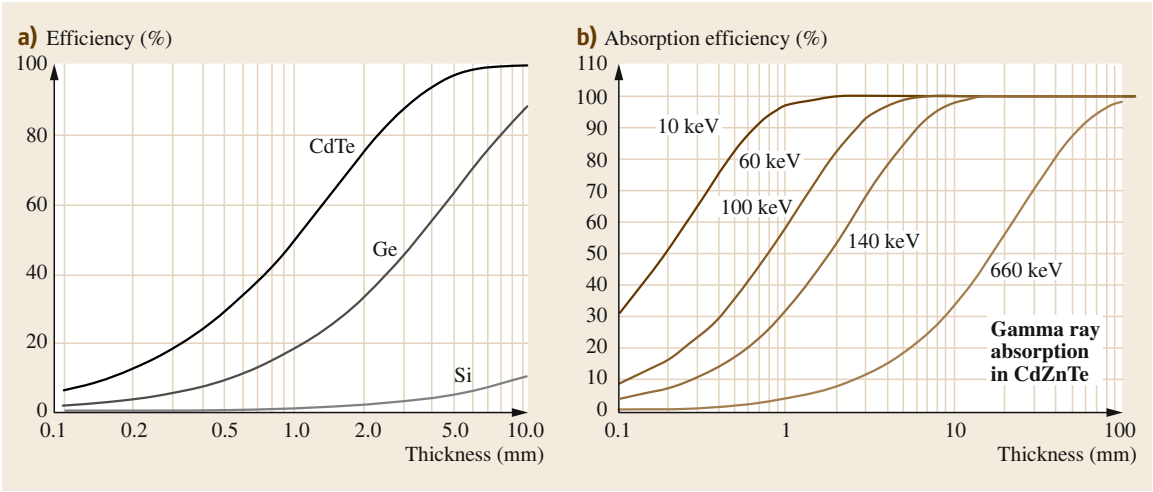

Fig. 33.8a,b γ-ray absorption in CdTe **(a)** and CdZnTe **(b)** detectors as a function of thickness

Figure 33.8 shows the γ-ray absorption efficiency in CdTe (Fig. 33.8a), and CdZnTe (Fig. 33.8b) detectors as a function of thickness. It was reported that, for a detector with a thickness of about 10 mm detecting 100 keV γ-rays, the detection efficiency for a CdTe detector is 100%, for a Ge detector 88%, for a Si detector only 12% [33.38]. In the case of a CdZnTe detector, CdZnTe with a thickness of only about 7 mm can absorb 100% of the γ-rays [33.39]. This efficiency assumes that the γ-ray is completely absorbed and the generated electron–hole pairs are completely collected. In fact, a large amount of charge loss occurs in CdTe and CdZnTe detector, depending on the quality of the materials.

33.3.3 Performance of CdTe and CdZnTe Detectors

Although CdTe and CdZnTe have many advantages over Si and Ge, including higher attenuation coefficients and lower leakage currents due to the wider bandgap, their disadvantages limit their application range [33.40]. The main disadvantage is that their crystals usually contain higher density defects. These defects are remaining impurities and structural defects such as mechanical cracks, twins, grain and tilt boundaries, and dislocations all lower the crystalline perfection of the materials.

In CdTe and CdZnTe detectors, the charge transport determines the collection efficiency of generated electron-hole pairs, and structural properties of materials control the uniformity of the charge transport. The problem of poor transport and collection of carriers, especially hole, can be overcome by applying high voltage to device and a range of electrode config. The former is related to high resistivity material, and later is related to the design of a detector. In addition, it was found that detected pulse signal intensity degraded with the time [33.41, 42]. This phenomenon was thought to be mainly related to the defects existing in bandgap. When the detector starts to work, these defects could act as slowly ionized acceptors. The low resistivity and poor quality material always exhibits such a polarization effect.

Summarizing above, improvement of a detector performance is equivalent to the improvement of the crystallinity of CdTe and CdZnTe. The key feature of all applications except substrate materials of CdTe and CdZnTe is the resistivity. This is because high resistivity can be obtained only by controlling native defects and impurity concentration. For many years, much effort was done in preparing high quality CdTe and CnZnTe single crystals.

Progresses in Crystal Growth of High Quality CdTe and CdZnTe

Various techniques have been applied to grow high-quality CdTe and CdZnTe single crystals. The Bridgman method [33.43, 44], the traveling-heater method [33.45, 46], growth from Te solvent [33.47], the gradient-freeze method [33.48, 49], and physical vapor transport [33.50, 51] are the most widely used. Crystals with applicable quality and size have become available, and have also fostered the rapid progress of research on CdTe.

As-grown CdTe single crystals commonly contain high concentration of both residual impurities and intrinsic defects. Preparation of high-purity high-resistivity CdTe and CdZnTe crystals has been widely attempted [33.52]. Early works was done by *Triboulet*

and *Marfaing* [33.53] in obtaining high-purity lightly compensated zone-melting growth following synthesis by the Bridgman method. The room-temperature carrier concentrations range from $1-5\times10^{13}\,\mathrm{cm}^{-3}$, and the resistivity from 100 to 400 Ω cm. The carrier mobility at 32 K reaches as high as $1.46\times10^{5}\,\mathrm{cm}^{2}/(\mathrm{V\,s})$. The total concentration of electrically active centers was estimated to be about $10^{14}\,\mathrm{cm}^{-3}$.

Usually, as-grown CdTe crystal shows p-type conductivity owing to the existence of remaining acceptor impurities or native defects. For this reason, many results have been reported in preparing high-resistivity CdTe. Chlorine (Cl) is thought to be a suitable donor for the compensation of these remaining acceptors because Cl can be doped quite uniformly due to its very small segregation coefficient [33.54].

The growth of high-resistivity CdTe:Cl single crystals with device quality was successfully performed by the traveling-heater method (THM) [33.54]. Solvent alloys for THM growth were synthesized in ampoules filled with Te, CdTe and $CdCl_2$ so that the molar ratio of Te/Cd was the same as in the solvent zone during the growth. The Cl concentration in the grown crystal was 2 weight-ppm. According to the dynamics of the crystal growth, it is important to control the shape of the solid–liquid to grow high-quality single crystals. Therefore, the solvent volume was optimized. The use of a slightly tilted seed from ⟨111⟩B was also effective in limiting the generation of twins with different directions. Single-crystal (111) wafers, larger than $30\times30\,\mathrm{mm}^2$ were successfully obtained from a grown crystal with a diameter of 50 mm. Pt/CdTe/In detectors with dimensions of $2\times2\times0.5\,\mathrm{mm}^3$ showed better energy resolution, because a higher electric field can be applied. The effective detector resistivity was estimated to be 10^{11} Ω cm.

CdTe doped with chlorine (Cl) or indium (In) with a resistivity of 3×10^{9} Ω cm and CdZnTe with a resistivity of 5×10^{10} Ω cm were grown by the high-pressure Bridgman (HPB) technique [33.55]. The material was polycrystalline with large grains and twins. Although the crystalline quality of HPB CdTe and CdZnTe is poor, the grains are large enough to obtain volume detectors of several cm^3. Photoluminescence (PL) spectra at 4 K showed that the free exciton could be observed and the FWHM of the bound excitons is very low. Some impurity emissions were identified. The detectors were fabricated from HPB CdTe and CdZnTe. These detectors showed excellent performance. Gamma-ray spectra were presented with high-energy resolution in an energy range from 60 to 600 keV. Using a $10\times10\times2\,\mathrm{mm}^3$ HPB detector, at a bias of 300 V, the peak at 122 keV from ^{57}Co had a FWHM of 5.2 KeV. Detectors with high-energy resolution were fabricated.

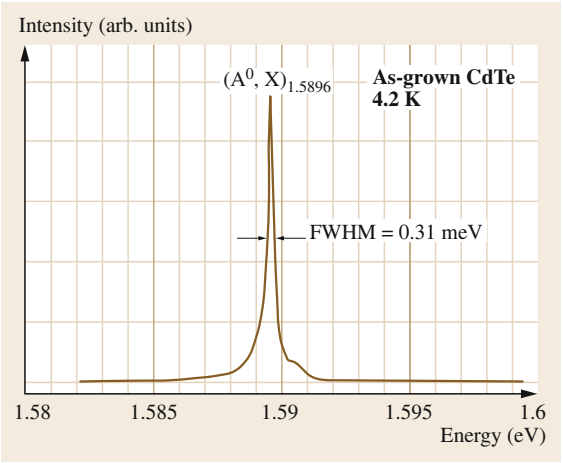

Fig. 33.9 A typical high-resolution PL spectrum of a high-purity CdTe sample

Because of the difference in vapor pressure between Cd and Te, grown crystals contain a large number of Cd vacancies (V_{Cd}). These Cd vacancies manifest acceptor behaviour. Therefore, high-resistivity CdTe can also be obtained by controlling the concentration of Cd vacancies. However, a prerequisite is that the purity of the CdTe crystal is high enough that the remaining impurities do not play a substantial role in determining the conductivity. Recently, the preparation of ultra-high-purity CdTe single crystals was reported [33.56, 57]. In order to obtain a high purity the starting materials of Cd and Te, Cd were first purified by vacuum distillation (VD) and the overlap zone-melting (OZM) method [33.56], while Te was purified using the normal freezing method [33.57]. The results of glow-discharge mass spectroscopy (GDMS) and the measurement of the residual resistivity ratio (RRR) showed that refined Cd and Te had the purity of 6N-up. Using the refined Cd and Te as starting materials, extremely high-purity twin-free CdTe single crystals were prepared by the traditional vertical Bridgman technique. Figure 33.9 shows a typical high-resolution PL spectrum of a high-purity CdTe sample. Only a sharp and strong emission line of (A^0, X) (an exciton bound to a neutral acceptor) at 1.5896 eV was observed. The FWHM of the (A^0, X) line is 0.31 meV. This is the narrowest value ever reported for CdTe single crystals grown by the Bridgman method. All of the above indicate that the sample is of high purity and quality. For a good performance detector, the leakage current must not exceed a few nanoamps, which requires a material with high resistivity. When growing CdTe crystals, the CdTe contain large number of Cd vacancies due to the extreme volatility of Cd. For these reason, CdTe single crystals were annealed in a Cd atmosphere in order to

obtain a high-resistivity crystal. Hall-measurement results showed that the conductive type changed from as-grown p-type to n-type at a Cd pressure around 1.5×10^{-2} atm, corresponding to a Cd source temperature of 500 °C. Samples annealed under these conditions showed a resistivity as high as $10^9\ \Omega$ cm.

Lachish [33.58] grew CdTe and CdZnTe crystals with excess cadmium in order to avoid the Te precipitates found in crystals grown by Bridgman method. During crystal growth one ampoule end was kept at a low temperature, which determines a constant, nearly atmospheric, vapor pressure in the system. The constant vapor pressure maintains a constant liquid composition and balanced amounts of cadmium and tellurium within the crystal. Although the highly donor-doped crystals are highly electrically conducting, successive annealing in Te vapor transforms the crystal wafers into a highly compensated state showing high electrical resistivity and high gamma sensitivity, depending on the doping level.

Improvements of Transport and Collection of Carriers in CdTe and CdZnTe Detectors

The transport and collection of carriers in CdTe and CdZnTe, especially holes, are the main problems that affect their performance. Poor carriers transport causes position-dependent charge collection and limits their capability as high-resolution spectrometers [33.59]. As a result, this limits the volume of detector. Therefore, the efficient detecting resolution and range are decreased. *Amman* et al. [33.60] studied the affect of nonuniform electron trapping on the performance of a γ-ray detector. An analysis of the induced charge signals indicated that regions of enhanced electron trapping are associated with inclusions, and that these regions extend beyond the physical size of the inclusions. Such regions introduce nonuniform electron trapping in the material that then degrades the spectroscopic performance of the material as a γ-ray detector. The measurements showed that the degree of nonuniformity that affects detector performance could be at the 1% level. Consequently, any useful characterization and analysis technique must be sensitive down to this level.

Detectors equipped with Ohmic contacts, and a grounded guard ring around the positive contact, have a fast charge-collection time. Conductivity adjustment, in detectors insensitive to hole trapping, optimizes the detector operation by a trade-off between electron lifetime and electrical resistance. Better hole collection has been achieved by designing detectors and electrodes of various geometries. *Nakazawa* et al. [33.61] improved the CdTe diode detectors by fabricating the guard-ring structure in the cathode face, and the leakage current of the detector decreased by more than an order of magnitude. The new CdTe detector was operated with a bias as high as 800 V at 20 °C and showed a good energy resolution (0.93 keV and 1 keV FWHM for 59.5 keV and 122 keV, respectively) and high stability for long-term operation at room temperature. Furthermore, they also developed a large-area ($20 \times 20\ \text{mm}^2$) detector with very high resolution. Owing to its high stopping power and high resolution at room temperature, pixel imagers have also been developed in the same group, and it is thought that this large diode detector could possibly be a substitute for scintillation detectors.

Since the carriers drift slow and have a short lifetime in CdTe detectors, the number of photons in the photo-peak is reduced and the spectrum is distorted by a tail towards lower energies. For these reasons, CdTe detectors are usually made into Schottky diodes, because this structure can withstand much higher bias voltage with a leakage current orders of magnitude lower than detectors with Ohmic contacts. *Takahashi* et al. [33.62] adopted the configuration of Schottky CdTe diode, which due to the low leaking current, makes it possible to apply a much higher bias voltage to ensure complete charge collection in relatively thin (< 1 mm) devices. Both the improved charge-collection efficiency and the low leakage current lead to an energy resolution of better than 600 eV FWHM at 60 keV for a $2 \times 2\ \text{mm}^2$ device without any electronics for charge-loss correction. Meanwhile, they also fabricated large-area detectors with dimensions of $21.5 \times 21.5\ \text{mm}^2$, with a thickness of 0.5 mm and an energy resolution of 2.8 keV. Stacked detectors can measure the energies as high as 300 keV. Furthermore, a large-array detector, consisting of 1024 individual CdTe diodes, was also made. Every detector had a dimension of $1.2 \times 5.0\ \text{mm}^2$. The total area, including the spaces between the detector elements, is $44 \times 44\ \text{mm}^2$. This array detector is expected to be used in next-generation Compton telescopes.

33.3.4 Applications of CdTe and CdZnTe Detectors

Owing to the convenience of the smaller collimator, better resolution and temperature stability, CdTe and CZT detectors have been used in safeguard applications by the International Atomic Energy Agency (IAEA) and some countries for over ten years [33.63, 64]. With the gradual improvement in performance, CdTe and CdZnTe detectors are replacing NaI detectors used in spent-fuel attribute tests [33.65], though their sensitivity is still low compared to NaI and Ge detectors, although already sufficient for many applications. CdTe detectors have a sensitive volume of

about 20–100 mm^3 and a probe diameter of 8–9 mm. CdZnTe detectors have a larger volume than CdTe detectors. The largest commercial CdZnTe detectors have a geometric volume of 1687 mm^3 ($15 \times 15 \times 7.5\ mm^3$). Detectors are mainly of hemispheric design to obtain high carrier-collection efficiency. These large-volume detectors have been made into portable and hand-held isotope-identification devices and are being used to detect radioactive sources.They will become commercially available in the near future.

At present, conventional x-ray film or scintillator mammograms are used in medical diagnostics such as screening for breast cancer. However, these show a nonlinear response to x-ray intensity and the detection quantum efficiency is low. Room-temperature semiconductor detectors such as CdTe and CdZnTe have favorable physical characteristics for medical applications. From the start of these investigations in the 1980s, rapid progress has been achieved [33.66–71]. *Barber* [33.67] presented results concerning, first, a CdTe two-dimensional (2-D) imaging system ($20 \times 30\ mm^2$ with 400×600 pixels) for dental radiology and, second, a CdZnTe fast pulse-correction method applied to a $5 \times 5 \times 5\ mm^3$ CdZnTe detector (energy resolution of 5% for a detection efficiency of 85% at 122 keV) for medical imaging. After that, a 2 mm-thick CdZnTe detector was fabricated for application to digital mammography [33.69]. The preliminary images showed high spatial resolution and efficiency. Furthermore, CdTe and CdZnTe detectors with a thickness of 0.15–0.2 mm were fabricated [33.71]. The detectors are indium-bump-bonded onto a small version of a chip. Their detection quantum efficiency was measured as 65%. This result showed that CdTe and CdZnTe detectors are superior to scintillator-based digital systems, whose quantum efficiency is typically around 30–40%. This showed that CdTe and CdZnTe detectors have potential applications in medical imaging, as well as industrially for nondestructive evaluation inspection.

In universe exploration, Cd-based detectors can be used in an advanced Compton telescope (ACT) planned as the next-generation space-based instrument devoted to observations of low/medium-energy γ-rays ($\approx$ 0.2–30 MeV) and to the nonthermal energy exploration telescope (NeXT) [33.72]. In the universe, radiation rays have a wide energy range of 0.5–80 keV. In order to detect this wide range of radiation, *Takahashi* et al. [33.73–75] proposed a new focal-plane detector based on the idea of combining an x-ray charge-coupled device (CCD) and a CdTe pixel detector as the wide-band x-ray imager (WXI). The WXI consists of a soft-x-ray imager and a hard-x-ray imager. For the detection of soft x-rays (10–20 keV) with high positional resolution, a CCD with a very thin dead layer will be used. For hard x-rays, CdTe pixel detectors serve as absorbers. This study is now under way.

33.4 Conclusions

Devices fabricated from Cd-based compounds, such as solar cells and radiation detectors, are being applied in our daily life. In the case of solar cells, although recent success have improved their conversion efficiency and reduced the cost, many problems remain. Fundamental understanding of the CdTe-based solar-cell properties is limited, particularly as a result of their polycrystalline nature. Therefore, the fundamental electronic properties of polycrystalline Cd-based thin films should be studied deeply. Other challenges are to reduce the cost and to lengthen the operating life span. These problems are being studied and solved [33.76].

In the case of radiation detectors, CdTe and CdZnTe detectors have many advantages, such as room-temperature operation, high count rates, small size, and direct conversion of photons to charge, which make them attractive candidates for a wide variety of applications in industrial gauging and analysis, as well as medical instrumentation and other areas. These detectors are being made available commercially at present. However, they have severe problems such as polarization effects, long-term stability and their high price. Further efforts should still be focused on the preparation of high-quality materials and improvement of the stability and reliability of detectors. We are confident that radiation detectors made from Cd-based compounds will achieve more widespread application.

34. II–VI Narrow Bandgap Semiconductors: Optoelectronics

Ian M. Baker

The main purpose of this chapter is to describe the applications and technology of II–VI narrow bandgap semiconductors, focussing on HgCdTe for infrared sensors. It provides a historical record of the development HgCdTe through photoconductors and photodiode arrays. The solid-state physics of HgCdTe is described to provide a foundation to explain the main crystal growth processes and device technologies. It concludes with a review of the research and development programs in centers around the world on third-generation infrared detector technology (so-called GEN III detectors). These include small pixel technology, higher operating temperature (HOT) device structures, two-color array technology, electron avalanche photodiodes (e-APDs), multifunctional HgCdTe detectors, retina level processing, and future trends for HgCdTe infrared detector arrays.

34.1 Overview

The main commercial application for narrow bandgap semiconductors is in infrared radiation detection. There are relatively few simple, elemental, or compound semiconductors with the correct forbidden energy gap to sense photons within the infrared spectrum, particularly at longer wavelengths. It is also beneficial to accurately match the spectrum to certain atmospheric windows, so the ability to tailor the wavelength is very important. A great deal of work has been carried out to synthesize crystals using an alloy of two different compounds with widely separate forbidden energy gaps (or bandgaps). II–VI compounds have crystal properties that make them very suitable for mixing, and they have a range of bandgaps from near zero for the semimetal Hg compounds to more than 1 eV.

However, among the wider bandgap II–VI semiconductors, only Cd, Zn, Mn, and Mg have been shown to open up the bandgap of the Hg-based semimetals HgTe and HgSe. By far the most developed alloy system is $Hg_{1-x}Cd_xTe$ (HgCdTe), a semiconductor formed from the semimetal HgTe and the wide bandgap semiconductor CdTe. By adjusting the alloy composition x, the

© Springer International Publishing AG 2017
S. Kasap, P. Capper (Eds.), *Springer Handbook of Electronic and Photonic Materials*, DOI 10.1007/978-3-319-48933-9_34

properties, including bandgap, can be varied smoothly between HgTe and CdTe. The advantages of this system arise from a number of features, notably: close lattice matching, high optical absorption coefficient, low-carrier generation rate, high electron mobility, and readily available doping techniques.

There has been some interest in developing alternative ternary alloys to replace HgCdTe since from theoretical considerations the already weak Hg–Te lattice bond is further destabilized by alloying with CdTe, and there is a potential for obtaining materials with increased hardness and detectors with better temperature stability. Most other compound combinations have crystal growth problems or doping limitations that make them unsuitable for device fabrication with the possible exception of $Hg_{1-x}Mn_xTe$, $Hg_{1-x}Zn_xTe$, and $Hg_{1-x}Cd_xSe$. Photoconductive detectors have been reported using $Hg_{1-x}Mn_xTe$, and photovoltaic detectors using both materials, but devices have not reached the maturity of $Hg_{1-x}Cd_xTe$. Also, the technology reported for these materials is very similar to that of HgCdTe, and so many of the detector design, technology, and performance factors described in this chapter for HgCdTe are also relevant to other II–VI alloys.

The main purpose of this chapter is to describe the applications, device physics, and technology of II–VI narrow bandgap devices, focussing on HgCdTe. It concludes with a review of the research and development programs in centers around the world on third-generation infrared detector technology (so-called GEN III detectors).

34.1.1 Introduction to Solar and Infrared Imaging

The Earth's atmosphere is conveniently transparent in the visible region, but it severely filters much of the radiation at longer wavelengths. Figure 34.1 shows the quantum spectra for solar and thermal radiation at the Earths' surface for specific conditions. The solar spectrum is scaled to a lux equivalent of 17 500 which is typical of a bright sunlit day. The thermal spectrum is the natural photon radiation emitted by all objects around us and depends on the temperature and the spectral emissivity of the materials in the scene. Passive thermal imaging is the term used to describe imaging of this radiation. Figure 34.1 shows the photon emittance of a body at a temperature of 20 °C peaking around 10 μm. After atmospheric absorption, the solar and infrared spectrum is divided into many windows which have names or letters as shown. The thermal infrared is particularly compromised by water vapor absorption, and there are only two windows used for imaging: the so-called medium wave infrared band (MWIR) between

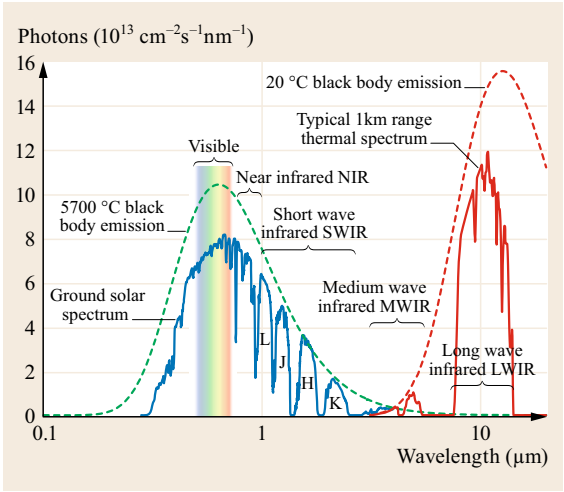

Fig. 34.1 Solar and thermal quantum spectra at the Earths' surface with associated band definitions. The solar data corresponds to a bright sunlit day of 17 500 lux

3.2 and 5.0 μm with a carbon dioxide notch around 4.3 μm and the long wave infrared band (LWIR) from 7.7 to 14 μm. The change in photon flux with temperature is small requiring sensitive detectors in contrast to visible sensors that need a wide dynamic range. HgCdTe is uniquely sensitive to the whole solar and thermal infrared range from 0.4 to 14 μm.

Figure 34.1 shows that the flux levels in the visible and thermal infrared are quite similar. In fact, the flux in the MWIR band is similar to the flux in the visible band at a scene illuminance of 250 lux corresponding to average room lighting. Infrared sensors can, therefore, exploit many of the focal plane technologies and signal processing developed for digital cameras.

34.1.2 Historical Perspective and Early Detectors

The first infrared photon detectors, based on thallous sulfide, were developed in the United States during World War I and were sensitive to about 1.4 μm. The next important developments occurred before and during World War II in Germany, with work on thin-film polycrystalline PbS devices with a response up to 2.5 μm, later extended further to the 3–5 μm region using PbSe and PbTe. During the 1950s and 1960s, indium antimonide (InSb) detectors emerged with a wavelength to 5.5 μm, and during the same period, impurity photoconductivity was studied in doped germanium and doped silicon. Germanium was favored at this time because it was available with fewer compensating impurities and gave better detector performance. Ge:Hg, with an impurity activation energy of 0.09 eV,

provided the first practical detector to be used in real-time thermal imaging, employing linear arrays for the 8–13 μm region. Because it required cooling to below 30 K extrinsic silicon devices have not found favor for terrestrial applications.

The next important phase of semiconductor infrared detector research took place during the late 1960s and 1970s, when research efforts were directed toward an intrinsic detector for the 8–13 μm band that would operate more conveniently at around 80 K. Two alloy semiconductors were developed, $Hg_{1-x}Cd_xTe$ (HgCdTe) and $Pb_{1-x}Sn_xTe$ (LTT). The first report of the synthesis of the semimetal HgTe and the wide-bandgap semiconductor CdTe to form the semiconductor alloy HgCdTe was published by the Royal Radar Establishment in Malvern, UK, by *Lawson* et al. [34.1]. This landmark paper reported both photoconductive and photovoltaic response at wavelengths extending out to 12 μm, and pointed out that this new alloy semiconductor showed promise for intrinsic infrared detectors. Soon thereafter many centers around the world switched detector development for major thermal-imaging programmes to the HgCdTe system. High-performance LW and MW linear arrays were produced for the first generation of thermal imaging equipment developed and manufactured in the 1970s through to the present. Many hundreds of thousands of detectors have been delivered.

34.1.3 HgCdTe Infrared Detector Market in the Modern Era

LWIR clearly has the most energy and was favored in older optically scanned systems where the dwell time was short and high flux was essential. Since the late 1990s, the LWIR market has been dominated by infrared detectors based on heat absorption. These include ferroelectrics, such as barium strontium titanate, or microbolometers, such as vanadium oxide (VOx) or amorphous silicon (α-Si). Uncooled cameras have an established volume market for relatively short-range imaging. They tend to need fast optics to achieve useful sensitivity and a typical focal ratio is F/1.2. For longer ranges, the diameter and weight of the germanium objective lens become an important issue. High-performance, cooled cameras based on HgCdTe have so much sensitivity in reserve that they can use focal ratios around F/4. It is straightforward and affordable to use long telephoto optical designs. They can also have fast frame rates with some cameras able to run at more than 1000 frames per second.

At first sight, the MW window looks compromised by the photon flux, some two orders lower than the LW window. However, it is much easier to make two-dimensional (2-D) detectors for this wavelength, and the photon flux disadvantage can be offset by staring architectures that enable a longer integration (or stare) time. The pixel size can be proportionately smaller with wavelength and typical sizes range from 8 to 15 μm. Array formats can be much larger than uncooled arrays, and HD 1024×768 and 1280×768 formats are used in the top-end cameras. High-performance thermal imaging market is currently shared between two material systems: indium antimonide (InSb), which has sensitivity to 5.5 μm, and HgCdTe. InSb has most of the cooled thermal imaging market because it was the earliest to be developed. HgCdTe has some key discriminators that may make it the material of choice for future *third-generation* developments. HgCdTe can be operated at much higher temperature than InSb so cameras can be smaller and have lower power consumption. HgCdTe can be grown in complex heterostructures with layers of different bandgap and doping for advanced sensors. The device technology is amenable to small pixels with small optical crosstalk. The dark current is relatively low in HgCdTe, providing opportunities in scientific applications and long-range imaging, especially in association with avalanche photodiode arrays.

The SW window is rarely used for passive thermal imaging because of low flux, but active imaging using a source, such as infrared illuminators, lasers, or even nightglow, is of continuing interest and it is the main band used in astronomy. Other materials can be used for SW detectors but products such as InGaAs tend to have high noise beyond 1.7 μm due to defects arising from the lattice mismatch with the InP substrate. HgCdTe has almost ideal solid-state properties for electron avalanche photodiode (e-APD) devices). The high mobility ratio of HgCdTe results in single-carrier multiplication with low noise figures, and such devices are exploited in photon-starved applications, such as long-range imaging and astronomy.

There are emerging technologies for the higher performance market based on quantum effects in III–V materials, such as type II superlattices, barrier photoconductors (so-called nBn devices), and multiple quantum well (MQW) detectors (usually using AlGaAs/GaAs technology). These systems are claimed to have higher ultimate performance than HgCdTe, better reliability, and lower manufacturing cost. Recent developments in wafer scale growth of HgCdTe, however, have set new standards. Also, the two drawbacks of lower quantum efficiency (QE) and the absence of a good surface passivation process (HgCdTe can use interdiffused CdTe) may limit how close these systems can get to the ultimate performance.

34.2 Applications and Sensor Design

Often the detector is the performance-limiting component in the camera, and it is necessary to use detectors with a sensitivity limited only by the random rate of arrival of photons from the scene (so-called background limited detectors, BLIP detectors). In a narrow gap semiconductor using both photoconductive and photovoltaic detectors, it is necessary to cool so that the thermal generation and associated excess noise are suppressed and the sensitivity becomes *BLIP limited*. The choice of cooler is, therefore, a key technology in an infrared detector, and the common options are described here. One of the points to emphasize is that the focal plane array is only one of a number of components that need to be optimized to preserve the BLIP performance. The optical design, cryogenics, and signal processing are also important to maintain the sensitivity of the focal plane array.

The means of cooling depends on the detector type and application. For instance photoconductive arrays often need a lot of cooling power, because of the Joule heating on the focal plane and the need for many bond wires that add to the thermal load. Two-dimensional arrays, on the other hand, often consume little power and have few connections, allowing alternative cooling methods. Other considerations are cooldown time, power, weight, space volume, robustness, and life.

Historically, the Joule–Thompson cooler was the first available method of cooling, relying on compressed gas bottles for power. The cooling power can be very high. Most first generation detectors use Joule–Thompson cooling. In more recent times, the high cooling power is exploited routinely in fast cooldown applications. Figure 34.2 illustrates a typical fast cooldown product, which can be cooled in a few seconds to liquid argon temperature (92 K) where BLIP performance is easily achieved.

Most modern thermal imaging applications use a cryocooler based on the Stirling cycle, which can achieve temperatures as low as 55 K but is normally regulated to a temperature in the range of 80–140 K. Figure 34.3 shows a typical integrated detector–cooler assembly (IDCA). The cut-away in Fig. 34.3 shows the front end of the detector in more detail. The infrared array is bonded directly on the cold finger of the cooler. To ensure only photons from the scene reach the de-

Fig. 34.4 Typical thermoelectrically cooled detector. (Courtesy of Leonardo MW Ltd)

tector, a cold stop or a radiation shield is bonded to the cold finger. The cold stop will have internal baffles and special coatings to stop internal reflections and is a vital component to achieve the BLIP operation of the array. The detector will have an optical pass-band filter that controls the upper and lower wavelengths. This will vary with the application, but typical bands are 3.2–4.2 μm, 3.7–5.0 μm, or 7.7–10.6 μm. Two methods are commonly used. The filter can be incorporated in the cold stop, and is, therefore, cooled, producing a very efficient block to stray radiation from other parts of the dewar. Almost as good performance can be achieved with filters on the front window, and a well-designed cold stop.

The third means of cooling is Peltier cooling (usually based on bismuth telluride devices). A typical detector is illustrated in Fig. 34.4. State-of-the-art coolers can achieve temperatures as low as 180 K, but in general they are not as efficient as Stirling cryocoolers, and the cooling performance can be poor in high ambient temperatures. Nevertheless, the main strengths of long-term reliability, greater shock resistance, and smaller weight and space volume have created a large volume market, especially for small photoconductor arrays. The temperature of 180 K is not quite cold enough for thermal imaging, and the applications tend to be those that can tolerate lower performance infrared detectors.

34.3 Photoconductive Detectors in HgCdTe

A photoconductor usually comprises a small slab or element of material with two contacts. The aim is to detect the change in resistance of the element when the photon flux is changed. The first HgCdTe devices were photoconductive because of the simplicity of the technology, and the relative ease of achieving near-ideal infrared performance and excellent reliability. Photoconductors were developed in the early 1970s when only bulk grown material (from a Bridgeman process or a solid-state recrystallization process) was available. HgCdTe quickly proved to be the best option and other systems including $Hg_{1-x}Cd_xSe$, $Hg_{1-x}Zn_xTe$, and $Hg_{1-x}Mn_xTe$ could not be developed to the same level. HgCdTe photoconductive detectors have been in routine production since the early 1980s and are often called first-generation detectors. They are the key component of the US Common Module Thermal Imager and, in the form of the SPRITE detector they feature in the UK Class II Common Module imager. Detectors for thermal imaging are most commonly fabricated with a peak response in the 8−12 μm atmospheric window region and are cooled to 80 K by means of a Joule–Thompson expansion cooler or, more recently, a Stirling engine cryocooler. They are also quite commonly made for operation in the 3−5 μm atmospheric window, and either use cooling to 80 K or employ Peltier (or thermoelectric) coolers to cool to around 200 K. Peltier-cooled MW detectors are used in many small, hand held cameras, and a whole host of heat sensing applications. The reliable performance, low levels of defects and easily understood physics has led to a long product life for photoconductive arrays. However, the array size is limited and first-generation thermal imaging systems need to employ complex optics to scan the infrared image over the array to build up a scene.

Early HgCdTe used bulk crystal growth techniques and the simple device geometry allows arrays to be manufactured by chemomechanical polishing of thick slices of material. Because the electron mobility is many orders higher than the hole mobility, it is advantageous to work with n-type material where the photoconductive gain is very high. N-type material with a low doping level can be manufactured directly, using the Bridgeman growth process, or can be produced by two-temperature annealing. Low doping is essential for long-carrier lifetime. N-type material can utilize anodic oxidation to passivate the surfaces and provide an accumulated surface that repels minority carriers, preventing them from interacting with surface recombination sites. Surface recombination velocity as low as 50 cm s^{-1} is routinely achieved. Also, crystalline defects in n-type material appear to have a weak effect on the carrier lifetime.

Ion milling is used to prepare the contact windows. The resulting highly doped n^+ layer provides an excellent ohmic contact for electron flow, and a blocking contact to minority carrier holes (so-called excluding contact). This leads to nonequilibrium effects. When the bias is applied, no holes can be injected into the material to sustain the flow of holes in the bulk away from the contact. As a consequence, both hole and electron densities drop to maintain space–charge neutrality. The dominant thermal generation process in n-type material is Auger 1, and the generation rate can drop by an order and can substantially increase the responsivity and detectivity [34.2].

Figure 34.5 shows a photomicrograph and scanning electron microscope view of a typical photoconductive element. It comprises a small slab of material, typically 50 μm square and 8 μm thick with two ohmic contacts.

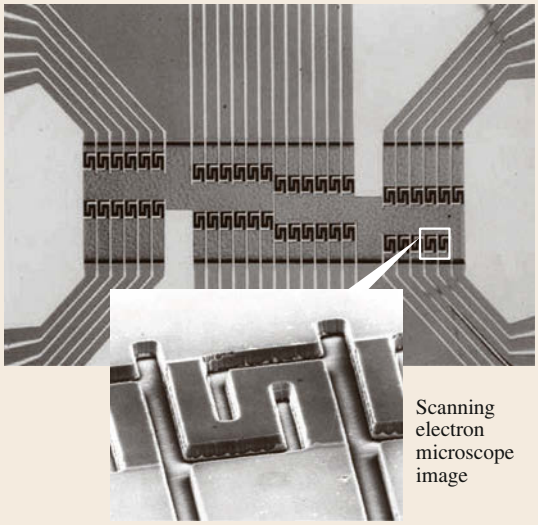

Fig. 34.5 Photomicrograph of 48-element photoconductive array using labyrinthed structures for enhanced responsivity. (Courtesy of Leonardo MW Ltd) ◄

The element illustrated has been *labyrinthed* to improve its performance. The device is operated using a constant current bias, supplied by means of a voltage source, and a series resistance, large compared to the detector resistance. The signal is measured as a voltage change across the detector, so that the device is essentially a radiation-sensitive resistor.

Despite its apparent simplicity, a rigorous analysis of photoconductor operation is quite complex [34.2, 3]. The analysis here is restricted to a one-dimensional treatment. *Kolodny* and *Kidron* [34.4] and *Oda* [34.5] have performed a 2-D and 3-D treatment.

Photoconductive HgCdTe detectors have been very successful in producing arrays of up to a few hundred elements for use in first-generation thermal imaging systems. The limitations of photoconductive detectors are apparent when very large focal plane arrays are required. The low impedance of the photoconductor makes it unsuitable for injecting into silicon charge transfer devices or field effect transistors; therefore, each element requires a lead-out through the vacuum encapsulation to an off-focal plane amplifier. The complexity of the dewar, therefore, limits the size of the array and the technology is not suitable for 2-D arrays.

34.4 Sprite Detectors

The SPRITE detector was invented in the early 1970s [34.6, 7] and it forms the basis of the UK Common Module detector, produced in large numbers. A thorough description of the device is reported by *Elliott* and *Jones* [34.8]. It is a very elegant method for amplifying the sensitivity of a photoconductive device. It is also a very compact device which enables highly efficient radiation shielding and economical use of material. SPRITE detectors are used in serial–parallel scan-imaging systems, because they perform a time-delay and signal integration function, in addition to a detector function. The operating principle of the device is illustrated in Fig 34.6. It consists of a strip of n-type HgCdTe, typically 700 μm long, 60 μm wide, and 10 μm thick, with three ohmic contacts. A constant-current circuit provides a bias through the two end contacts. The third contact is a potential probe for signal read-out.

There are two important points concerning the operation of the device. First, the bias field must be sufficiently high to ensure that excess minority carriers, generated along the filament length, can reach the negative end contact before recombination occurs. Second, the bias field must be chosen so that the ambipolar drift velocity, V_a, is equal to the image scan velocity. Consider now an image feature scanned along the filament, as illustrated in Fig. 34.6. The density of excess carriers increases during the scan as $[1-\exp(-x/V_a\tau)]$, where x is the distance from the positive bias contact along the scan direction, and τ is the excess-carrier life-

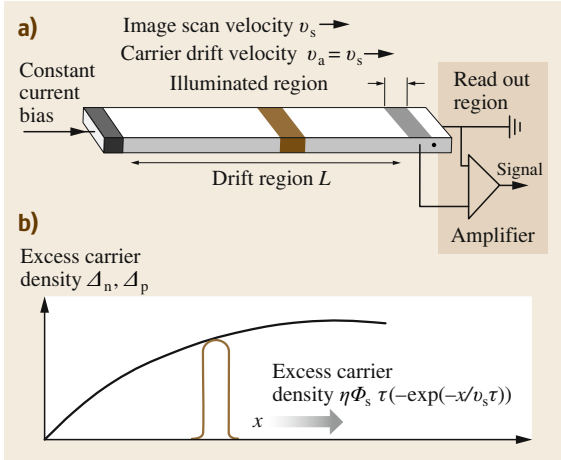

Fig. 34.6a,b Operating principle of a SPRITE detector

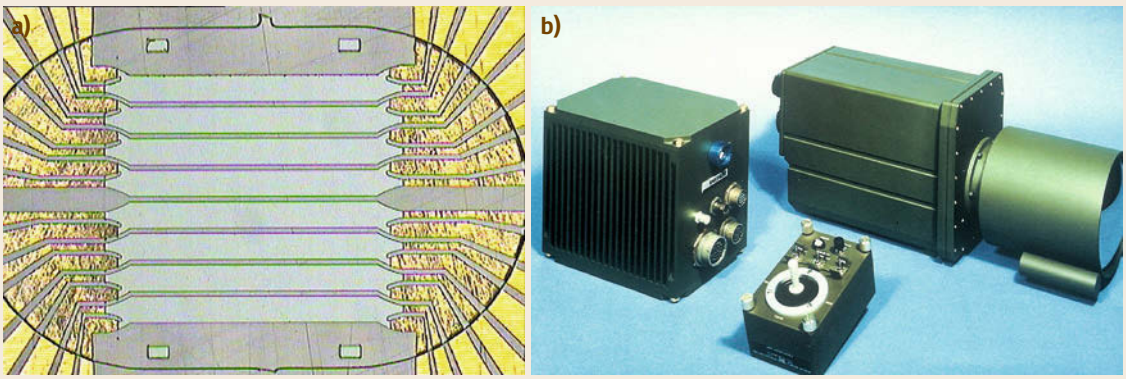

Fig. 34.7a,b UK Class II Common Modules Imager, **(a)** Horned OctoSPRITE **(b)** Camera modules. (Courtesy of Leonardo MW Ltd)

time. When the illuminated region enters the readout zone, the increased conductivity modulates the voltage on the contact and provides an output signal. Since the integration time of the signal flux, which is τ in a long element (or L/V_a in a shorter element), is greater than the dwell time on a conventional discrete element in a fast-scanned, serial system, a larger conductivity modulation and, hence, a larger output signal is observed. Therefore, the SPRITE detector continuously performs a time-delay and integration TDI function, and the signal-to-noise ratio is improved as a result of coherent integration of the signal and incoherent integration of the noise. The net gain in the signal-to-noise ratio is proportional to the square root of the integration time. For an amplifier-limited or a Johnson noise-limited detector, the gain is proportional to the integration time. Sprites can achieve a signal-to-noise improvement of a factor of 4 over a single photoconductor element.

The device depends on three aspects. The minority-carrier lifetime must be maximized to give the longest possible integration length, the speed of the carriers (holes) must match a practical image-scanning speed, and the thermal spread of the carriers must be minimized as this will blur the image. In practice, this implies the need for large minority-carrier lifetime, and low minority-carrier diffusion lengths. Lifetime values up to $\approx 10\,\mu s$ are obtained in alloy compositions suitable for 8–14 μm, 80 K operation, with N-type extrinsic carrier density $\approx 10^{14}\,cm^{-3}$. Recombination is principally by the Auger 1 process in these compositions. Lifetime values of 15–30 μs are obtained in compositions used for 3–5 μm operation at thermoelectric temperatures. The hole mobility is low in HgCdTe and results in short diffusion lengths even with long lifetimes, yielding a spatial resolution in the 8–14 μm band SPRITE devices of $\approx 50\,\mu m$ and $\approx 100\,\mu m$ in 3–5 μm devices if the full integration is used. Frequency response into the MHz region is achieved.

SPRITE detectors have been commonly used in 8-, 16-, and 24-row arrays and are commercially available in these forms. Larger Sprite arrays are limited by Joule heating in the elements which increases the heat load of the cooler to impractical levels. The Horned OctoSPRITE was the final development used in the UK Class II Common Module as shown in Fig. 34.7.

For comprehensive reviews, see [34.2, 9–11].

34.5 Introduction to Photovoltaic Devices in HgCdTe

Photovoltaic arrays have inherently low power consumption and can be easily connected to a silicon integrated circuit to produce a retina-like focal plane array (FPA). Photovoltaic devices emerged in the early 1980s and tended to fall into two categories: small matrix arrays mostly in the MW (3–5 μm) and long linear arrays mostly in the LW band.

Long linear arrays were first developed for systems with just one dimension of scanning. Because the image is scanned across the array very quickly, the dwell time is as short as a few tens of microseconds, and it is essential to use LW detectors with high QE and near BLIP-limited performance. HgCdTe became quickly established as the sensor of choice. Development work in the 1980s and 1990s in the United States and Europe has led to a family of detectors for LW thermal imaging, such as the US SADA II system based on a 480×6 format or the UK STAIRS *C* system based on a 768×8

array format (producing a high definition 1250×768 image). In the detector examples quoted, there are six or eight rows of diodes, and the signal from each row is delayed in time and added to provide an enhancement. This is called TDI. An important advantage of this scheme is that defective pixels can be deselected, so typically the STAIRS system will only use the best six of the eight diodes in one channel. Consequently, the detector performance can be relatively insensitive to defects in the HgCdTe and this is the reason why LW long linear arrays have reached maturity much earlier than LW matrix arrays.

Long linear arrays can also use the MW band, but the flux levels are over an order less than the LW band and the performance is compromised by the short integration time in a scanned system. MW detectors then tend to use matrix arrays where the integration time can approach the frame time. MW detectors have now reached maturity in large 2-D arrays with near-ideal performance and few pixel defects, and they produce remarkable sensitivities down to 10 mK. The MW band thermal imaging market ranges from small arrays using half-TV (320×256 or 384×288) or full-TV formats (640×480 or 640×512) to high-definition formats. The market is divided between indium antimonide (InSb) and HgCdTe. Broadly, manufacturing companies from the United States and Israel tend to prefer InSb and European, and some US companies have specialized in HgCdTe. Figure 34.8 shows a representative image from a state-of-the-art HgCdTe 2-D array. Larger arrays are produced for science applications, such as astronomy, and up to $4\,\mathrm{K} \times 4\,\mathrm{K}$ arrays are under development [34.12].

Unlike photoconductive arrays, manufacturers use a variety of different technologies for photovoltaic arrays. Sections 34.5.1–34.5.4 describe the theory of photovoltaic detectors and the fundamental principles behind the HgCdTe device technology. These principles help to explain the various approaches used by manufacturers to produce detectors in both the LW and MW bands described in Sect. 34.6.

34.5.1 Ideal Photovoltaic Devices

The current–voltage characteristic for an ideal diffusion-limited diode exposed to a photon flux φ_λ is given by

$$I_\mathrm{d} = I_\mathrm{s}\left[\exp\left(\frac{qV_\mathrm{d}}{k_\mathrm{B}T}\right) - 1\right] - qA\eta\phi_\lambda \,, \tag{34.1}$$

where I_d is the diode current, I_s is the diffusion current, V_d is the diode bias voltage (taking negative values in reverse-bias), η is the QE, and A is the detector area. The second term in (34.1) is the photocurrent, I_ph. The QE is given by

$$\eta = (1-R)\left[1 - \exp\left(-\alpha_\lambda t\right)\right] F \,, \tag{34.2}$$

where R is the reflectivity of the front surface, normally minimized by an antireflection coating, α_λ is the absorption coefficient, t is the optical path length through the absorber, typically around $5-10\,\mu\mathrm{m}$ to give adequate absorption in HgCdTe detectors, and F is a geometry factor that describes the number of photogenerated carriers within the pixel which reach the junction before recombining.

The condition that the detector be background limited is crucial for high-performance systems and to meet this condition the internal thermal generation must be much less than the photon generation in the lowest flux case, that is, $I_\mathrm{s} \ll I_\mathrm{ph}$. By differentiating (34.1), I_s is given by $k_\mathrm{B}T/qR_0$, where R_0 is the zero bias resistance.

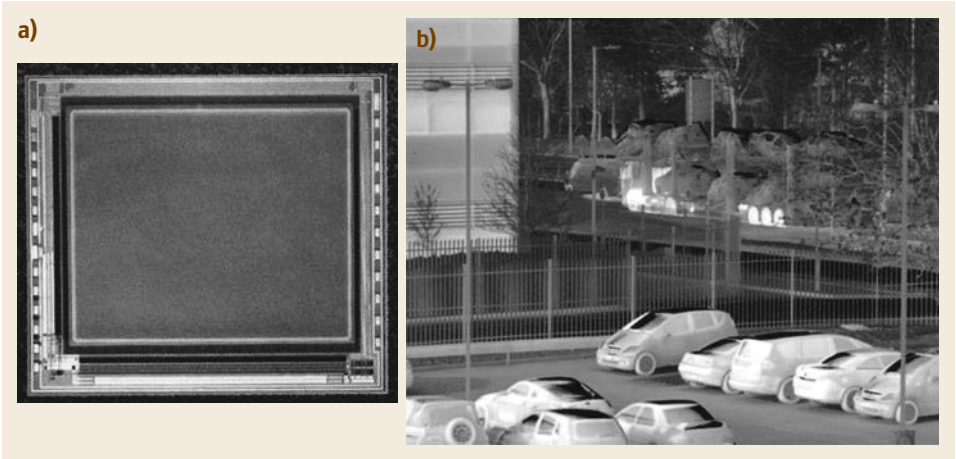

Fig. 34.8a,b Typical focal plane array **(a)** and thermal image **(b)**. (Courtesy of Leonardo MW Ltd)

The condition for background-limited performance is, therefore, often written as $R_0 \gg k_B T/qI_{ph}$, and this is the origin of the commonly used figure of merit, R_0A. As an example, in the case of an LW band system, say 10 μm cut-off, with an F2 optic and a lowest background scene temperature of −40 °C, an R_0A of greater than 30 Ω cm^2 is required. Detectors need to be cooled sufficiently to suppress thermally generated currents, but there are always pressures to avoid very low temperatures to give savings in power and cooldown time and better engine reliability. This is particularly the case for cut-off wavelengths longer than 10 μm, and detector technologies have emerged that provide high R_0A as a first priority.

The white noise current at low frequencies is given by

$$i_n^2 = 2qI_s\left[1+\exp\left(\frac{qV_d}{k_BT}\right)\right]B + 2q\,(qA\eta\phi_\lambda)\,B\,, \tag{34.3}$$

where B is the bandwidth in hertz. In the absence of photocurrent, the noise at the zero bias is equal to the Johnson noise, $4k_BTB/R_0$. In reverse bias, it tends to the normal expression for shot noise, $2q(I_s + I_{ph})B$. Note that the mean-square shot noise in the reverse bias is half that of the Johnson noise at the zero bias.

For photoconductor arrays, the established figure of merit is detectivity, D^*. For photodiode arrays, the photocurrent is integrated on a capacitor, so a better figure of merit is noise-equivalent temperature difference (NETD) [34.13]. For an integrated charge Q_{int} (comprising photocurrent, dark current, and stray photons), the minimum variance is the square root of Q_{int}. To derive the equation for NETD, it is useful to introduce the *thermal contrast ratio*, c. This is the proportional increase in photon flux per degree change in blackbody temperature. Typical values for c are 4 %/K in the MWIR and 2 %/K in the LWIR.

In terms of integrated charge,

$$cQ_{ph} = \frac{dQ_{ph}}{dT} \quad \text{or} \quad dT = \frac{dQ_{ph}}{cQ_{ph}} = \text{NETD}$$

if dQ_{ph} is replaced by the noise rtQ_{int}. The expression for NETD is shown in the following equation

$$\text{NETD} = \frac{1}{cQ_{ph}}\sqrt{Q_{int}}\,. \tag{34.4}$$

Note that in the ideal BLIP case, $Q_{int} = Q_{ph}$, and the NETD is given by the simple expression

$$\text{NETD} = \frac{1}{c\sqrt{Q_{ph}}}\,. \tag{34.5}$$

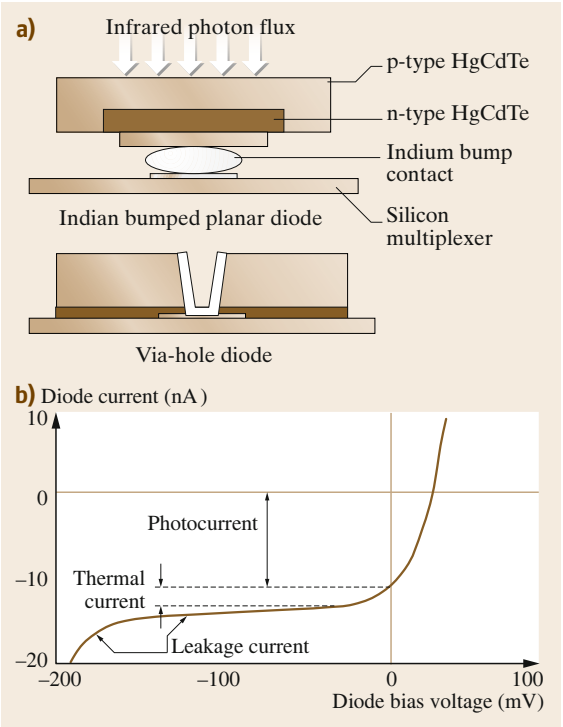

Fig. 34.9a,b Types of HgCdTe diodes **(a)** and a typical current–voltage characteristic for an LW diode showing main nonideal features **(b)**

34.5.2 Nonideal Behavior in HgCdTe Diodes

At longer wavelengths or higher operating temperatures, a number of leakage currents can impact the I–V characteristics and degrade the performance of the detector. Figure 34.9 illustrates a typical I–V characteristic for an LW diode, along with two types of HgCdTe photodiodes, a planar diode and a via-hole diode. The diagram illustrates how factors such as thermally generated current, shunt resistance, and breakdown currents at a high bias can affect the diode behavior. The performance can be degraded directly, for example, extra currents produce white noise which may be significant if the leakage currents are of the same order as the photocurrent. In addition, some leakage current mechanisms are associated with trapping or tunneling and often produce excess, low frequency noise (often called $1/f$ noise for the typical trend with frequency).

34.5.3 Influence of Silicon on Photodiode Array Performance

Additional constraints arise from the need to inject photocurrent into a silicon-integrated circuit often called an ROIC for readout integrated circuit. The simplest

method is called direct injection and literally means injection of the photocurrent into the source of a common gate MOSFET. A capacitor on the drain performs the integration. Good injection efficiency is only achieved if the diode has a dynamic resistance higher than the input impedance of the MOSFET. Unless the dynamic impedance of the diode is high enough, the signal can be attenuated, additional noise added, and nonlinearity generated in the response. Achieving a high dynamic resistance has been a driver in the development of most infrared technologies. In MW arrays with cut-offs up to 6 μm, high injection efficiencies are seen routinely because the photodiodes are near-ideal. In the LW band, there will be a limit to the upper cut-off wavelength and/or flux levels that routinely allow high injection efficiencies using direct injection.

The input impedance of a MOSFET is a function of the source–drain current (in this case, the total diode current) and is usually expressed in terms of the transconductance, g_m, given by $qI_d/(nk_BT)$ for low injected currents (n is an ideality factor that can vary with technology usually in the range of 1−2). The expression for injection efficiency, ε, is approximately given by

$$\varepsilon = \frac{R_v I_d}{R_v I_d + \dfrac{nk_BT}{q}} , \tag{34.6}$$

where R_v is the dynamic impedance of the diode and I_d is the total injected diode current equal to I_{ph} in the background-limited case.

In the background-limited case, (34.6) becomes a simple function of $I_{ph}R_v$. For a system requiring an efficiency of 99.9%, the value for $I_{ph}R_v$ approaches 10 V and in systems with slow optics and low background temperatures, the requirement for R_v can exceed $10^9\,\Omega$. There are more complex injection circuits that effectively reduce the input impedance and allow lower HgCdTe resistances to be used. Good comprehensive summaries are presented by *Kozlowski* [34.14] and *Kozlowski* et al. [34.15]. These buffer amplifier circuits may not be compatible with small pixels and consume more power but for some low photon flux applications offer a practical solution.

The ROIC can have a controlling effect on the sensitivity of 2-D arrays. Both charge coupled devices (CCDs) and standard foundry complementary metal-oxide-semiconductor (CMOS) devices have been used for multiplexing infrared 2-D arrays, but CMOS is now the preferred choice and CMOS circuits will operate well at low temperatures. The function of the multiplexer is to integrate the photocurrent from the photodiode array, perform a limited amount of signal processing, and sequentially readout the signals. As shown in Sect. 34.5.1, the sensitivity depends on the number of electrons integrated and this requires the integration capacitance in each pixel to be fairly high. Normally, the capacitor is created using a MOSFET structure with a thin gate oxide dielectric and capacitance values approaching 1 pF are possible producing NETD values as low as 10 mK. It is important to note that this NETD limitation has nothing to do with the HgCdTe, but it only depends on the pixel design. Furthermore, as the pixel size is reduced, the capacitance is decreased disproportionately, so the NETD cannot always be maintained in small pitch arrays.

34.5.4 Theoretical Foundations for HgCdTe Array Technology

Good detailed summaries of photodiode fundamentals have been provided by *Reine* et al. [34.16, 17] and the reference lists contained therein. The purpose of this section is to highlight the key issues that control the thermal generation, leakage currents, and QE in detectors. From this analysis, it is easier to understand the measures taken by detector manufacturers to make practical high-performance detectors.

Thermal Diffusion Currents in HgCdTe

When minority-carrier generation occurs due to a thermal process within a diffusion length from the p-n junction, it gives rise to a current that cannot be distinguished from the photocurrent. This is called thermal diffusion current and has two commonly reported generation mechanisms: Auger or Shockley–Read–Hall (S-R-H).

Auger recombination in HgCdTe is a phenomenon involving the interaction of three carriers. For instance, Auger 1 generation in n-type material is due to the interaction of two electrons and a hole and is dependent on the square of the carrier concentration. Fortunately, it is relatively easy to produce low-carrier concentrations in n-type HgCdTe ($< 5\times10^{14}\,\mathrm{cm}^{-3}$), and where there is a choice, this will be selected as the absorber type. In p-type material, Auger recombination involves two holes and an electron, and is referred to as Auger 7. It is well reported that Auger 7 lifetimes are an order greater than Auger 1, so in p-type material, the lifetime will transition from Auger 7 to Auger 1 at higher temperature. An empirical relationship for the minimum Auger generated dark current has been proposed called *Rule 07* by *Tennant* et al. [34.18, 19] and it is applied across a wide parameter space. This is often used as a baseline for HgCdTe devices when judging newer infrared technologies.

In p-type material, dark current generation through trap levels often dominates Auger 7. The reason may be

that crystal defects such as dislocations tend to decorate n-type and create local stress fields exposing trap levels. The lifetime in p-type HgCdTe is reported by *Lacklison* and *Capper* [34.20], *Polla* et al. [34.21], and *Radford* et al. [34.22] to show an inverse, linear dependence on doping, and this is attributed to the S-R-H proces. S-R-H recombination has been associated with the Hg vacancy and can be modeled by a strong donor level located $\approx 30\,\mathrm{mV}$ from the conduction band, which appears to be independent of composition in the $x = 0.2$–0.3 range. The density of these donor S-R centers is said to be proportional to the Hg vacancy concentration, but lower by a factor of ≈ 20. If Hg vacancies are replaced by acceptor atoms, such as Cu, Ag, Na, or Au, the lifetime can be increased by over an order. The use of extrinsic doping is an effective way to reduce thermal currents from the p-side in homojunction devices. A summary of the lifetime limiting mechanisms in "n"-type and "p"-type material as a function of composition, temperature, and doping level is given by *Kinch* [34.23].

Expressions for the diffusion current in photovoltaic devices have been derived by *Reine* et al. [34.16]. The fundamental R_0A expression is given by

$$R_0A\,(n-\mathrm{side}) = \frac{N_\mathrm{d}}{qn_\mathrm{i}^2}\sqrt{\frac{k_\mathrm{B}T\tau_\mathrm{h}}{q\mu_\mathrm{h}}}\,, \tag{34.7}$$

where N_d is the net donor concentration on the n-side, n_i is the intrinsic carrier concentration, which dominates the temperature dependence, and τ_h and μ_h are the minority carrier lifetime and mobility, respectively.

A similar expression describes the contribution of the p-side. In practice, the diffusion length, L, in normally doped HgCdTe is often larger than the typical absorber thickness of 3–5 μm. In this case, the volume available for the generation of diffusion current is restricted, and a suitable modified expression is

$$R_0A\,(n-\mathrm{side}) = \frac{k_\mathrm{B}TN_\mathrm{d}\tau_\mathrm{h}}{q^2n_\mathrm{i}^2t_\mathrm{n}}\,, \tag{34.8}$$

where t_n is the thickness of the n-type material.

In the case of L being greater than t_n, the surfaces and contacts can act as sources of extra diffusion current if the surface recombination velocity is greater than the diffusion velocity, D/L. It is essential to ensure properly passivated surfaces and for contacts employ a minority carrier barrier, such as a higher doped or wider bandgap layer under the metal contact.

In order to engineer a detector with low thermal diffusion current (or high R_0A), it is important to recognize that it is only necessary to use one side of the junction for collecting photocurrent; the other side, in principle, can be made wider bandgap, thereby minimising the thermal current contribution. Devices with layers of different bandgaps are called heterostructures. The most common design is to use a wider bandgap on the p-side to reduce the thermal diffusion current and use the n-side as an absorber taking advantage of long minority carrier diffusion lengths to maximise the QE.

Thermal Generation Through Traps in the Depletion Region

The thermal generation rate, g_dep, within the depletion region via traps, is given by the usual Shockley–Read–Hall expression

$$g_\mathrm{dep} = n_\mathrm{i}^2\left(n_1\tau_\mathrm{n0} + p_1\tau_\mathrm{p0}\right)^{-1}\,, \tag{34.9}$$

where n_1 and p_1 are the electron and hole concentrations, respectively, which would be obtained if the Fermi energy was at the trap energy, and τ_n0 and τ_p0 are the lifetimes in the strongly n- and p-type regions.

The leakage current is often known as the g–r current. Normally, one of the terms in the denominator of (34.9) will dominate, and for the case of a trap at the intrinsic level, n_1 and $p_1 = n_\mathrm{i}$, giving $g_\mathrm{dep} = n_\mathrm{i}/\tau$. It is the weaker dependence on n_i, and, therefore, on temperature, which distinguishes generation within the depletion layer from thermal diffusion current.

Where the depletion region intercepts the surface, there is often enhanced generation due to the presence of a high density of interface states. This can be exacerbated if the surface passivation is not properly optimized to give a flat band potential at the junction. In an extreme case, the surface on one side of the junction may become inverted, creating an extension of the depletion layer along the surface, and leading to high-generation currents. A practical solution to this mechanism is to widen the bandgap in the material where the junction intercepts the surface, the so-called heteropassivation. This can be achieved by using a thin film of CdTe together with a low-temperature anneal [34.24], and this is the commonest passivation technique used by manufacturers.

Interband Tunneling

Due to the very low effective mass of the electron in HgCdTe, direct band-to-band tunneling can occur from filled states in the valence band to empty states at the same energy in the conduction band. An expression for the current due to this process has been developed by *Anderson* [34.25]. The tunneling current increases very rapidly as the applied voltage or doping is increased, or the bandgap or temperature decreased. It is the normal

modern practice to use low doping on one side of the junction to minimize interband tunneling under normal operating conditions; nevertheless, at low temperature or for very long wavelength devices, interband tunneling can become dominant.

Trap-Assisted Tunneling

Trap-assisted tunneling is generally accepted to be one of the main causes of leakage current and excess noise in LW diode arrays, but it is not a fundamental limitation, often being associated with impurities or structural defects within the depletion region. The definition of a trap is a center with a capture coefficient for minority carriers many times larger than that for majority carriers. (Otherwise, it is a generation center.) The role played by traps in the depletion region is very complicated allowing for three possible two-step processes: thermal–tunnel, tunnel–thermal, and tunnel–tunnel. The nonthermal step can include tunneling of electrons from the valence band to traps, and tunneling from the traps to the conduction band.

The formulation for trap-assisted tunneling (TAT) for HgCdTe was developed by *Wong* [34.26] and by *Anderson* and *Hoffman* [34.27], based upon original work by *Sah* [34.28] in silicon. *DeWames* et al. [34.29], *Nemirovsky* et al. [34.30], and *Rosenfeld* and *Bahir* [34.31] have shown that models based on a thermal-tunnel process can explain the bias-dependent behavior of the reverse-bias current in long wavelength diodes.

Nemirovsky et al. [34.32] have shown that many of the observed properties of their n^+-p diodes can be explained by a TAT process via a thermally excited, bulk S-R-H center, modeled for the special case of the trap residing at the Fermi level. The physical picture for this assumption is that there is a uniform distribution of trapping centers throughout the bandgap, and the barrier for tunneling is lowest at the uppermost center that is still occupied. Hence, the occupied trapping center that coincides with the Fermi level has the highest transition probability and plays the dominant role in the thermal TAT process. This model helps to explain several unusual properties, such as the observed weak dependence of the leakage current on temperature and the doping level. Note that this is in contrast to direct band-to-band tunneling. Also, there is a much weaker dependence on diode bias voltage. The model also predicts the commonly observed *ohmic* region illustrated in Fig. 34.9 at a bias around −100 mV.

The physical origin of the trap has not been established yet but it appears to be an acceptor-type impurity or defect within the depletion region. The population of such traps is likely to be dependent on the HgCdTe material and the junction-forming technology, and so the quality of LW diodes is highly process specific.

Impact Ionization

Underlying TAT a more fundamental source of leakage current has been proposed which is called impact ionization. The effect arises because in HgCdTe, the electron scattering mechanisms tend to be weak and hot electrons can penetrate deep into the conduction band where they readily avalanche. Leakage current arises because extra electron–hole pairs are created within the depletion region due to impact ionization by minority-carrier electrons from the p-side. The leakage mechanism has been confirmed to have a linear relationship with optically injected minority carriers over a wide temperature range [34.33, 34]. To suppress this source of leakage current, the n-side doping must be very low [34.35]. Routinely achieving low-carrier concentrations ($< 5 \times 10^{14}\,\mathrm{cm}^{-3}$) is an important aim for homojunction technology. Most manufacturers introduce a donor, such as indium, to the crystal to control the n-type level to around $3-5 \times 10^{14}\,\mathrm{cm}^{-3}$. The carrier concentration in the p-region has a second-order effect compared with that of the n-region, for the range of concentrations normally used.

Photocurrent and Quantum Efficiency

HgCdTe has a strong optical absorption coefficient, and only thin absorber layers are needed to produce high QE. Most device structures have a back-reflector which enables two optical passes, so typically in MW detectors, the absorber need only be $2-3\,\mu\mathrm{m}$ thick and about twice this in LW detectors. Ideally, the absorption should occur well within a diffusion length of the p-n junction to avoid signal loss due to recombination. Potential recombination mechanisms are radiative, Auger, and S-R-H. Photons generated in radiative recombination may be reabsorbed in a process called photon recycling. In many device structures, this effectively extends the lifetime and radiative recombination is negligible, but it also poses a risk for crosstalk, especially in two-color devices. A long-carrier lifetime is nearly always observed in n-type material with low-carrier concentration. Device engineers tend to favor using n-type absorbers for the best QE and try to minimize the volume of the p-region for lower thermal leakage currents.

An interesting idea for improving QE and dark current is to perforate the absorber with tube-like holes to create a so-called photon-trapping structure (PTS). *Schuster* and *Bellotti* [34.36] summarise the status.

Excess Noise Sources in HgCdTe Diodes

For most applications, the detector performance depends on operating the diode in a small reverse bias where the dynamic resistance is at a maximum. It is then necessary to minimize extraneous leakage currents. The control of these leakage currents and the

associated low frequency noise is, therefore, of crucial interest to the device engineer.

In the field of thermal imaging, HgCdTe FPAs can now be manufactured with very few non-BLIP pixels over a wide spectral range from 1.0 to 12 μm. Most manufacturers use interdiffused CdTe as a passivant and have eliminated surface effects which currently is the weakness of many emerging III–V technologies. At higher operating temperature or very long wavelength, it becomes more difficult to suppress the effect of crystal defects and so it is important to summarise the research.

Firstly, there is a clear distinction between early research on LPE technologies grown on (111) CdZnTe and later work on molecular beam epitaxy (MBE) or metal organic vapor phase epitaxy (MOVPE). The reverse-bias characteristics and $1/f$ noise of HgCdTe diodes made in LPE are well known to depend strongly on dislocations intercepting the junction as revealed by defect etches. Threading dislocations, emanating from the substrate and possibly decorated during growth, are the most potent forms (for instance [34.34] and the references therein) giving excess dark current and noise, often of a bimodal nature. Some authors [34.37, 38] report that the dark current and noise mechanism through dislocations are TAT. Earlier many authors reported an empirical relationship between TAT leakage current and $1/f$ noise with a trend roughly given as $\alpha i_{\mathrm{L}}^{\beta}$, where α and β are device-dependant variables with β taking a value close to 0.5 (for instance [34.39]).

Some device structures have lateral collection architectures such as via-hole and planar devices. Here there is a possibility for n-type dislocation pipes to extend the depletion layer into the P-region. This has been discussed by *Kinch* et al. [34.40] and *Strong* et al. [34.41]. The n-type pipe can be viewed as a one dimensional MOSFET whose conductivity can be affected by nearby trapping events. In this way, a single trap can modulate the absorber volume and produce fluctuations in dark current, photocurrent and junction capacitance. A slow trap will result in a random telegraph signal spectrum (RTS) and a fast trap a $1/f$ noise spectrum. This type of noise source is reduced in VPE processes because the absorber volume is usually less than the diffusion length.

The current trend is to move toward lower temperature growth processes and growth on substrates with poor lattice match and this has refocused attention on grown-in dislocations. Also, the modern trend to operate infrared detectors at higher temperature (to reduce camera power) exaggerates the effect. MOVPE material on (100) orientation shows a faint pattern of etch pits suggesting no threading-type dislocations but a background of weak mosaic crystal boundaries [34.42]. It is apparent that the type of crystal defect affects the diode performance in different ways. Dislocations in the junction would be expected to contribute significant TAT current, but in VPE devices, the junction is routinely placed up the composition grade into a wider bandgap area and the thermal step in the TAT process is switched off. It is apparent then that VPE processes are much more tolerant of crystal defects due to bandgap engineering and the ability to control the absorber thickness.

34.6 Manufacturing Technology for Photodiode Arrays

There are four basic photodiode processes used commercially at present, two based on liquid phase epitaxy (LPE) growth and two on vapor phase epitaxy (VPE) growth. This section describes the processes but does not attempt to compare them as they are all under intense development toward smaller pixel sizes and higher operating temperature. All the processes are developed at least to 10 μm pixel size and manufacturers have different strategies to minimize crosstalk.

34.6.1 Liquid Phase Epitaxial (LPE)-Based Processes

LPE of HgCdTe at present provides the lowest crystal defect levels, and very good short and long-range uniformity. *Capper* et al. [34.43] has produced a detailed summary of the field. LPE layers are grown using an isothermal super saturation or programmed cooling technique or some combination. A detailed knowledge of the solid–liquid–vapor phase relation is essential to control the growth particularly in view of the high Hg pressure. Challenges include: the compositional uniformity through the layer, the surface morphology, the incorporation of dopants, and the specifications for thickness, wavelength, etc. A common component leading to high structural quality is the use of lattice-matched substrates of CdZnTe. These are grown by bulk processes, such as horizontal Bridgman, and can supply layers as large as 60 cm^2. The CdZnTe substrates must be of the highest quality and often this is a significant cost driver for the process.

Two different technical approaches are used: growth from Hg-rich solutions and growth from Te-rich solutions. Advantages of the Hg-rich route include: excel-

lent surface morphology, a low liquidus temperature, which makes cap layer growth more feasible and the ease of incorporation of dopants. Also, large melts can provide for very good compositional and thickness uniformity in large layers and give consistent growth characteristics over a long period of time. Growth from Te-rich solutions can use three techniques to wipe the melt onto the substrate: dipping, tipping, and sliding. A sliding boat uses small melt volumes and is very flexible for changing composition, thickness, and doping. Tipping and dipping can be scaled up easily and can provide thick, uniform layers, but the large melts limit flexibility. Double layers are also more difficult to grow.

Most manufacturers have taken their chosen growth system and tailored it to provide optimum material for their device technology. In particular, the use of dopants and the deliberate introduction of compositional grades are very specific to the device structure. A crucial figure of merit, however, is the dislocation count that controls the number of defects in 2-D arrays. Etch pit densities of $3-7\times10^4\,\mathrm{cm}^{-2}$ are typically seen in the Te-rich sliding boat process reproducing the substructure of the CdZnTe substrate [34.44]. The etch pits are associated with threading dislocations which appear to be normal or near normal to the layer surface. The substrate defect level can be as low as mid-$10^3\,\mathrm{cm}^{-2}$ in some horizontal Bridgman CdZnTe, but this is not easy to reproduce. Similar defect densities are found in CdTeSe material, but the impurity levels have proved difficult to control in the past. Device processing, therefore, must expect to cope with defect levels in the mid-$10^4\,\mathrm{cm}^{-2}$ range for routine CdHgTe epilayers and this will set the ultimate limit on the number of defects in HgCdTe 2-D arrays. Several groups have used the LPE process on low cost substrates including: CdZnTe or CdTe on GaAs/Si wafers [34.45] or the PACE technology on sapphire described in detail in Sect. 34.6.2, *Wafer Scale Processes Using Low Cost Substrates*.

Junction-Forming Techniques

For n–p devices, crystal growers can obtain the desired p-type level by controlling the density of acceptor-like mercury vacancies within a carrier concentration range of, say, 10^{16}–$10^{17}\,\mathrm{cm}^{-3}$. Neutralizing the Hg vacancies and relying on a background level of donors to give the n-type conversion create the photodiode junctions. Mercury can be introduced by thermal diffusion from a variety of sources but high temperature processes are not very compatible with HgCdTe at the device level. However, type conversion can be readily achieved by processes such as: ion beam milling, as described by *Blackman* et al. [34.46], and ion implantation, as described by *Margalit* et al. [34.47], *Kolodny* and *Kidron* [34.48], *Bubulac* et al. [34.49] and *Bubulac* and *Viswanathan* [34.50], and *Syz* et al. [34.51]. *Kinch* [34.52] also reports type conversion using plasma-enhanced milling in the VIAP process and *White* et al. [34.53] has similar observations for H_2/CH_4 plasmas. The common feature is that the conversion depth is much deeper than would be expected from the implantation range alone.

The current knowledge on type conversion using ion beam milling is described by *Baker* and *Maxey* [34.34], and the current knowledge for ion implantation is summarized by *Bubulac* and *Viswanathan* [34.50]. The explanation for the behavior of HgCdTe under ion beam bombardment involves a number of physical mechanisms. Firstly, the low binding energies, ionic bond nature, and open lattice of HgCdTe facilitate the liberation of free mercury at the surface and subsequent injection by the ion beam. The injection mechanism probably involves a recoil implantation process. Once the Hg interstitial is injected, the mobility is apparently extremely high, and there is some evidence that this is stimulated by the ion beam in a process related to the anomalously high diffusion rates of impurities often observed in SIMS analysis. Another factor is the movement of dislocations under the influence of the ion beam and possibly stimulated by strain fields. A number of workers report that the n-type carrier concentration in the converted region is very low and in fact, fast-diffusing impurities, such as Group IB elements Cu, Ag, and Au, and Group IA elements Na, K, and Li, which reside on the metal sublattice, are swept out of the n^- region of the diode by the flux of Hg interstitials. This impurity sweep-out effect is serendipitous because it means that in ion-beam-generated junctions, the n-regions are very pure, free of S-R centers, and have weak doping, creating an ideal structure for high-performance detectors. The detailed atomic level processes taking place, including the role of mercury interstitials, dislocations, and ion bombardment in the junction-forming process, are complex and not well understood in detail. Despite the complex physics involved, manufacturers have achieved good phenomenological control of the junction depth and n-dopant profiles with a variety of processes.

Via-Hole Technologies Using LPE

Via-hole devices share many of the process stages of photoconductive arrays and have been commercially produced since 1980. Arrays generated using this process are known as loophole devices [34.54] and HDVIP devices [34.52]. By using a thin monolith of HgCdTe bonded rigidly to the silicon, the thermal expansion mismatch problem is overcome because the strain is

taken up elastically. This makes the devices mechanically and electrically robust and suitable for very long linear arrays up to 16 mm in length [34.44].

The process flow of the via-hole device using LPE material is illustrated in Fig. 34.10. The process has two simple masking stages. The first defines a photoresist film with a matrix of holes of, say, 5 µm diameter. Using ion beam milling, the HgCdTe is eroded away in the holes until the contact pads are exposed. The holes are then backfilled with a conductor, to form the bridge between the walls of the hole and the underlying metal pad. The junction is formed around the hole during the ion beam milling process as described in Sect. 34.6.1, *Junction-Forming Techniques*. The second masking stage enables the p-side contact to be applied around the array. Figure 34.10 shows a photomicrograph of one corner of the hybrid illustrating the membrane-like nature of the HgCdTe on the silicon.

The HDVIP process [34.52] results in a similar structure but uses a plasma-etching stage to cut the via-hole and an ion implantation stage to create a stable junction and damage region near the contact. In order to achieve higher lifetimes and lower thermal currents, Cu is introduced at the LPE growth stage. This is swept out during the diode formation and resides selectively in the p-region, partially neutralising the S-R centers associated with Hg vacancies and achieving dark currents approaching that of fully doped heterostructures. In via-hole processes, the cylindrical shape of the junction minimizes the intersection with threading dislocations (see Sect. 34.5.4, *Excess Noise Sources in HgCdTe Diodes*). This has been demonstrated by the difference in yields when the HDVIP device is extended by a planar junction [34.52].

LW HgCdTe detectors were originally developed for long linear arrays and the processes can be extended to 2-D arrays with one additional consideration. The earth plane of the array must carry the sum of the photocurrent from all the pixels in the array, and if there is insufficient conductance, a voltage will appear between the center and edge of the array. This is called *substrate debiasing* and in the extreme case will inhibit injection in the center diodes. In any event, it provides a potential long-range crosstalk mechanism and detector designers will try to minimize the resistance of the earth plane layer. In homojunction arrays, the p-type common layer cannot be doped high enough and a special metal grid is needed, as shown in the array in Fig. 34.11. In other technologies, the common layer must be doped high enough to prevent long-range crosstalk and use junctions with high dynamic resistance.

Planar Device Technology Using LPE

The planar device structure illustrated in Fig. 34.12 is the simplest device structure currently used. It is consistent with a number of junction-forming processes, e.g., ion implantation, diffusion, and ion milling. The matrix of junctions is mass connected to a silicon ROIC using indium bumps. The strength of the process is the simplicity and the compatibility with epitaxially grown materials. *Tribulet* et al. [34.55] describe a process based on high-quality LPE material and ion-implanted junctions, which is conducive to good quality detectors and volume production. In the simplest form,

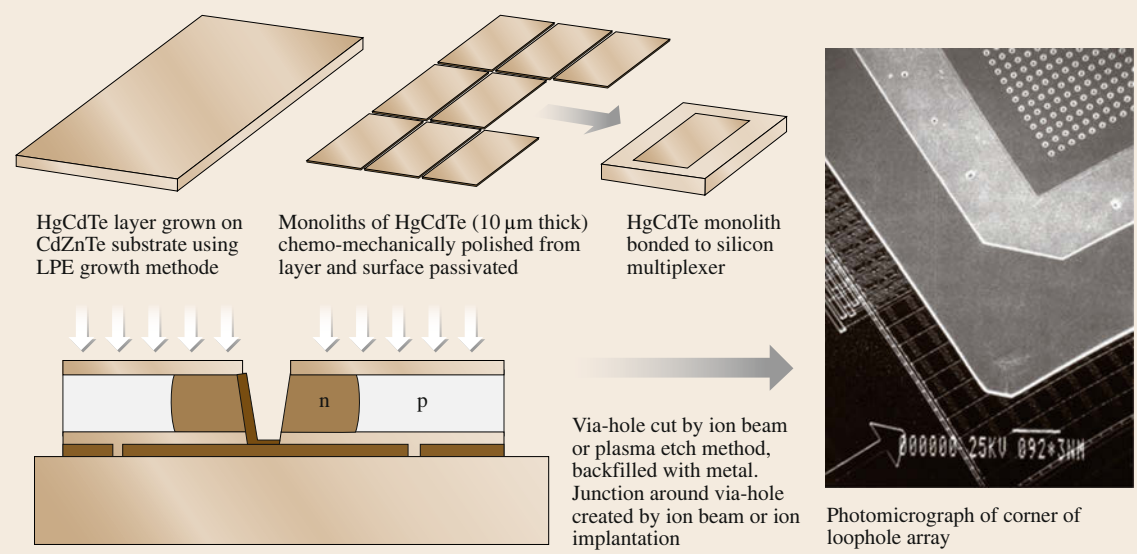

Fig. 34.10 Schematic of via-hole process

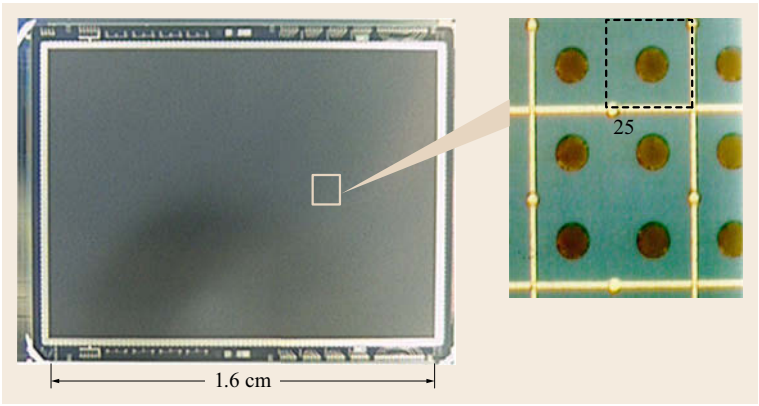

Fig. 34.11 LW HDVIP array with metal grid for substrate debiasing control. (Courtesy of DRS Technologies)

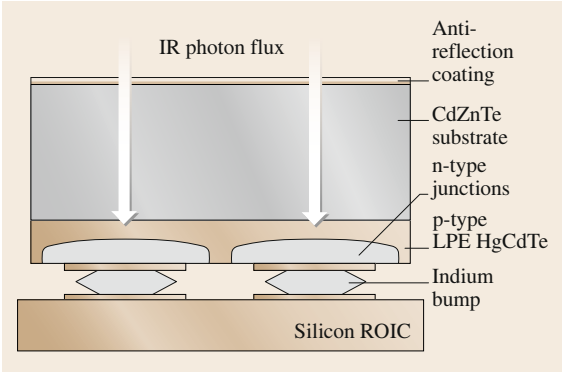

Fig. 34.12 Schematic of planar indium-bumped hybrid

the process needs three masking stages, for the junction and pixel contact, and one for the contact to the p-side. More recent publications have described the status at two manufacturing centers for instance: [34.56, 57] with the listed references.

The device is backside illuminated, that is, it is illuminated through the substrate, and because of interdiffusion, there is a graded bandgap region which aids diffusion of carriers to the junction. Careful control of the junction geometry is needed to avoid crosstalk due to the diffusion of minority carriers into adjacent pixels, especially in the case of small pixel sizes. The thermal expansion mismatch between the HgCdTe/CdZnTe substrate combination and the silicon multiplexer requires that in larger arrays, the CdZnTe substrate is thinned. In this case, the spectral sensitivity can be extended into the visible.

34.6.2 Vapour Phase Epitaxial (VPE)-Based Processes

Two growth processes are widely used: MBE and MOVPE. A good detailed summary of MBE technology has been prepared by *Wu* et al. [34.58]. *Maxey* et al. [34.59] describe in detail the MOVPE process. A brief comparison is included here.

MBE offers the lowest temperature growth under an ultra-high vacuum environment, and in common with MOVPE in situ doping and control of the composition and interfacial profiles. These are essential for the growth of advanced and novel device structures. Typically, growth is carried out at 180–190 °C on (211) CdZnTe substrates. Effusion cells of CdTe, Te, and Hg are commonly used. Hg is incorporated in the film only by reacting with free Te; thus, the composition depends on the Te-to-CdTe flux ratio. The structural perfection depends strongly on the Hg-to-Te flux ratio, and growth is usually restricted to a tight temperature range. Indium is the most widely used n-dopant and is well activated. P-type dopants are less conveniently incorporated in situ, but manufacturers have devised a number of processes to force As onto the proper Te site. Again the Hg-to-Te ratio and growth temperature are crucial to achieve good activation. MBE structural problems center mainly on pinholes or voids.

MOVPE offers higher growth rates which enable multiple runs per day to be achieved with a single growth reactor. MOVPE growth depends on transporting the elements cadmium and tellurium (and dopants iodine and arsenic) at room temperature as volatile organometallics. They react along with Hg vapor in the hot gas stream above the substrate or catalytically on the substrate surface. The drive to lower temperatures and, hence, Hg equilibrium pressures has resulted in the adoption of the Te precursor di-isopropyl telluride, which is used for growth in the 350–400 °C range. A key step in the success of this process is to separate the CdTe and HgTe growth, so that they can be independently optimized. This is called the IMP process for interdiffused multilayer process. The resulting stack of alternating CdTe and HgTe layers relies on the fast interdiffusion coefficients in the pseudobinary to homogenize the structure at the growth temperature. The

wavelength of $Hg_{1-x}Cd_xTe$ is determined by the composition x which is, in turn, dependent on the growth rates during the CdTe and HgTe cycles. The key difference to MBE is that control of HgCdTe composition can be simply accomplished by the length of time the Cd source flows into the reactor for the CdTe part of the IMP cycle. Also, since the dopants are incorporated on the CdTe cycle, the doping density is relatively independent of composition. Arsenic is used for p-doping (*Tris*-di-methyl amino arsine) and iodine for n-doping (*Iso*-butyl iodide), and are actively incorporated during growth without a requirement for an ex-situ anneal. The main morphological risk for MOVPE is the creation of hillocks that can cause a cluster of pixel defects. Particles or other surface roughening features can lead to the creation of these hillock features due to the fast ⟨111⟩ microcrystal growth rates that enhance any surface perturbation. Growth orientations 3–4° off (100) are used primarily to reduce both the size and density of hillocks.

Double-Layer Planar Heterojunction Devices (DLPH)

When a device uses different compositions or doping levels, a nomenclature is adopted for describing the structure. The definition used in this chapter is as follows. A diode comprising an n-type layer on a p-type layer is described as an n on p device, so the first letter is the layer nearest the contact. A superscript '−' or '+' denotes particularly low or high doping. Wider bandgap materials such as those used in barriers or contact areas are described as N or P.

Mesa heterostructures have a technologically difficult passivation stage on the sidewalls of the mesa, which can lead to reverse-bias leakage and uniformity problems if not optimum. *Arias* et al. [34.60] have demonstrated a clever diffused heterostructure, which overcomes the sidewall problem, called double-layer planar heterostructure (DLPH). This is a back-illuminated arsenic-implanted p–n–N planar buried junction structure [34.61] illustrated in Fig. 34.13. The junction is formed by arsenic implantation into a three layer N–n–N film grown in situ by MBE onto a CdZnTe substrate. The unique feature of this structure is that the junction is buried beneath the top wide bandgap n-type layer. The junction intercepts the surface in wider gap CMT, thereby reducing the generation rates for any surface defects that may be present. The arsenic-doped region must extend deep enough into the narrow gap absorber layer in order to collect photocarriers. This necessitates that the wide bandgap layer be thin (on the order of 0.5 μm) and that the compositional interdiffusion between the wide gap and absorber be minimal. Growth by MBE at low temperature (175 °C) satisfies these requirements. Another feature of this structure is

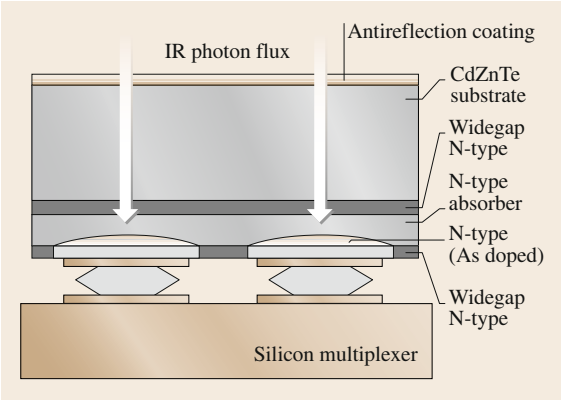

Fig. 34.13 Schematic of double-layer planar heterostructure (DLPH)

the wide bandgap N-type buffer layer between the absorber and the substrate. This buffer layer keeps carriers that are photogenerated in the absorber away from the substrate interface where there can be interface recombination. An empirical relationship for the dark current across a wide parameter space has been proposed called Rule 07 by *Tennant* et al. [34.18, 19]. This is often used as a baseline for HgCdTe devices when judging newer infrared technologies.

Recent progress on FPAs manufactured by the DLPH process is described by *Beletic* et al. [34.12]. The arrays are aimed at the civil space and astronomy markets, and they must meet very demanding specifications. For astronomy, the zodiacal background sets the specification for dark current as 0.01 e/s/pixel, a figure routinely met in specialized HgCdTe devices. In order to maximize the science return, the arrays need to be physically large and are often mosaicked into larger focal planes. The practical limit for DLPH arrays is around 6 cm^2 limited by the availability of single-crystal substrates of CdZnTe, and the largest array is 4 k × 4 k with 15 μm pixel size. Manufacturing such an array represents a triumph of electronic and thermo-mechanical engineering, and a photograph is shown in Fig. 34.14.

Mesa Heterojunction Devices (MHJ)

For heterostructures that are grown in situ, it is necessary to completely isolate the junction forming a so-called mesa device. The device structure is illustrated in Fig. 34.15, and this is sometimes called a double-layer heterojunction device (DLHJ). Each pixel is electrically isolated by a mesa slot that extends through the absorber to eliminate lateral collection which can often degrade the MTF of LPE-based processes. Manufacturers will create the mesa slot by the use of wet etches or dry processes such as ion beam milling, or a combina-

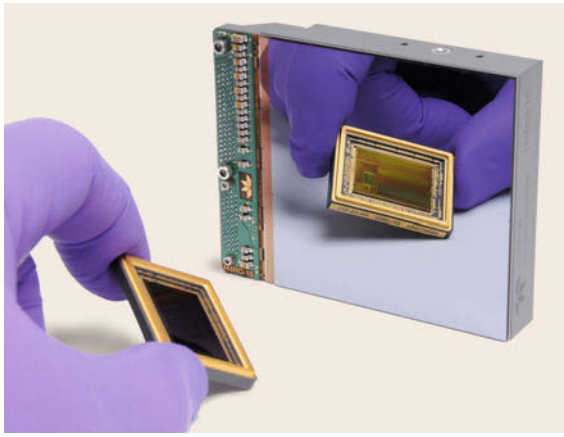

Fig. 34.14 4 k × 4 k SW array with 15 μm pixel size for astronomy. (Courtesy of Teledyne Imaging Sensors)

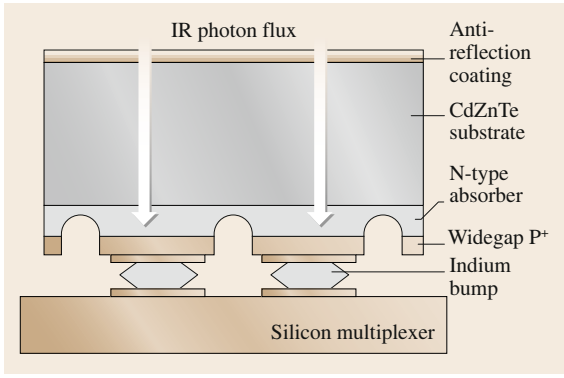

Fig. 34.15 Schematic of mesa heterojunction (MHJ)

tion of both. The sidewalls are then coated with a CdTe layer that is interdiffused at high temperature. The widening of the bandgap around the edges of the absorber effectively separates carriers from surface states and minimizes junction currents where the junction intercepts the sidewall. The high temperature anneal also promotes long-term stability and immunity from life at high operational temperatures. HgCdTe is the only infrared material that permits so-called heteropassivation, and it has a strong impact on the manufacturing yields and long-term process stability.

The main advantage of this process is that the electro-optic properties of the heterojunctions can be fully exploited. Layer thicknesses and doping levels are set at the growth stage. Normally, n-type material is chosen as the absorber because it is easier to get low doping levels and this provides long diffusion lengths and is relatively free of S-R-H centers. The more problematic P-side can then have a wider bandgap which tends to deactivate dark current generation. Because the absorber can have minimal volume in this process the dark currents are usually an order less than LPE homojunction technologies.

The first double-layer heterojunction devices, DLHJs, were reported from the United States in the 1980s with work continuing into the 1990s with LPE material. For summaries of this work, see *Tung* et al. [34.62], *Wang* [34.63], *Pulz* et al. [34.64], and *Norton* et al. [34.65]. *Tung* [34.66] reported the first n^-–P^+ structure grown from MBE which has the advantage of very low crosstalk because of the complete electrical isolation of the absorber.

In the modern era, mesa heterojunction technology is a commonly used technology for MBE and MOVPE wafer scale processes. A review of MOVPE is given by *Hipwood* et al. [34.37, 38] and *Baker* et al. [34.42]. With mesa sidewall shaping, the cone can become an optical concentrator with photons trapped within the mesa cone and completely absorbed. This ensures that stray photons do not scatter and contribute to the background current of other pixels. Stray photons reduce the integration time and have a direct impact on thermal contrast. Figure 34.16 shows a mesa heterojunction array with a 16 μm pitch and the ray-tracing analysis. The sidewall reflections have skewed paths through the absorber effectively lengthening the absorber by about a factor of 3. MHJs can, therefore, have the low optical and electrical crosstalk and this is especially important in small pixels.

Wafer Scale Processes Using Low-Cost Substrates

There is a dual purpose in developing vapor phase epitaxy technologies. Firstly, it opens up the possibility of growing complex multilayer materials for a whole range of new device structures and secondly it allows growth on lower cost substrates than CdZnTe. CdZnTe is expensive and only available in sizes up to about 60 cm^2, limited mainly by Zn segregation in the boule. It is brittle and soft making wafers hard to handle and can have a recurring problem of impurity outdiffusion. Also, cadmium is the subject of a number of international protocols concerning its use and disposal. CdZnTe substrates are mined from sawn up slices taken from large bulk crystal ingots grown by either vertical gradient freezing (VGF) or Bridgman methods. Conservative estimates predict that growth on alternative substrates reduces the cadmium utilization by two orders of magnitude.

Silicon, gallium arsenide, germanium, and sapphire are the most common substrates used because they are available commercially in large area wafers at relatively low cost. Figure 34.17 illustrates a typical process flow.

Of the four candidate substrate materials, silicon has the worst lattice mismatch and the worst ther-

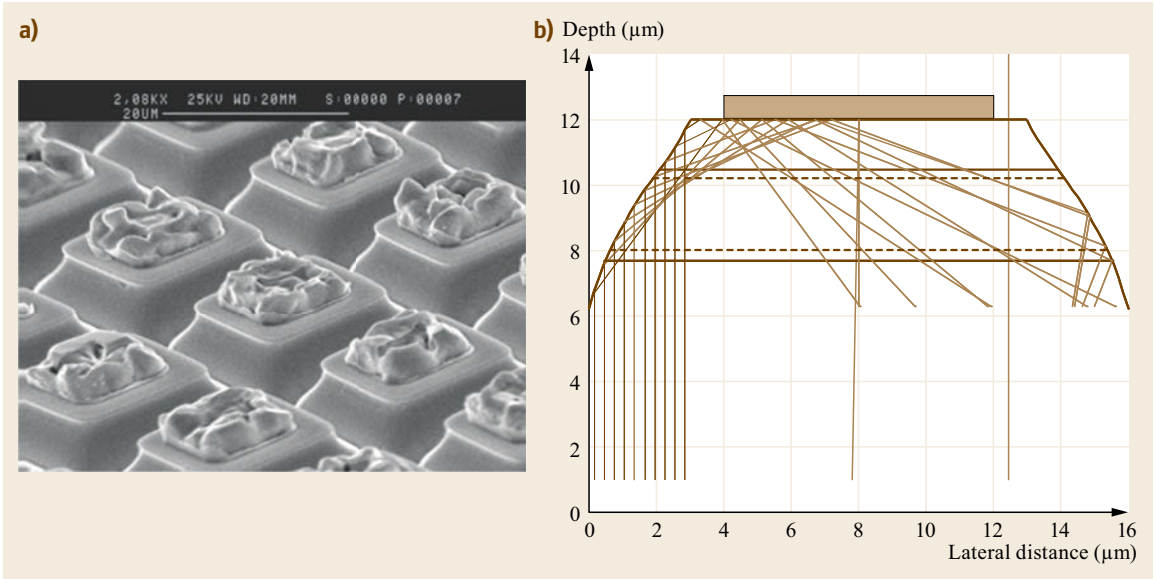

Fig. 34.16a,b 16 μm pitch mesa MOVPE device **(a)** and optical modeling **(b)**

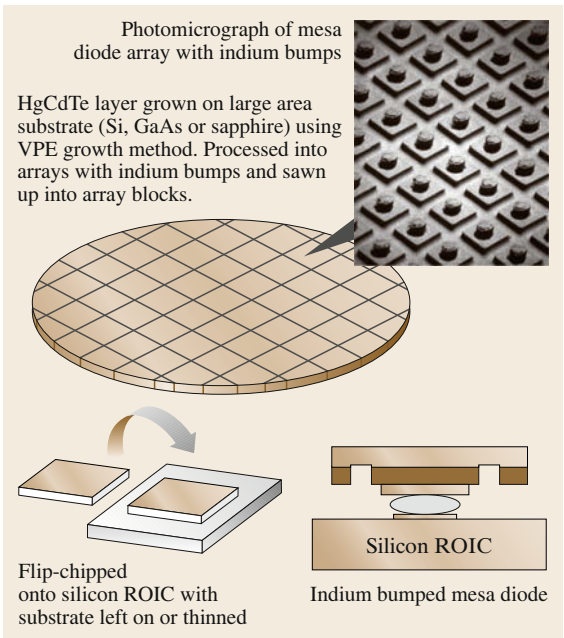

Fig. 34.17 Wafer scale processing using VPE HgCdTe material, mesa diodes, and indium bump interconnect technology

mal expansion difference. Nevertheless, the elegance of matching the ROIC thermal expansion is a powerful advantage when considering very large arrays and some early work explored growth on silicon. *Maxey* et al. [34.59] report a variety of device structures made using MOVPE layers grown on 75 mm diameter GaAs on silicon layers; however, the arrays had poor uniformity compared to those on GaAs alone. Similarly, *Carmody* et al. [34.67] found that buffer layers of CdTe grown on GaAs had better crystal quality, fewer dislocations, higher mobility, and longer minority carrier lifetimes than grown-on silicon. In general, silicon has fallen out of favor because of the device quality.

Commercial GaAs substrates have a number of advantages for use as substrates: they are readily available at low cost, have good crystal quality and an oxide that is easy to remove prior to growth. GaAs substrates of 76.2 mm diameter cost some five times less than GaSb (used in III–V detectors) and about 50 times less than CdZnTe. Since the substrate is at the front end of the process, the cost impact per array is divided by the yield and the number of arrays per wafer. It, therefore, has a superlinear relationship on the size of the array. There are also selective etches to remove the substrate at the end of the process and this is essential for two reasons: First, the thermal expansion difference between the ROIC and GaAs is high enough to cause cracking and, second, the thick substrate can cause optical crosstalk. *Arias* et al. [34.68] pioneered MBE growth on GaAs and demonstrated that good quality material could be grown. MBE growth on silicon substrates of 100 mm diameter has been used to grow MW HgCdTe layers as described by *Varesi* et al. [34.69]. The MBE used buffer layers of CdZnTe and CdTe to minimize the density of misfit dislocations.

Another approach, known as PACE, has been reviewed by *Bostrup* et al. [34.70]. The process uses a 75 mm diameter substrate of highly polished sapphire,

which remains with the device throughout. The thermal expansion problem is overcome by using a carrier substrate of sapphire, so that the silicon multiplexer is sandwiched in the middle. The process starts with a buffer layer of CdTe deposited using an organometallic vapor phase epitaxy (OMVPE) process to 8.5 μm thickness followed by a 10 μm thick p-type HgCdTe layer grown by LPE. The n–p diodes are formed by ion implantation. This process has been used to fabricate arrays up to 2048×2048 ($37\,mm^2$) in the SW band [34.14, 71]. The arrays are backside illuminated through the sapphire substrate.

A number of device types including SW, MW, LW, e-APD, and two-color arrays have been fabricated using MOVPE growth on low-cost 75 mm GaAs [34.42]. The process consists of growing a 2 μm thick layer of CdTe which begins the process of turning over misfit dislocations as revealed by transmission electron microscopy. Then, a thick layer of HgCdTe is grown which continues the process of improving the crystal quality. Provided the p–n junction is far from the substrate, the dark current performance of LW diodes can exceed that of the best LPE. The GaAs substrate is removed after bump bonding.

34.7 Advanced HgCdTe Technologies

Third Generation or GEN III is a commonly used term to describe advanced infrared detectors. The definition of a *GEN III* detector can differ between different nations, but the general guideline is any detector that offers an imaging advantage over conventional first- and second-generation systems. Common agreed examples are, for instance, megapixel arrays with high density, dual color or even multispectral arrays, higher operating temperature, fast readout rates, very low NETD due to pixel-level signal compression, and retina-level signal processing. Some of the research progress is described here in more detail.

34.7.1 Small Pixel Technology

Electro-optic systems strive to reduce the pixel size because it has a direct effect on the cost, size, weight, and power consumption of the overall camera. Alternatively, in conjunction with faster optics, the resolution can be improved and this is a useful retrofit path for existing cameras. Faster optics also increases the ratio of photocurrent to dark current, allowing higher operating temperatures. Clearly, the limitation of small pixel sizes is set by the diffraction limit of the optics (for instance [34.72]). *McEwen* et al. [34.73] have proposed that the pixel size should satisfy *Sparrow*'s *Undulation Condition* [34.74], setting a minimum value of $0.5\lambda f_{no}$ where λ is the mean photon wavelength that depends on the scene temperature and atmospheric conditions and f_{no} is the focal ratio of the optic. Even this is not exact because the human eye can resolve beyond this. However, many authors argue that oversampling the image provides benefits in the IR notably reduction of aliasing, suppression of point sources, and improved image processing. For cameras searching for small subpixel targets, there is the potential to suppress false alarms. On the negative side, small pixels can be difficult to manufacture compromising yields and performance. Also, maintaining a good resolution (MTF) in the presence of optical and electrical crosstalk limits the choice of technology. In very small pixels, the silicon ROIC becomes challenging as the integration capacitance is reduced and silicon MOSFETs tend to become noisy at small geometries. The degree that manufacturers can reduce the scale of their technologies depends on a detailed analysis of all these arguments.

Pixel sizes in the 10–12 μm range for MWIR systems are available in the market place with good maturity from planar devices [34.75], via-hole devices [34.52], DLPH [34.76], mesa heterojunctions [34.77].

Mesa heterojunctions based on MOVPE have been described by *McEwen* et al. [34.73] with a pixel size of 8 μm and implemented in a 1280×1024 pixel array called SuperHawk. The paper stresses the design of the mesa cone to act as an optical cavity and minimize crosstalk mechanisms limiting the spatial resolution of the device. Near-perfect MTF was measured using an F/2.8 optic and 3.5–5.0 μm spectral range.

The fabrication of 5 μm pixel dimension arrays on the DARPA Lambda Scale Program has been described by *Kinch* et al. [34.78] and *Robinson* et al. [34.79] using the HDVIP $n^+/n^-/p$, homo-junction, via-hole technology, and *Tennant* et al. [34.80] using a modified DLPH technology. Very large arrays can be made economically, and the small pixel size suits the fast optics often required in wide-area surveillance applications.

34.7.2 Higher Operating Temperature (HOT) Device Structures

Operating FPAs at higher temperatures are a key modern requirement and have far-reaching consequences on the size, weight, power, and cost of future thermal

imaging systems. The power consumption of high-performance thermal imaging cameras is often dominated by the Stirling cooling engine and operating a small cooler at 150 K instead of 80 K approximately halves the power as well as reducing the cooldown time. Higher temperatures also significantly improve the mean time before failure of a Stirling engine cooler. A satisfactory operating temperature clearly depends on the optics, scene temperature, waveband, and signal processing. Making comparisons from the literature is, therefore, difficult but rationalizing the data to a typical practical camera specification of F4, 290 K background, 3.5–5.0 μm waveband, and 50 mK NETD provides a rough guide to the status quo. Epitaxial InSb can be operated up to 100 K with a stretch potential to 120 K. LPE processes, nBn barrier devices, and Type II superlattices currently operate around 140–150 K. VPE processes using mesa cones can operate at 160 K with the stretch potential to 200 K. The main reason why VPE processes can be better is due to geometry. The absorber thickness can be minimized and reflections within the mesa cone effectively create long path lengths to maintain QE.

It is important to recognize that the bandgap of HgCdTe varies with temperature. For instance, a 5.7 μm cutoff array at 80 K becomes 5.0 μm at 200 K and so for HOT operation a lower x value should be selected. In contrast, InSb has a narrowing bandgap at higher temperature which further degrades its potential.

For each process, there are some common denominators for improving the performance at higher temperature. Manufacturers try to reduce the absorber volume for instance by using thinner structures and employ weak doping levels to limit Auger generation. However, the limit of acceptable image quality is not usually controlled by dark current but rather by the generation of excess noise and the increase in defective pixels. To that extent, it is not fundamental but should improve with a reduction in crystal defects. Ultimately, thermal emission from the radiation shield will start to dominate over about 200 K.

The best reported HOT imaging is described by *Pillans* et al. [34.81] using mesa heterodiodes in MOVPE with lightly doped p-type absorbers. Figure 34.18 shows an image at 210 K from a scene on a warm day using a 16 μm pixel array in the full MWIR band. The higher temperature has more temporal noise (not evident in the image) but completely acceptable spatial resolution. One of the reasons this is possible is that arrays at 80 K can have NETD values around 15 mK and the NETD can be degraded by an order of magnitude before there is recognisable degradation in an image. First generation cameras had equivalent NETD values

Fig. 34.18 Imaging at 210 K operating temperature. (Courtesy of Leonardo MW Ltd)

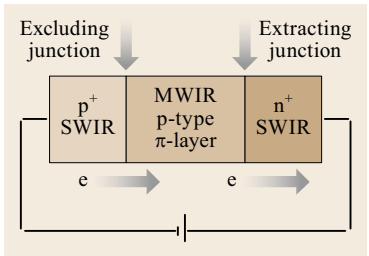

Fig. 34.19 Schematic of non-equilibrium HOT device structure

of 200 mK and were completely acceptable. Also, the application of image-processing software can mitigate many of the noise artifacts.

Operation at close to room temperature has been proposed primarily as a result of research in the UK in the 1980s and 1990s. Good summaries have been reported by *Elliott* [34.82] and *Elliott* et al. [34.83]. The possibility of operating detectors at temperatures near room temperature was proposed by *Elliott* and *Ashley* [34.84]. The basic structure is a $Pp^{-}N$ illustrated in Fig. 34.19.

The active volume of the absorber is small relative to a minority carrier diffusion length and it is operated in strong non-equilibrium by reverse biasing the minority carrier contact to completely extract all of the intrinsically generated minority carriers. To preserve space–charge neutrality the majority carrier concentration drops to the background dopant concentration and Auger generation is effectively suppressed. Remaining components are associated with S-R centers and possibly injection from the contact and surface regions. The realization of HOT LW arrays will depend on the suppression of high $1/f$ noise associated with the reverse bias operation. In MW arrays it is also important to suppress competing recombination mecha-

nisms. Nevertheless the device concept is a route toward high-performance infrared detectors with minimal cooling.

34.7.3 Two-Color Array Technology

Thermal emission from scenes with a mixture of materials can have spectral variations analogous to color in the visible. For instance the Si–O bond in many rocks can suppress LW radiation in comparison to man-made materials. Realtime multicolor sensors are still in development but a good stepping stone is the dual-waveband detector (DWB) with simultaneous readout of flux levels in 2 separate infrared bands. MW/LW arrays are well developed because there are visibility benefits to both bands depending on the conditions. MW has longer range in high humidity and better spatial resolution giving increased identification ranges in good conditions. In contrast, LW is better in more turbulent conditions, more useful for fast-moving targets and is also better for penetrating most smokes and fogs. Another interest is to separate hot objects from solar reflections and this can performed by comparing the thermal waveband with the SW band or two thermal bands. DWBs incorporate both wavebands into a single detector, giving the user the ability to switch between the two as circumstances require. This clearly offers a cost advantage over the need for two separate detectors. Image fusion can be used to highlight areas of interest by exposing spectral differences. For a given system aperture, MW offers twice the usable resolution of LW, which can be exploited in various ways in system design.

Systems designers would prefer to have co-spatial and co-temporal pixels but this is very difficult to achieve in practice. Such arrays need two indium bumps per pixel and a deep etch to make contact to the intermediate layer. Manufacturers will try to make the colors side by side within the blur circle of the optics for quazi-co-spatial or butt the integration periods of the MW and LW for quazi-co-temporal. In this case, it may be acceptable because the MW integration period usually dominates.

A common approach is to use a so-called bias-selectable detector [34.85–87] which needs only one bump and is compatible with small pixel sizes. Figure 34.20 shows a schematic structure. The simplest device is an n^-–P–n^- structure. The two n-type regions are the MW and LW absorbers, with appropriately chosen bandgaps. The intermediate wide-gap p-type region prevents transistor action between the two absorbers. The design uses one indium bump per pixel. The two junctions are stacked vertically so that the radiation travels through the MW absorber before the LW absorber, and the band to be detected is selected by the polarity of the applied bias.

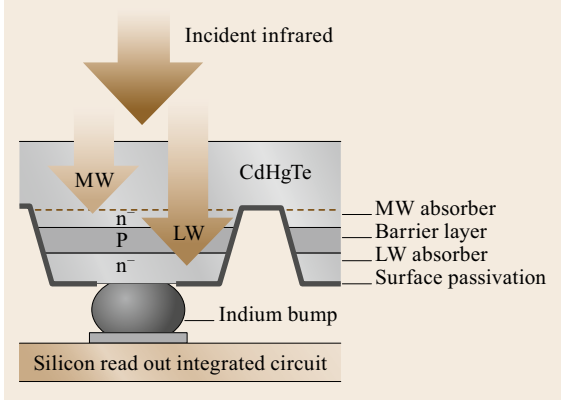

Fig. 34.20 MW/LW bias-selectable architecture for VPE processes

Several successful arrays have been reported. *Reine* et al. [34.88], report a 64×64 simultaneous MW/LW dual-band HgCdTe array on 75 μm pitch. The array is fabricated from a four-layer P–n–N–P film grown in situ by MOVPE on CdZnTe and mounted on a custom ROIC. This approach has been applied to the double layer planar heterostructure, DLPH, in a process called SUMIT for Simultaneous Unipolar Multispectral Integrated Technology [34.89]. The DLPH structure can be turned into a two-color device by having two absorbers of different bandgap separated by a wide bandgap barrier. An etch step is used to expose the lower, shorter wavelength absorber, and form an arsenic doped junction. A pixel size of 40 μm for each color is used in 128×128 demonstrators for MW/MW arrays. A variant of this basic process has also been presented by AIM [34.90], and they have achieved two colors in a concentric arrangement in 192×192 and 256×256 arrays with 56 μm pitch, again using a full custom ROIC.

Kinch [34.52] reports a quazi-co-spatial via-hole type structure with a 5.2 μm monolith on top of 4.2 μm material. Each cell has two via holes connecting the two layers. One is for connecting the longer wavelength array to the silicon in the normal way and the other is isolated from the longer wavelength material and connects the shorter wavelength to the silicon. The 2-color arrays utilize standard 640×480, 25 μm pitch ROICs (as used in LW FPAs). The unit cell design in these ROICs incorporates one buffer amplifier circuit for every 2 HgCdTe pixels. The 2-color array actually uses 4 mono-color pixels to form a 2-color unit cell, thus resulting in $50\,\mu m \times 50\,\mu m$ geometry, with 2 buffer amplifiers per unit cell, one for each color. Figure 34.21 shows a typical spectral separation.

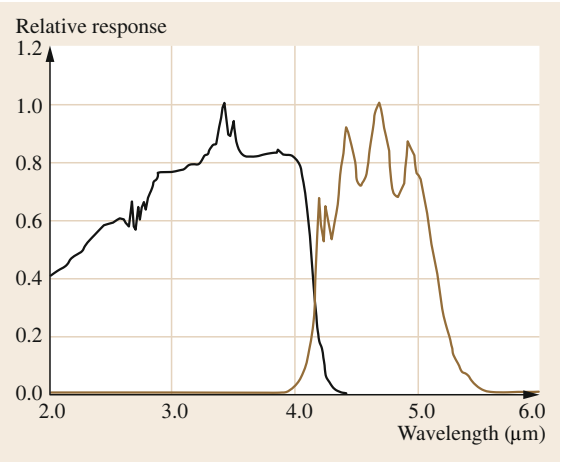

Fig. 34.21 Spectral response of MW/MW 2-color HDVIP HgCdTe FPA. (Courtesy of DRS Technologies)

DWB detectors in the LW and MW bands have been realized through multilayer VPE growth structures ([34.91–93] and references therein). These papers detail the array sizes that are commercially available and the quality of the arrays in each band.

Spectral crosstalk is an important performance parameter for dual-band detectors. There are two components of spectral crosstalk. One is unabsorbed MW radiation which appears as LW signal. The second is from photon recycling, where carriers in the MW absorber recombine radiatively with the generated photon passing into the LW absorber. Optical filters are employed in DWB detectors and when weighted for radiation from a 293 K blackbody, the spectral crosstalk of dual-band detectors can be as low as 0.2% [34.77].

34.7.4 HgCdTe Electron Avalanche Photodiodes (e-APDs)

Avalanche photodiode arrays (e-APDs) are proving to be vital components in many future infrared systems especially those with low photon counts. Although the concept dates back to the 1980s [34.33] the first e-APD arrays were produced in the early 2000s (for instance [34.94]). A number of centers developed e-APDs for laser-gated imaging (LGI) or burst-illumination LIDAR (BIL), now well established for long-range target identification [34.95]. Without avalanche gain the best detectors can sense a return signal of around 200 photons, but some requirements call for single photon detection. In this case avalanche gains of up to 100× are needed. It is remarkable that HgCdTe e-APDs have been able achieve this in arrays as large as 320×256 and at pixel sizes ≈ 20–$30\,\mu$m. In the commercial area there is growing interest in avalanche photodiode arrays for the 1.0–2.5 μm region. Ground-based astronomical telescopes now rely on adaptive optics to correct for atmospheric distortion. The trend is to sense the wavefront using guide stars in the 1.0–2.5 μm region. In current detectors the best sensitivity is typically around 30 photons, but this can be reduced to a few photons with avalanche gain providing much faster and more accurate wavefront correction. Atmospheric science, particularly remote gas analysis, is calling for LIDAR systems with near-single photon sensitivity. Typically the pulse laser would be tuned to a resonant frequency of the target gas molecule and the return signal would be tracked in time to give a depth profile.

The solid-state mechanisms for avalanche gain in HgCdTe have been well described and three recommended papers are [34.96–98] and the references therein. Figure 34.22 shows a potential energy schematic for a typical photodiode and it illustrates the single-carrier, cascade-like gain mechanism, together with the history-dependent behavior that leads to the observed low noise figures. The heavy hole mass is $\approx 0.55\,m_o$ across the entire HgCdTe composition range, resulting in low hole mobility values, and a significant degree of optical phonon scattering. Thus the heavy hole acquires energy from applied fields very inefficiently, and readily loses what it does gain to optical phonons. The effective mass of the electron, on the other hand, is very small, $m_e^*/m_o \approx 7 \times 10^{-2}\,E_g$, where E_g is the bandgap in eV. Its mobility is high, particularly at low temperatures, and scattering by optical phonons is weak, which results in significant energy gain at even modest applied fields. The conduction band of HgCdTe is also devoid of any low-lying secondary minima, which allows for large electron energy excursions deep into the band, and hence the high probability of impact ionization, with the generation of electron–hole pairs. In HgCdTe, this is an electron gain mechanism so the absorber must be p-type, which dictates an n-on-p structure. Theoretical studies indicate that there is an optimum width for the depletion region (gain zone) of 1.5–2.5 μm; at the lower end is a risk of gain saturation and tunneling currents; and at the upper end, alloy or phonon scattering starts to impact the ionization threshold voltage. One of the reasons APD arrays have matured so quickly is that these conditions are easily met using near-standard manufacturing processes.

In fact, the e-APD offers an extraordinary amplifier specification: voltage controlled gain at the point of absorption, electron gain values up to 1000×, virtually zero power consumption, bandwidths to GHz, high stability, high uniformity, no impact on the silicon pixel design and negligible added noise. On the cautionary side, the noise figure of HgCdTe e-APDs is often

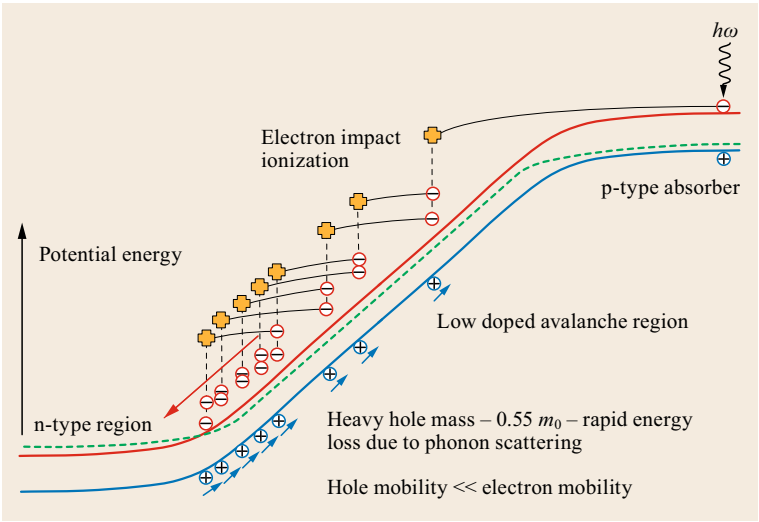

Fig. 34.22 Potential energy schematic – illustrating history-dependent avalanche gain in HgCdTe

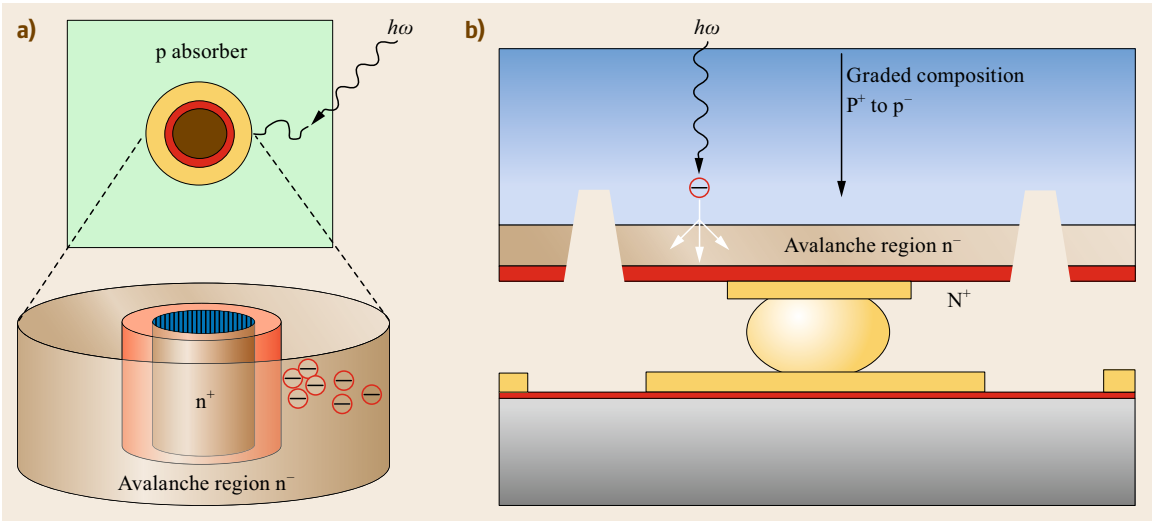

Fig. 34.23a,b Schematics of the device structures used for APDs: **(a)** LPE/via-hole technology; **(b)** MOVPE/mesa technology

quoted as being negligible but APD noise figures only describe the gain fluctuation. Noise due to dark current is not included and can be significant particularly as it is gain-amplified in many devices. Most photon starved applications can exploit avalanche gain but some care needs to be taken with dark current.

Three technologies are currently used for e-APDs – planar diffused processes as described in Sect. 34.6.1, *Planar Device Technology Using LPE*, via-hole processes as described in Sect. 34.6.1, *Via-Hole Technologies Using LPE* and mesa heterojunctions as described in Sect. 34.6.2, *Mesa Heterojunction Devices (MHJ)*. The via-hole and mesa heterojunction e-APD devices are illustrated in Fig. 34.23. In via-hole processes [34.99] the open-ended n^+n^-/p^+ cylindrical diode geometry is attractive because of the stronger dependence of diode potential with distance away from the n^+ region. This allows for large bias voltages to be used before the diode depletion width attains a value equal to a phonon mean free path, resulting in efficient, phonon-free, electron avalanche gain. Heterojunction processes allow the absorber, junction region, and multiplication region to be independently optimized. This is important for controlling the peak fields around the junction to allow high voltages without incurring excessive dark current.

Avalanche gain normally has an exponential dependence on applied voltage but the exponent and ioniza-

tion threshold voltage are dependent on device level parameters such as the electric field distribution and the composition through the depletion region. *Rothman* et al. [34.100] have developed a local field impact ionization and gain model for SW e-APDs that takes into account gain saturation and phenomenological expressions for the local impact ionization. Equation (34.10) is a good baseline for illustrating the behavior of avalanche gain with voltage, composition, and depletion layer width.

$$M = \exp\left[aE_g^{-1}V^c W^{1-c}\exp\left(-\frac{bW}{V}\right)\right], \quad (34.10)$$

where M is the avalanche gain, a, b, and c are fitted constants taken here as 22.6, 32 500 and 0.6, respectively, V is the applied voltage and W the depletion layer width in cm. Figure 34.24 shows an illustrative example of how the gain varies.

At first sight, it would appear to be beneficial to always use narrow bandgap compositions but in practical systems there is a risk of increased dark current and stray light. In this case, the noise equivalent photons (NEPh) can be calculated as a function of the e-APD parameters and extra noise. The derivation involves the solution of a quadratic and a useful form is given by

$$\mathrm{NEPh} = \frac{F}{2Q}\left(1+\left[1+\left(\frac{2\mathrm{FN}}{FTM}\right)^2\right]^{0.5}\right), \quad (34.11)$$

where F is the noise figure, Q is the QE, FN is the fixed noise, and T is the transfer function (gain from pixel to output – typically in the region of 0.7).

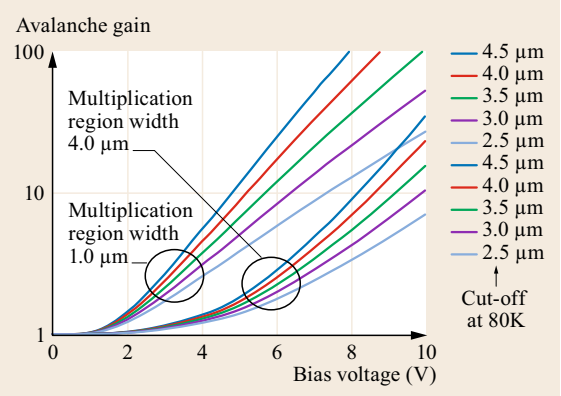

Fig. 34.24 Variation of avalanche gain with bias voltage and cut-off wavelength for two different multiplication region widths. (After [34.100])

e-APDs are being increasingly considered for astronomy, initially for wavefront sensors but increasingly for imaging and spectroscopic instruments. *Finger* et al. [34.101] and *Atkinson* et al. [34.102] summarise the progress with the Saphira device which is designed for the fast frame rate and non-destructive readout. They show that the avalanche gain can increase the photon sensitivity in proportion to the gain. Low noise measurements can be achieved by multiple sampling and Fowler sampling techniques for read noise as low as 0.27 electrons rms – an order better than with conventional detectors. This class of detector will be used for single-photon sensing for a range of scientific and defence applications.

34.7.5 Multifunctional HgCdTe Detectors

An important consequence of the avalanche gain is that it allows much more complex FPAs to be designed. This is because the photon noise is amplified and it relaxes the noise requirement on the silicon. In effect, the size of the silicon components can be decreased allowing for more complex circuits in the pixel and more functionality. There are often no disadvantages to using more avalanche gain, so it can be used as an enabling step for multifunctional FPAs.

An essential modern requirement is the ability to perform detection, recognition, identification, and intent over long ranges, day and night. Burst-illumination LIDAR (BIL) is an emerging field [34.103]. Collimated pulse lasers can give instantaneous brightness far in excess of passive infrared emission levels even at extreme long range. The brightness allows the use of long focal length telescopes made from glass (because of the 1.55 μm wavelength). Also at 1.55 μm there is better optical resolution compared with the longer wavelengths of passive IR systems. It is therefore fairly straightforward to achieve resolution improvements of over an order of magnitude compared with standard thermal imaging. Another advantage stems from the short laser pulse (typically 20 ns wide) which has the effect of freezing the scene, including any own-platform jitter, and atmospheric effects. There will be distortion from frame to frame but images can be de-rotated and re-registered to restore stable displayed scenes. Such systems also need thermal imaging for scene context and a detector which combines BIL and conventional thermal imaging reduces the number of apertures and system complexity.

It is very straightforward to manufacture e-APD arrays from HgCdTe with a wavelength in the MW band so they can be used for both SW active and MW passive applications. Multifunctional arrays have been

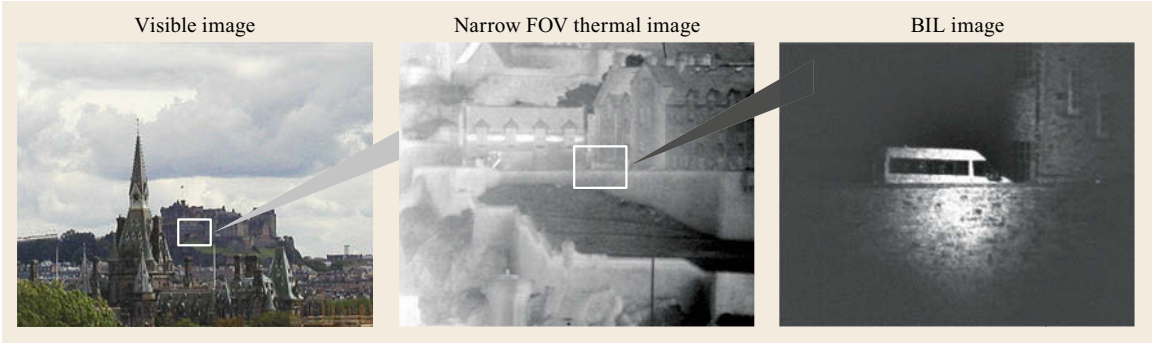

Fig. 34.25 Example of dual-mode passive and active imaging. The active BIL image is for a focal ratio of F10 and avalanche gain of ×30. (After [34.103])

manufactured with a 3.2–4.2 μm thermal channel and three-dimensional (3-D) BIL [34.104]. Figure 34.25 shows nonmilitary sample images demonstrating the dual-mode behavior.

34.7.6 Retina-Level Processing

In very large arrays operating at high frame rates, the downloading of signal data and the subsequent signal processing can be daunting, and it is called the data processing bottleneck problem. The human retina presents an example of how evolution has dealt with the problem. The eye performs a number of image-processing operations in the *z-plane* including, in order logarithmic photon sensing, spatial filtering, temporal filtering, motion sensitivity, and data decomposition. An essential function is the difference of Gaussian or DoG filter which is used for both edge and contrast enhancement [34.105].

FPAs with neuromorphic processing have been explored at a number of centers [34.106, 107]. A good example is the MIRIADS program (Miniature InfraRed Imaging Applications Development System). MIRIADS uses a neuromorphic FPA, with temporal high pass filtering, frame co-adding, and a DoG operation to detect motion, enhance edges, and reject ambient light levels. The current reported array is a 64×64. More information is presented by *Baxter* et al. [34.108].

34.7.7 Conclusions and Future Trends for Photovoltaic HgCdTe Arrays

Photovoltaic 2-D HgCdTe detectors are serving many applications worldwide and are supplanting photoconductive detectors in second-generation systems for military, commercial, and scientific applications, offering improved temperature sensitivity, lower power consumption, weight, and volume. The continuing development work within manufacturing centers, supported by the wider scientific community, is aimed at increasing the operating temperature and reducing manufacturing costs. Medium-term research is being directed at the best advanced materials and device structures for the next generation of HgCdTe arrays, which will combine the state-of-the-art background-limited performance with low-cost wafer-scale processing, including growth on the silicon readout for wafer-scale devices. Band-gap engineering will produce heterostructure detectors with much higher operating temperatures. This will enable background-limited operation in MW arrays above 200 K to exploit novel cryogenic engines. Device structures will be extended to produce bi-spectral and multispectral capability. Arrays will have larger physical size, smaller pixels, higher sensitivity, and on-focal plane signal processing to achieve a faster frame rate. The ultimate performance potential of HgCdTe will ensure that it is the material of choice for all high-performance infrared systems.

34.8 Emission Devices in II–VI Semiconductors

Infrared emission devices, in the form of light-emitting diode (LEDs) and laser diodes, are used in a broad range of applications, such as gas sensors, infrared scene simulators, molecular spectroscopy, free-space communications, fiber-optic communications, and LIDAR (light detector and ranging). A useful summary of emission device theory and current progress has been presented by *Gordon* [34.109]. There is competition from lead salt semiconductors (in the 3–4 μm range) and narrow gap III–V compounds. HgCdTe LEDs use

a forward-biased junction to inject minority carriers into an n-type region typically with low doping to encourage radiative recombination. The external photon efficiency is limited by factors, such as competing recombination mechanisms, re-absorption of the photons, and internal reflection. Nevertheless, efficiencies as high as 5% have been achieved at 4 μm using an immersion lens to overcome internal reflection [34.110].

One of the disadvantages of the LED is that the spectrum is often too broad for many applications and lasers are needed. Lasers also offer greater output power and higher spatial coherence, but they are more difficult to make and have additional noise mechanisms. Infrared lasers covering the 3–5 μm band have been demonstrated with pulsed operation at 80 K. It is only recently that the complex double heterojunction structures needed for lasing have been available from low-temperature VPE processes, so the field is relatively young. Nevertheless, peak powers up to several milliwatts have been recorded in diode-pumped lasers and over 1 W in optically pumped lasers.

Using a structure similar to that reported in Sect. 34.7.2 and illustrated in Fig. 34.19 the carrier densities, in reverse bias, can be lowered to well below the thermal equilibrium values. Under this condition, the absorption of photons can exceed the emission rate and the surface of the device can look cold. This is called negative luminescence [34.111], and devices have been developed for use as temperature references in thermal imaging cameras.

Infrared LEDs have also been reported [34.112] in the dilute magnetic semiconductors $Hg_{1-x}Mn_xTe$ and $Hg_{1-x-y}Cd_xMn_yTe$, where, in principle, the bandgap could be tuned by the applied magnetic field.

34.9 Potential for Reduced Dimensionality in HgTe–CdTe

The emergence of low-temperature growth processes will enable HgTe–CdTe structures to be grown with dimensions small enough to show quantum confinement effects. At present, this research is in its early stages, and there are no active programs to make devices but this could change in future. HgTe–CdTe superlattices offer many benefits for detectors. The minority carrier lifetime could be enhanced beyond that of bulk material providing better QE. The optical absorption coefficient can be much larger than bulk material, allowing LW detectors to use absorbers as thin as a few microns. Furthermore, tunneling currents can be reduced by orders of magnitude, permitting operation at much longer wavelengths. The state of the art of reduced dimensionality material is summarized by *Meyer* and *Vurgaftman* [34.113].

Quantum well lasers are also known to offer significant advantages over double heterojunction devices with bulk active regions. For instance, the maximum operating temperatures for pulsed and CW lasers could be increased by over 100 K, and this would have important consequences for the attractiveness of narrow gap II–VI emitters.

Acknowledgments. The author would like to acknowledge the advice and support of my management and colleagues at Selex Southampton, in particular, Drs Peter Capper and Chris Maxey for their scientific contributions over many years. It is appreciated that many scientists and associates in other companies around the world have maintained dialog to advance scientific knowledge in this field. Thanks also to my wife Lesley for patience and help with the English.

35. Optoelectronic Devices and Materials

Stephen J. Sweeney, Jayanta Mukherjee

Unlike the majority of electronic devices, which are silicon based, optoelectronic devices are predominantly made using III–V semiconductor compounds such as GaAs, InP, GaN, and GaSb, and their alloys due to their direct-band gap. Understanding the properties of these materials has been of vital importance in the development of optoelectronic devices. Since the first demonstration of a semiconductor laser in the early 1960s, optoelectronic devices have been produced in their millions, pervading our everyday lives in communications, computing, entertainment, lighting, and medicine. It is perhaps their use in optical-fiber communications that has had the greatest impact on humankind, enabling high-quality and inexpensive voice and data transmission across the globe. Optical communications spawned a number of developments in optoelectronics, leading to devices such as vertical-cavity surface-emitting lasers, semiconductor optical amplifiers, optical modulators, and avalanche photodiodes. In this chapter, we discuss the underlying theory of operation of some important optoelectronic devices. The influence of carrier–photon interactions is discussed in the context of producing efficient and high-performance emitters and detectors. Finally, we discuss how the semiconductor band structure can be manipulated to enhance device properties using quantum confinement and strain effects, and how the addition of dilute amounts of elements such as nitrogen and bismuth is having a profound effect on the next generation of optoelectronic devices.

35.1 Introduction to Optoelectronic Devices

In this chapter, we introduce the underlying theory and operating principles of semiconductor optoelectronic devices. There exist today a plethora of optoelectronic devices that are used in a multitude of applications. These devices include sources such as light-emitting diodes (LEDs) and laser diodes, photodetectors, optical amplifiers, and optical modulators. With such devices, one can generate, modulate, detect, and switch photons in an analogous way to electrons in an electrical circuit. We begin this chapter by considering the underlying physical interactions between electrons and photons that occur in semiconductors and how they may be harnessed to produce a wide variety of devices. At the time of writing, optoelectronic devices have found their way into many different aspects of modern life whether it be the ubiquitous indicator LEDs on hi-fi systems, televisions, computers, solid-state lighting and countless other items or in the bar-code scanning systems at the supermarket, compact disk (CD), digital versatile disk (DVD) and blu-ray systems at home, the laser printer in the office, or when using a telephone or watching cable television. Over the past decade or so there has been an information explosion whereby information from all over the world can be quickly accessed by anyone with an Internet-enabled device. In all of these applications, it is a semiconductor-based optoelectronic device that forms an essential part of the system.

One of the major advantages of semiconductor devices is their small size. For example, a typical edge-emitting laser measures approximately $500 \times 250 \times 100\ \mu m^3$. Several thousands such devices can be made from a single wafer. Thus, even when packaged, these form very compact sources of coherent radiation. Other types of laser, such as the gas laser, simply cannot be compared with the semiconductor laser in terms of size, modulation rates, flexibility of application, and power consumption. Furthermore, semiconductor devices can be tailored to meet the exacting requirements of an application by simply altering the composition of the various layers forming the structure.

Of the uses of semiconductor devices outlined above, their use in telecommunications stands out as having the largest impact on modern life. Digital-based data transmission allows information to be transmitted over large distances with a much lower degradation in signal quality compared with older, analog-based systems. Optical telecommunications are ideal for use in digital systems, enabling data transmission rates well in excess of 10 Gbit/s using short optical pulses of < 100 ps in duration. Even at this exceptionally fast rate of data transmission, bit error rates of better than 1 in every 10^9 bits can be routinely achieved. Such capabilities are a direct consequence of significant research and development work that has gone into producing semiconductor devices for the emission and detection of light. In the next section, we give a brief history of this development before proceeding to discuss the key elements of physics and technology related to the device operation.

35.1.1 Historical Perspective

The development of optoelectronic devices began in the early 1960s with the development of the LED and soon thereafter, the semiconductor laser. *Holonyak* had been experimenting with the alloy GaAsP to produce visible light via spontaneous emission (SE) and was successful in producing visible (red) LEDs [35.1]. Stimulated emission was first predicted by *Albert Einstein* in his famous 1917 paper, *Zur Quantentheorie der Strahlung* (On the quantum theory of radiation) [35.2]. In 1961, the possibility of obtaining stimulated emission in semiconductors was discussed by *Bernard* and *Duraffourg* who, for the first time, derived the condition for lasing action in semiconductor materials [35.3]. This became known as the Bernard–Duraffourg condition, as discussed later in this chapter. In the following year, the first reports of lasing action in semiconductor materials were published by four independent groups, *Nathan* et al. [35.4], *Hall* et al. [35.5], *Quist* et al. [35.6], and *Holonyak* et al. [35.1]. These lasers were based upon GaAs which, with its direct-band gap, made it suitable for use as an optical source. The first devices consisted of simple p–n homojunctions which have a single interface between the n- and p-doped regions. With a wavelength of near to 900 nm, these lasers emitted in the near-infrared region of the electromagnetic spectrum. Following on from his success with LEDs, Holonyak produced visible (red) semiconductor lasers. The first semiconductor lasers had very high threshold current densities, J_{th} (defined later in this chapter), and they could only be operated under pulsed conditions. This made such devices impractical but started a period of intensive research into producing the first continuous-wave (CW) room-temperature semiconductor-based laser. After much investment into developing the growth technology of liquid-phase epitaxy (LPE), it became possible to produce a high-quality double heterostructure consisting of GaAs sandwiched between higher band gap $Al_xGa_{1-x}As$ layers. The double heterostructure brought two key advantages over the homojunction; firstly, the lower band-gap GaAs region formed a reservoir for the carriers (carrier confinement) where they could recombine across

the band gap, and secondly, the higher refractive index of GaAs with respect to $Al_xGa_{1-x}As$ provided better confinement of the optical field. These two improvements resulted in a significant reduction in J_{th} of two orders of magnitude and enabled CW operation at room temperature to be achieved for the first time [35.7, 8]. Almost 30 years later, in 2000, Alferov and Kroemer were co-recipients of the Nobel prize for physics for their pioneering work on the development of semiconductor heterostructures. In the late 1970s, further improvements in semiconductor growth technology led to the development of molecular-beam epitaxy (MBE) and vapor-phase epitaxy (VPE) which enabled increasingly thin layers to be grown reproducibly. The layer thicknesses of the order of less than 100 Å became achievable and introduced the regime in which quantum-confinement effects could be harnessed. These quantum well (QW) structures [35.9] brought about further improvements in laser performance, including a further increase in carrier confinement, narrower line width, and extended wavelength tunability for a given material composition. The splitting of the degeneracy of the valence band (VB), also resulted in a reduced density of states at the top of the VB. These improvements led to a substantially reduced J_{th}. In 1986, *Adams*, and also *Yablonovitch* and *Kane*, independently predicted that the introduction of biaxial strain into the active region of QWs would result in a further improvement in the laser characteristics [35.10, 11]. The proposed benefits of strain included a further reduction in the density of states at the top of the VB (for compressive strain) and the ability to tailor the symmetry of the carrier distribution to that of the laser beam. The introduction of tensile strain made it possible to produce a semiconductor laser with transverse magnetic (TM) polarization, something that was not previously possible. Strained-layer QWs are now included in the majority of commercially available semiconductor laser products. More recent material developments include quantum dot QD lasers, in which carriers are restricted in all three dimensions. There is a major effort to develop QD lasers with better performance than existing QW lasers with QD lasers now in commercial production. More than 20 years ago the first theoretical prediction [35.12] showed that using three-dimensionally (3-D)-confined structures with an atomic-like discrete density of states in the active region of semiconductor laser should allow the development of devices with low threshold current density and very high thermal stability. Since then, QD lasers have been demonstrated with record low room-temperature threshold current densities, $< 20\,A/cm^2$ [35.13]. Work is ongoing to produce temperature-insensitive QD lasers, particularly at 1.3 μm.

In the late 1970s and early 1980s, single-mode lasers such as the distributed feedback (DFB) laser were also developed, which have made long-haul optical communications possible [35.14]. The development of such advanced semiconductor laser devices spawned research into other semiconductor optoelectronic devices such as monolithic tunable lasers (discussed in detail by [35.15]), the semiconductor optical amplifier (SOA), optical modulators, and advanced photodetectors. These devices are discussed in the latter part of this chapter.

In parallel with the developments mentioned above, other technologies were being investigated such as the vertical-cavity surface-emitting laser (VCSEL) originally proposed by *Iga* in 1977 and demonstrated by his group in 1979 (for a comprehensive review, see [35.16]). VCSELs promise low-cost single-mode lasers which can easily be made into arrays. There remains intense activity to develop VCSELs for operation at the important telecommunications wavelength of 1.55 μm. VCSELs are discussed in later in this chapter. Other devices of note include the quantum cascade laser (QCL) developed by *Capasso* et al. in 1994 [35.17]. The development of QCLs was driven by the need to produce lasers emitting in the mid-infrared (mid-IR) ($\approx 3-12\,\mu m$) for gas sensing and environmental monitoring applications. For conventional interband lasers as discussed above, this requires narrow-band gap materials that are much less developed than materials such as GaAs and InP. QCLs get around this problem by utilizing *intraband* transitions involving only one type of carrier, for example, electrons (thus they are unipolar devices), and can be grown using conventional GaAs- or InP-based materials. In such devices, the carrier cascades through several QWs, giving rise to many photons per injected electron, quite unlike conventional interband devices. Clearly, QCLs offer great possibilities for the future development of mid-IR lasers and perhaps, with suitable materials such as GaN, they may allow emission in the near-IR (for a review see [35.18]).

Unfortunately, it is impossible to go into detail about the developments of the full range of optoelectronic devices in only one chapter of a book. However, we hope that this chapter provides a basic grounding on the relevant physics of the most important optoelectronic devices allowing the interested reader to investigate further, starting with the bibliography.

35.2 Light-Emitting Diodes and Semiconductor Lasers

35.2.1 Carrier–Photon Interactions in Semiconductors

In its simplest form, a semiconductor can be considered as a system containing two energy bands populated with electrons. In such a system, there exist three possible processes by which the electrons can move between the two bands:

1. The spontaneous emission
2. Absorption
3. Stimulated emission processes, as shown schematically in Fig. 35.1.

SE occurs when an electron in the conduction band (CB) with energy E_2 recombines with a hole in the VB at a lower energy E_1. The difference in energy (E_2–E_1) is emitted in the form of a photon. This process, as its name implies, is random and photons may be emitted in any direction with arbitrary polarization. The probability of SE is proportional to the density of electrons in the CB (n) and to the density of holes in the VB (p). In the absorption process, an electron in the VB is promoted to the CB by the absorption of a photon with an energy equal to the optical band gap. The probability of absorption is proportional to the photon density, the density of electrons in the VB, and the density of empty states in the CB. The stimulated emission process occurs when a photon of energy $E_2 - E_1$ interacts with an electron in the CB, causing it to recombine with a hole in the VB, thereby generating a photon. The photon released by this process has both identical energy, phase and momentum to that of the incident photon.

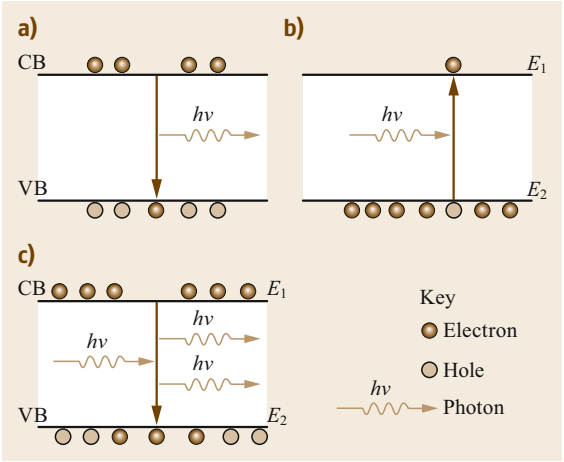

Fig. 35.1a–c The three electron–photon interactions in semiconductors: **(a)** SE, **(b)** stimulated absorption, and **(c)** stimulated emission

The probability of SE is therefore proportional to n, p and the photon density. In contrast to SE, stimulated emission produces photons that are essentially identical and therefore very pure monochromatic light is generated.

At room temperature in an undoped semiconductor, there are far fewer electrons in the CB than in the VB. As a consequence, absorption is far more likely than emission. To achieve an optical gain, the probability of stimulated emission must exceed that of absorption. By applying either an electrical current (electrical pumping) or by injecting light with photon energies greater than the transition energy (optical pumping), it is possible to inject electrons into the CB and holes into the VB. Electrical pumping is used for practical devices.

35.2.2 Direct- and Indirect-Gap Semiconductors

Semiconductors may exist in two basic forms where the band gap is either direct or indirect. Whether or not the band gap is direct or indirect has a profound influence on their suitability for use in optoelectronic devices. Figure 35.2 illustrates the difference between a direct- (e.g., GaAs) and an indirect-band gap (e.g., Ge) semiconductor. It can be seen that for the direct-band gap material, the CB energy minimum occurs at the same k-value as the VB maximum (direct). In contrast, for the indirect-band gap material, the CB minimum lies at a different k-value to the VB maximum. For any electron transition, the total energy and momentum must

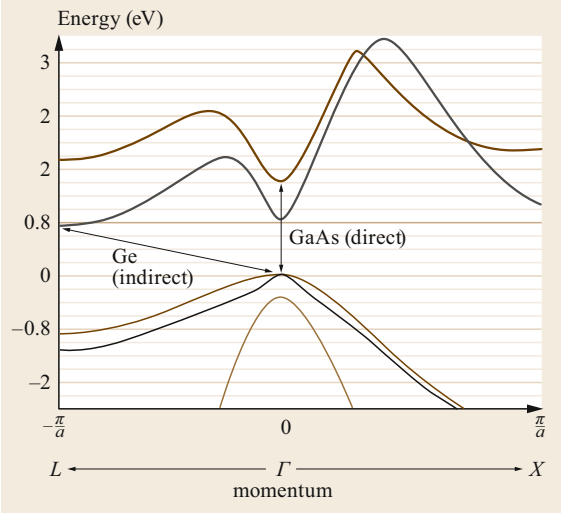

Fig. 35.2 Band structure of a direct-gap semiconductor (GaAs) and an indirect semiconductor (Ge)

be conserved. The photon wavevector has a magnitude given by $2\pi/\lambda$, where λ is typically $\approx 1\,\mu$m, while the magnitude of the electron wavevector ranges between $-\pi/\alpha$ and π/α within the first Brillouin zone, where α is the crystal lattice spacing, typically ≈ 1 Å. Clearly, therefore, the photon wavevector is much smaller than the possible electron wavevectors and, hence, if a photon interacts with an electron, the transition must occur with virtually no change in wavevector; hence, only vertical transitions are allowed. It is clear that such transitions can occur in the direct-band gap semiconductor. However, in the case of indirect semiconductors, such transitions are only possible via the interaction of a phonon. Since this becomes a three-particle interaction, the transition probability is significantly reduced. Stimulated emission is inhibited in indirect-band gap semiconductors, and it is for this reason that direct-band gap semiconductors (such as GaAs, InP, and related alloys) are primarily used to produce photoemissive devices such as LEDs and lasers. Indirect semiconductors, such as elemental germanium or silicon, are therefore impractical for the production of such devices. However, these are very effective semiconductor materials for detection, as will be discussed later in this chapter.

35.2.3 Emission and Absorption Rates and the Einstein Relations

The populations of electrons and holes in the CB and VB, respectively, are governed by both the densities of states and the Fermi–Dirac occupation probabilities. In a semiconductor, electron–electron and hole–hole scattering rates are typically ≈ 100 fs while electron–hole recombination times are ≈ 1 ns. We can therefore assume that the electrons and holes are in thermal equilibrium with themselves and can be described using a Fermi–Dirac distribution. It is useful to define two quasi-Fermi levels. These are referred to as F_c and F_v, corresponding to the energy at which the occupation probability equals 1/2 for *electrons* in the CB and VB, respectively. In thermal equilibrium, $F_c = F_v$. The corresponding energy-dependent Fermi functions are

$$f_c(E) = \frac{1}{1+\exp\left(\frac{E-F_c}{k_B T}\right)} \quad \text{and} \quad f_v(E) = \frac{1}{1+\exp\left(\frac{E-F_v}{k_B T}\right)} , \tag{35.1}$$

where k_B is the Boltzmann constant and T is the absolute temperature. By considering each of the processes illustrated in Fig. 35.1, one can obtain mathematical expressions relating each of the processes to the another. If we label states in the VB as 1 and states in the CB as 2, the *absorption rate*, r_{12}, for photons of energy $h\nu$ is given by

$$r_{12} = B_{12}\rho_v f_v (1-f_c)\rho_c P(h\nu) , \tag{35.2}$$

where ρ_c and ρ_v are the CB and VB densities of states, respectively. $P(h\nu)$ is the photon density at energy $h\nu$ and B_{12} is the Einstein coefficient for the absorption process. In a similar way, the stimulated emission rate, r_{21}, may be written as

$$r_{21} = B_{21}\rho_c f_c (1-f_v)\rho_v P(h\nu) , \tag{35.3}$$

where B_{21} is the Einstein coefficient for the stimulated emission process. For the SE rate r_{21}^{spon}

$$r_{21}^{\text{spon}} = A_{21}\rho_c f_c (1-f_v)\rho_v . \tag{35.4}$$

A_{21} is the Einstein coefficient for the SE process. Note that, since SE does not require a photon to initiate the process, r_{21}^{spon} does not depend on $P(h\nu)$. Under steady-state conditions, the total upward transition rate must equal the total downward transition rate, thus

$$r_{12} = r_{21} + r_{21}^{\text{spon}} . \tag{35.5}$$

Thus, by combining Equations (35.2)–(35.4), we obtain

$$\begin{aligned} &B_{12}\rho_v f_v (1-f_c)\rho_c P(h\nu) \\ &\quad = B_{21}\rho_c f_c (1-f_v)\rho_v P(h\nu) \\ &\qquad + A_{21}\rho_c f_c (1-f_v)\rho_v . \end{aligned} \tag{35.6}$$

In thermal equilibrium ($F_c = F_v$),

$$P(h\nu) = \frac{A_{21}}{B_{12}\exp\left(\frac{h\nu}{k_B T}\right) - B_{21}} . \tag{35.7}$$

The standard expression for black-body radiation is given by Planck's law as

$$P(h\nu) = \frac{8\pi^3 n^3 (h\nu)^2}{(hc)^3}\frac{1}{\exp\left(\frac{h\nu}{k_B T}\right)-1} . \tag{35.8}$$

Here, n is the refractive index of the semiconductor. For simplicity, here we assume that the medium is nondispersive. From these two expressions of $P(h\nu)$, we obtain the result that

$$B_{12} = B_{21} = B \tag{35.9}$$

and

$$A_{21} = B\frac{8\pi^3}{(hc)^3} n^3 (h\nu)^2 . \tag{35.10}$$

35.2.4 Population Inversion

The quantity of greatest importance to semiconductor laser operation is the net stimulated emission rate, which may simply be calculated as $r_{\text{stim}} = r_{21} - r_{12}$. Positive values of r_{stim} mean that an optical wave will grow in intensity as it travels through the semiconductor, while a negative r_{stim} implies that the optical wave would be reduced in intensity. From (35.2) and (35.3), r_{stim} can be written as

$$\begin{aligned} r_{\text{stim}} &= r_{21} - r_{12} \\ &= B_{21}\rho_c f_c\,(1-f_v)\,\rho_v P(h\nu) \\ &\quad - B_{12}\rho_v f_v\,(1-f_c)\,\rho_c P(h\nu)\,; \end{aligned} \tag{35.11}$$

therefore,

$$r_{\text{stim}} = r_{21} - r_{12} = B\rho_c\rho_v\,(f_c - f_v)\,P(h\nu)\,. \tag{35.12}$$

The ratio of SE to net stimulated emission is given by

$$\begin{aligned} \frac{r_{\text{spon}}}{r_{\text{stim}}} &= \frac{A_{12}\rho_c\rho_v f_c f_v}{B\rho_c\rho_v f_c(f_c - f_v)P(h\nu)} \\ &= \frac{A_{21} f_c f_v}{BP(h\nu)(f_c - f_v)}\,. \end{aligned} \tag{35.13}$$

Combining (35.13) with (35.10) leads to

$$\frac{r_{\text{spon}}}{r_{\text{stim}}} = \frac{8\pi^3 n^3 (h\nu)^2}{(hc)^3 P(h\nu)} \frac{f_c(1-f_v)}{(f_c - f_v)}\,. \tag{35.14}$$

Using the expressions for f_c and f_v (35.1), this can be simplified to

$$\frac{r_{\text{spon}}}{r_{\text{stim}}} = \frac{8\pi^3 n^3 (h\nu)^2}{(hc)^3 P(h\nu)} \frac{1}{\left[1 - \exp\left(\frac{h\nu - (F_c - F_v)}{k_B T}\right)\right]}\,, \tag{35.15}$$

and consequently

$$\begin{aligned} r_{\text{stim}} &= r_{\text{spon}} \frac{(hc)^3 P(h\nu)}{8\pi^3 n^3 h\nu^2} \\ &\quad \times \left[1 - \exp\left(\frac{h\nu - (F_c - F_v)}{k_B T}\right)\right]. \end{aligned} \tag{35.16}$$

From this expression, we see that, when $F_c - F_v = h\nu$, $r_{\text{stim}} = 0$. Thus, when the quasi-Fermi-level splitting equals the photon energy, the absorption and stimulated emission rates cancel. At this injection level, the semiconductor is effectively transparent. This is known as the Bernard–Duraffourg condition. For photons of energy $h\nu > F_c - F_v$, there will be absorption. However, for photons of energy $h\nu < F_c - F_v$ there is a gain. This defines the condition necessary to achieve population inversion in the semiconductor and lasing action can occur when $F_c - F_v > E_g$.

35.2.5 Gain in Semiconductors

If $\alpha(h\nu)$ is the rate of gain/loss per unit length and $P(h\nu)$ is the photon density, then the rate at which the photon density increases/decreases per unit length is simply $\alpha(h\nu)P(h\nu)$. The corresponding rate of increase of photon density per unit time is then

$$r_{\text{stim}} = P(h\nu)\alpha(h\nu)\frac{c}{n}\,, \tag{35.17}$$

where c/n is the speed of light within a semiconductor of refractive index, n. By equating our two expressions for r_{stim} (35.16) and (35.17), we find that

$$\begin{aligned} \alpha(h\nu) &= r_{\text{spon}} \frac{h^3 c^2}{8\pi^3 n^2 h\nu^2} \\ &\quad \times \left[1 - \exp\left(\frac{h\nu - (F_c - F_v)}{k_B T}\right)\right]. \end{aligned} \tag{35.18}$$

Under conditions of low pumping or at high photon energies ($h\nu > F_c - F_v$), (35.18) can be approximated to

$$\begin{aligned} \alpha(h\nu) &= -r_{\text{spon}} \frac{h^3 c^2}{8\pi^3 n^2 (h\nu)^2} \\ &\quad \times \exp\left(\frac{h\nu - (F_c - F_v)}{k_B T}\right), \end{aligned} \tag{35.19}$$

from which we have

$$\begin{aligned} r_{\text{spon}} &= -\alpha(h\nu) \frac{8\pi^3 n^2 (h\nu)^2}{h^3 c^2} \\ &\quad \times \exp\left(\frac{(F_c - F_v) - h\nu}{k_B T}\right). \end{aligned} \tag{35.20}$$

Typical plots of the absorption and SE rates can be seen in Fig. 35.3. From Fig. 35.3a, it can be seen that, with increasing pumping level (increasing quasi-Fermi-level splitting), the semiconductor moves from purely absorption and becomes a gain medium. With increasing pumping, the spread of photon energies over which the gain occurs also increases, with the peak gain moving toward higher photon energy. In Fig. 35.3b, the SE rate is plotted as a function of photon energy. From this, it can be seen that the emission spectrum is broad and corresponds to the output spectrum of an LED. With increasing pumping level, the integrated SE increases, while the peak shifts to higher photon energies. In practical devices, current-induced Joule heating may lead to a slight decrease in the band gap, which reduces the overall blue shift.

35.2.6 Density of States

As a semiconductor laser is put under the forward bias, the quasi-Fermi levels in the CB and VB move toward

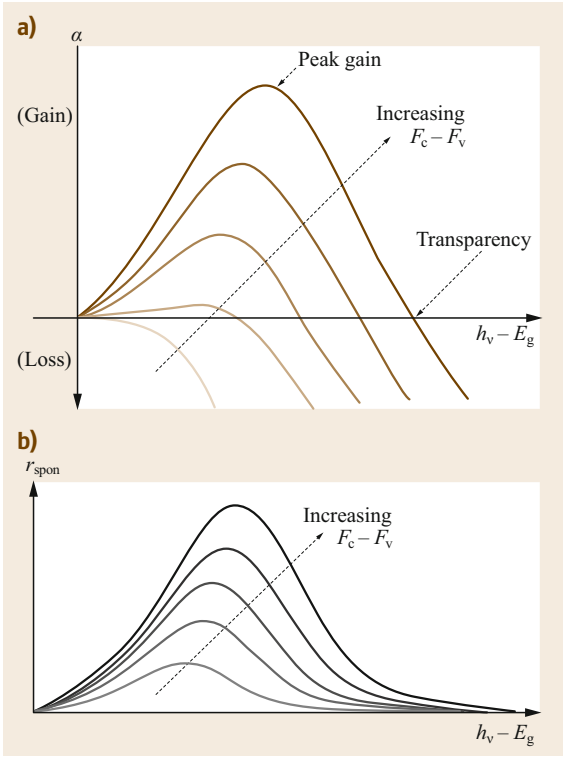

Fig. 35.3 (a) Gain/loss and (b) SE spectra as a function of increasing quasi-Fermi-level splitting

higher energies. The separation of the quasi-Fermi levels is dependent on the density of states $\rho(E)$ in the CB and VB. At laser transparency, where the quasi-Fermi-level separation equals the photon energy, the transparency carrier density, n_{tr}, and hence the threshold carrier density, n_{th}, depend upon the number of states in a given energy range. By reducing the number of available states, n_{th}, and consequently I_{th} (J_{th}), can be lowered. The density of states can be modified by changing the band structure. This can be achieved by reducing the dimensionality, thereby limiting the motion of the carriers, and also by introducing strain into the active region of the laser, as shall be described shortly.

Dimensionality

In conventional bulk semiconductor materials, the carriers have unrestricted motion in all directions and can be described by a 3-D density of states

$$\rho_{3\text{-D}} \propto m_{\text{eff}}^{\frac{3}{2}} \sqrt{E} \,, \tag{35.21}$$

where m_{eff} is the effective mass. This is illustrated in Fig. 35.4a, where the shaded region indicates the carrier population as a function of energy. In such (bulk) devices there are relatively few states near to the band

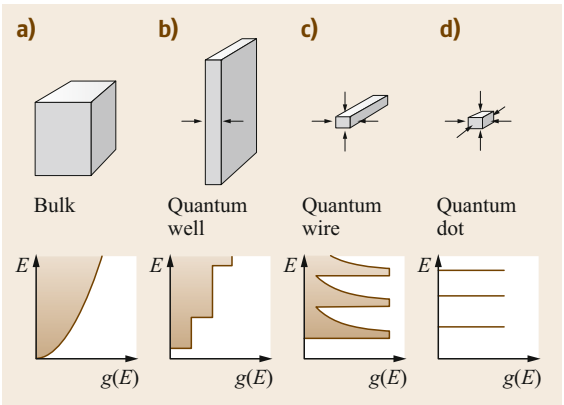

Fig. 35.4a–d Density of states in systems of differing dimensionality: (a) bulk, (b) QW, (c) quantum wire, and (d) QD

edges and hence the quasi-Fermi levels move toward higher energies (where there is a larger concentration of available states) in order to achieve the sufficient gain. This results in a broad output spectrum corresponding to radiative transitions over a wide energy range. By restricting the motion of the carriers along one dimension, as in QW structures, the density of states becomes independent of energy, with many states at the band edges. In a QW, the density of states is dependent only on the effective mass, m_{eff}, and the QW width, L_z as

$$\rho_{2\text{-D}} \propto \frac{m_{\text{eff}}}{L_z} \,. \tag{35.22}$$

In bulk structures, at the Brillouin zone center of the VB, the light- and heavy-hole bands are degenerate. Consequently, as the laser is pumped, states that do not contribute to the gain of the lasing mode also become filled. In a QW, the energy states form discrete levels. For an infinite square well, the confinement energy of the n-th energy level E_n is dependent on the QW width L_z and the growth-direction effective mass m_{eff}^z, and at the zone center can be simply expressed analytically as

$$E_n = \frac{\hbar^2}{2m_{\text{eff}}^z} \left(\frac{n\pi}{L_z} \right)^2 . \tag{35.23}$$

Thus, in a QW, the degenerate heavy- and light-hole bands become split (due to the difference in m_{eff}^z), resulting in a further reduction in the density of states at the VB Brillouin zone center. Therefore, in a QW laser, a higher proportion of the filled states can contribute to the gain of the lasing mode.

Further improvements in carrier confinement can be achieved by moving toward quantum wire or even QD structures. In quantum wire lasers, the carriers

are further confined, allowing the freedom of movement along one direction only (Fig. 35.4c). In principle, such structures can be realized, for example, by growth along lithographically defined V-grooves and lasers have been successfully produced in this manner [35.19], although the complexity of the processing has meant that they have yet to become a commercial product. In a QD laser, the carriers are confined still further so that they are restricted in all three dimensions (Fig. 35.4d). Thus, an ideal QD is analogous to an atom. By completely restricting the carrier motion, one may theoretically expect to achieve temperature-insensitive operation [35.12]. Initial attempts to produce QD lasers concentrated on lithographic processes, but it was not until the successful demonstration of self-assembled growth (the Stranski–Krastanov technique) that QD lasers became a reality. Record low room-temperature threshold current densities ($< 20\,\mathrm{A/cm^2}$) have been achieved using QD lasers [35.13]. However, due to the low gain, long lasers are required which increases the threshold current.

The Influence of Strain

A detailed discussion of strain in semiconductors is given in Chap. 20 of this book. However, due to the enormous importance of strain in optoelectronic devices, in this section, we discuss the influence of strain on device characteristics. For many years, manufacturers of semiconductor lasers struggled to produce dislocation- and strain-free material. In 1986, it was suggested independently by *Adams* and by *Yablonovitch* and *Kane* that the incorporation of strain into the active layer of semiconductor lasers would lead to improved performance [35.10, 11]. Many of these benefits have since been demonstrated [35.20–22]. The majority of the lasers currently manufactured in the world today are based upon strained layers.

In a strained-layer structure, the lattice constant of the epilayer material α_{epi} is different from the lattice constant of the substrate α_{sub} on which it is grown. When a thin epilayer of this material is grown onto the much thicker substrate, the lattice constant of the grown epilayer becomes equal to that of the substrate, α_{sub}, and the epilayer is in a state of biaxial stress. The resulting net strain in the (x–y) plane of the layer ε is given by

$$\varepsilon_{\parallel} = \varepsilon_{xx} = \varepsilon_{yy} = \frac{(\alpha_{\mathrm{sub}} - \alpha_{\mathrm{epi}})}{\alpha_{\mathrm{epi}}} , \qquad (35.24)$$

where it is assumed that the substrate is much thicker than the epilayer. Hence, $\alpha_{\mathrm{epi}} > \alpha_{\mathrm{sub}}$ results in compressive strain, while $\alpha_{\mathrm{epi}} < \alpha_{\mathrm{sub}}$ produces tensile strain. Figure 35.5 shows the three possible types of epilayer growth:

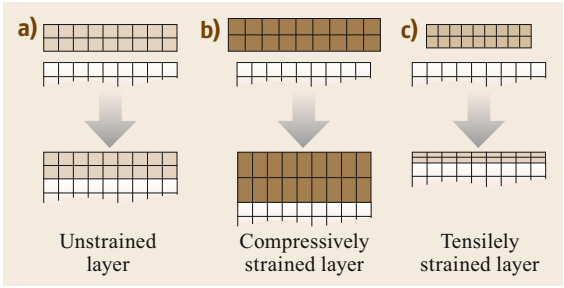

Fig. 35.5a–c Illustration of (a) unstrained, (b) compressively strained, and (c) tensile-strained layers. For the strained layers the epilayer expands (contracts) in the plane while expanding (contracting) in the growth direction, corresponding to compressive (tensile) strain respectively

1. Compressively strained
2. Tensile strained
3. Unstrained.

The sign convention used here is that positive strain indicates that the layer is under biaxial compression, while a negative strain corresponds to a layer being in a state of biaxial tension. For compressive strain, when the lattice constant of the epilayer is reduced in the plane, the lattice constant in the growth direction, $\alpha_{\perp}$, is increased. The strain in the growth direction $\varepsilon_{\perp}$ ($= \varepsilon_{zz}$) is governed by Poisson's ratio σ and is given by

$$\varepsilon_{\perp} = \varepsilon_{zz} = -\frac{2\sigma\varepsilon_{\parallel}}{1-\sigma} . \qquad (35.25)$$

In tetrahedral semiconductors, $\sigma \approx 1/3$; therefore, upon substituting this into (35.25), it can be seen that $\varepsilon_{\perp} \approx -\varepsilon_{\parallel}$. In order to understand how strain affects the band structure, it is useful to split the strain into an axial component $\varepsilon_{\mathrm{ax}}$

$$\varepsilon_{\mathrm{ax}} = \varepsilon_{\perp} - \varepsilon_{\parallel} \approx -2\varepsilon_{\parallel} , \qquad (35.26)$$

and a hydrostatic component, $\varepsilon_{\mathrm{vol}}$ ($= \Delta V/V$, the fractional change in volume of the epilayer)

$$\varepsilon_{\mathrm{vol}} = \varepsilon_{xx} + \varepsilon_{yy} + \varepsilon_{zz} \approx \varepsilon_{\parallel} . \qquad (35.27)$$

The axial and hydrostatic strain components affect the band structure as described in the next section. In direct-band gap semiconductors, while strain has only a small effect on the CB, it greatly alters the VB structure.

The maximum layer thickness that can be grown under a state of strain is determined by the critical thickness h_{c}. Above this thickness, it becomes energetically favorable to relieve the strain energy through the formation of dislocations. Thus, in order to grow high-quality (high-Q) strained material, it is necessary to

keep the thickness of each layer below h_c. As the strain in a layer is increased, the corresponding critical thickness decreases. The maximum strain–thickness product for InGaAs/GaAs materials is ≈ 200 Å% [35.23]. It is however possible to use alternating layers of compressive and tensile strain to produce zero-net-strain structures that can prevent the formation of dislocations. Strained-layer semiconductor lasers are often fabricated with strain-compensated wells and barriers when there are many strained QWs, thereby providing a large strain in the wells while reducing the overall strain in the structure.

The introduction of strain into the active region of semiconductor diode lasers brings about several changes in the band structure. The initial predictions of Adams and Yablonovitch and Kane concentrated on the benefits of compressive strain. It has since been shown that tensile strain can also enhance laser performance [35.24–26]. In the previous section, it was shown that the strain in an epilayer can be split into purely axial and hydrostatic components, ε_{ax} and ε_{vol}, respectively. The axial component of the strain splits the cubic symmetry of the semiconductor and hence the degeneracy of the heavy- and light-hole VBs at the Brillouin zone center is lifted (it should be noted that the VB will already be nondegenerate in a QW due to the effects of quantum confinement). In addition, the VB dispersion becomes anisotropic. In the case of compressive strain, the heavy-hole band is moved to higher energy with respect to the light-hole band, while the opposite is true for tensile strain. Also, for compressive strain, the *in-plane* (x–y) mass becomes lighter than the mass in the growth (z) direction. Again, the opposite is true for tensile strain. The hydrostatic component of the strain causes an increase in the mean band gap for compressive strain and a decrease in the mean band gap for tensile strain. These effects on the band structure of a strained *bulk-like* material are shown schematically in Fig. 35.6.

Due to the much reduced in-plane highest hole band mass, the density of states in a compressively strained laser is lower than that for an unstrained device. As a result, n_{tr} is decreased, which not only lowers the amount of unwanted SE [35.27] but also reduces carrier-density-dependent nonradiative processes such as Auger recombination [35.28]. Also, due to the increased heavy- and light-hole band splitting, carrier spillover into higher subbands can be substantially reduced. Consequently, compressively strained lasers have been shown to have much lower threshold current densities than similar unstrained devices [35.20, 29].

To understand the improvement in the performance of tensile-strained lasers, it is necessary to examine the character of the VB. The heavy-hole band consists

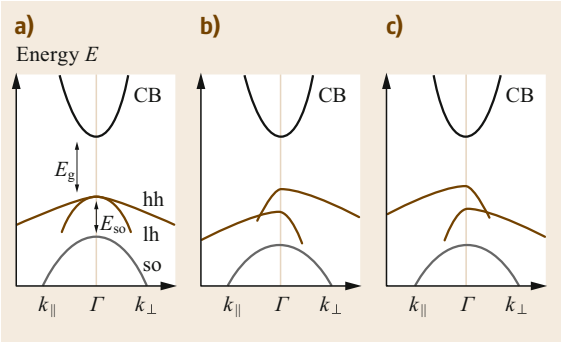

Fig. 35.6a–c Effects of strain for a bulk-like direct-band gap semiconductor for **(a)** unstrained, **(b)** tensile strain, and **(c)** compressive strain

of $1/2\,x$-like states and $1/2\,y$-like states, but contains no states with z-like character. In contrast, the light-hole band consists of $1/6\,x$-like states, $1/6\,y$-like states, and $2/3\,z$-like states. y-like states contribute to the transverse electric (TE) gain where the electric field oscillates across the facet (y-axis) and z-like states contribute to the TM gain, where the electric field oscillates along the growth direction. x-like states contribute only to SE, as the electric field vector lies in the propagation direction of the lasing mode. This is illustrated in Fig. 35.7. In bulk, unstrained QW and compressively strained QW lasers, the lasing mode is always TE-polarized as $g_{th}(\mathrm{TE}) < g_{th}(\mathrm{TM})$. With the inclusion of tensile strain in the QWs of semiconductor lasers it became possible for the first time to produce a device with TM polarization [35.25].

From Fig. 35.6, it can be seen that the in-plane mass of a tensile-strained laser is relatively large, resulting in an increased density of states. However, from Fig. 35.7, it can be seen that the top of the VB in a tensile-strained device contains $2/3\,z$-like states, which can contribute to the TM gain. Only one-third of the injected carriers will *not* produce gain in the lasing mode, compared with two-thirds in unstrained (bulk-like) and half in compressively strained QW devices. Hence, tensile-strained lasers can also exhibit a lower threshold current [35.25]. However, if only a moderate amount of tensile strain is incorporated into the QW, the threshold current will increase due to the heavy- and light-hole subbands becoming degenerate.

35.2.7 Optical Feedback in a Fabry–Perot Laser Cavity

The probability of stimulated emission depends not only on maintaining population inversion, but also on the photon density. In a laser, the photon density is sustained by the use of optical feedback. In a gas laser,

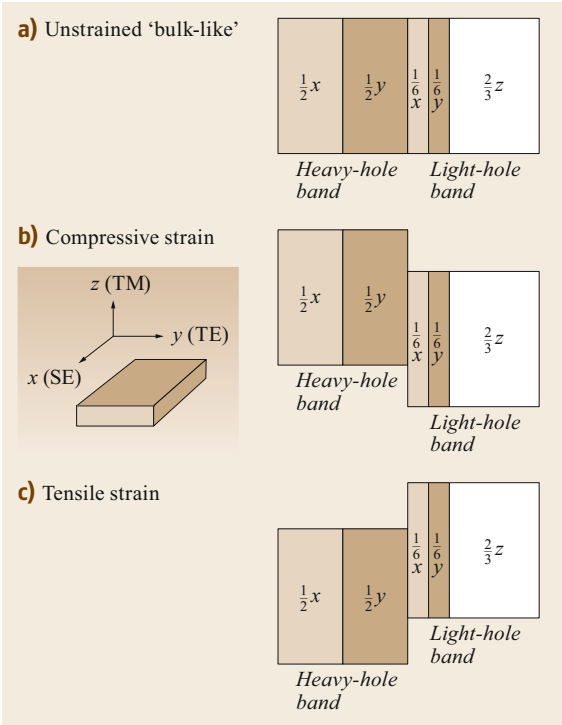

Fig. 35.7a–c Schematic illustration of the VB alignment for **(a)** unstrained bulk-like, **(b)** compressive strain, and **(c)** tensile strain

optical feedback is realized by the use of partially metallized mirrors, which form a Fabry–Perot cavity around the gain medium. When the light reaches the end of the cavity, a certain fraction (R) is reflected back into the gain medium, where it again becomes available to stimulate the emission of further photons. In a standard edge-emitting semiconductor laser, the same principle is used but the mirrors are formed by cleaving the semiconductor along a crystallographic plane (most commonly the (110) plane), forming laser facets. This is illustrated in Fig. 35.8. By using as-cleaved facets, the resulting reflectivity, R, is typically $\approx 30\%$ due to the refractive-index step between the laser material and (usually) air. This can be either increased or decreased with suitable facet coatings. Semiconductor lasers usually have roughened sides as a result of the fabrication process. This has the desirable effect of reducing the reflectivity of the sides of the laser and hence reduces the probability of generating unwanted transverse modes.

The application of optical feedback using a Fabry–Perot cavity has the effect of producing Fabry–Perot resonances or modes in the output spectrum of the laser. From Fig. 35.8, it can be seen that the optical field will form a standing wave when the cavity length is equal to

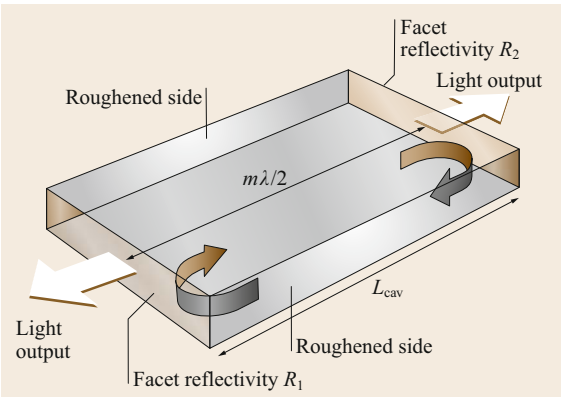

Fig. 35.8 Schematic diagram of a Fabry–Perot edge-emitting laser

an integer number of half-wavelengths, given by

$$\frac{m\lambda}{2} = nL_{cav} \quad m = 1, 2, 3, \ldots , \tag{35.28}$$

where m is the (integer) number of half-wavelengths, λ is the lasing wavelength (as measured), n is the refractive index of the laser cavity, and L_{cav} is the cavity length (typically $250\,\mu m \leq L_{cav} \leq 1500\,\mu m$). It can be seen that the maximum wavelength that the cavity can support is $\lambda = 2nL_{cav}$. If (35.21) is rearranged for λ and differentiated with respect to m, the mode spacing, $\Delta\lambda$ is found to be

$$\Delta\lambda = \frac{\lambda^2}{2nL_{cav}} . \tag{35.29}$$

Thus, the possible modes of a semiconductor laser consist of a comb of many hundreds of delta functions spaced $\Delta\lambda$ apart, as illustrated in Fig. 35.9. For a typical 1.5 μm laser with $L_{cav} = 500\,\mu m$ and $n \approx 3.2$, $\Delta\lambda \approx 0.7\,nm$. The wavelength at which lasing occurs is therefore determined by both the material gain curve and the mode spacing. The mode which lies closest to the peak of the material gain curve at threshold will lase (Fig. 35.9), although other modes near to the gain peak may also be present in the output spectrum of an edge-emitting Fabry–Perot laser. With increasing bias however, the relative strengths of these modes will decrease with respect to the dominant lasing mode. This produces a very narrow and spectrally pure output, in stark contrast with the SE spectrum of an LED.

35.2.8 Wave Guiding

As discussed earlier in this chapter, the stimulated emission process is not only dependent on the carrier density, but also on the photon density within the laser

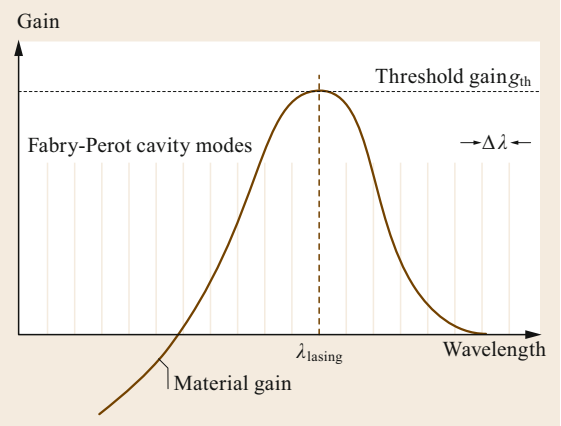

Fig. 35.9 Illustration of gain in a semiconductor laser. The cavity mode that lies closest to the material gain peak at threshold will lase

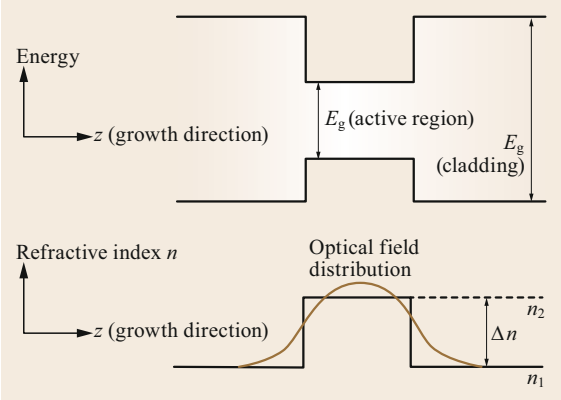

Fig. 35.10 Wave guiding in a double heterostructure

cavity. In particular, it is a requirement that the photon density is maintained as high as possible so that the probability of stimulated emission is maximized while still allowing sufficient radiation to escape. As the optical field propagates along the laser cavity, it can extend in both the growth (z) and transverse (y) directions. Hence, it is necessary for the optical field to be confined along two directions. In a semiconductor laser, wave guiding can be accomplished by two methods:

- Index guiding
- Gain guiding.

Index guiding is achieved by surrounding the active region with a material of larger band gap and, hence, lower refractive index. In the *growth* direction of an edge-emitting double-heterostructure semiconductor laser, the optical field is always index guided. Figure 35.10 shows an example of index guiding in a typical double-heterostructure laser together with the associated refractive-index profile in the growth direction. Index guiding confines most of the optical field within the active region due to total internal reflection at the cladding heterojunctions with only a small fraction of the field evanescently decaying into the higher band gap layers. The degree of confinement depends upon the refractive-index step between the active region and the surrounding layers.

In the transverse direction, the optical field can be confined by either index- or gain-guiding mechanisms. Gain guiding arises from a weak current-induced change in refractive index across the active region caused by the nonuniform carrier distribution. Index-guided structures can be considered as either strongly index-guided or weakly index-guided, corresponding to either a large or small refractive-index step in the transverse direction. Gain-guided structures are easier to fabricate than index-guided structures but are less effective in confining the optical field when compared with index-guided structures [35.30].

35.2.9 Carrier Confinement

In addition to confining the optical mode, laser characteristics can be greatly enhanced by improving the confinement of the electrons and holes, thereby increasing the probability of radiative recombination. The first laser structures [35.1, 4–6] were based upon single p–n junctions (homojunctions). In such structures, the injected electrons and holes recombine close to the junction. However, due to the nonuniform carrier distribution, as the electrons diffuse out of the gain region, there is a variation in gain with position. In addition, due to the small difference in refractive index at the edge of the gain region, a large amount of the optical field spread into absorbing regions. Thus, the combination of a poor carrier and field confinement gives rise to large threshold current densities $\approx 10^5\,\mathrm{A/cm^2}$ in homojunction lasers. The development of the double-heterostructure laser [35.7, 8] brought about a large decrease in J_{th} of two orders of magnitude. This results from the greatly improved carrier confinement due to the difference in the band gap between the active and cladding layers, which forms a potential barrier to the carriers. A further improvement in carrier confinement is obtained with QW structures. In a QW laser, the injected carriers rapidly diffuse into the thin ($\approx 25-150\,\text{Å}$) QW layers [35.9]. Due to the large potential barriers between the well and barrier material, it is difficult for the carriers to subsequently escape. In addition to improved carrier confinement, QW lasers offer many other benefits over bulk lasers as discussed later in this chapter. Figure 35.11 illustrates the improvement in carrier confinement obtainable on going from ho-

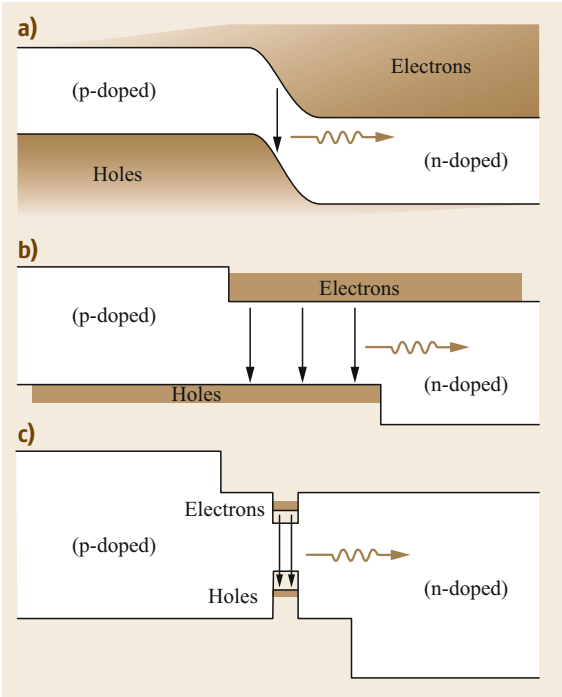

Fig. 35.11a–c Advances in carrier confinement **(a)** homojunction, **(b)** double heterostructure, and **(c)** QW

mojunctions to double heterostructures and QW laser structures.

35.2.10 Current Confinement

The threshold current of semiconductor lasers can be further decreased by reducing the area of the device that is being electrically pumped. Reducing the threshold current can also suppress current-heating effects and extend the operating lifetime of the laser. Current confinement can also help to produce a stable fundamental mode. There are several fabrication techniques and associated laser structures designed to increase current confinement [35.30]. The ridge structure, as shown in Fig. 35.12a, is a weakly index-guided type of laser. In this structure, following the epitaxial growth of the complete layer structure, the wafer is etched to produce a ridge that is $\approx 2-10\,\mu m$ wide. The wafer is then coated with a dielectric (usually SiO_2) and metallized. The weak index guiding is provided by the large refractive-index step between the active region material and the dielectric. The current is directly injected into the ridge and therefore travels through a relatively narrow region of the device. The two main other structures are strongly index-guided buried heterostructure (BH) devices. In double-channel planar buried heterostructure (DCPBH) lasers (Fig. 35.12b), following the growth of the layer structure, two channels, $\approx 3\,\mu m$ deep and $\approx 10\,\mu m$ wide, are chemically etched, forming a mesa. After cleaning, n- and p-doped current blocking layers are grown followed by the cladding and contacting layers. The current confinement is provided by the reverse-biased p–n junctions that surround the mesa.

The final structure considered is the semi-insulating planar buried heterostructure (SIPBH), as can be seen in Fig. 35.12c. In a similar way to the DCPBH devices, SIPBH lasers are based upon an etched mesa. In an SIPBH device, the current confinement is provided by semi-insulating layers that surround the mesa. In these structures, after wet-chemically etching the wafer to form the mesa (typically $1-2\,\mu m$ wide and $2-3\,\mu m$ high), an Fe-doped layer is grown, followed by an n-doped antidiffusion layer, p-doped cladding and contacting layers. The resistivity of the Fe-doped regions surrounding the mesa is typically $\approx 10^8\,\Omega cm$ thereby ensuring that the current only flows through the active region. Buried heterostructure lasers tend to have lower threshold currents than ridge structures due to the combination of excellent current and optical field confinement. For high-speed applications such as telecommunications, SIPBH devices outperform DCPBH lasers due to their much lower parasitic capacitance.

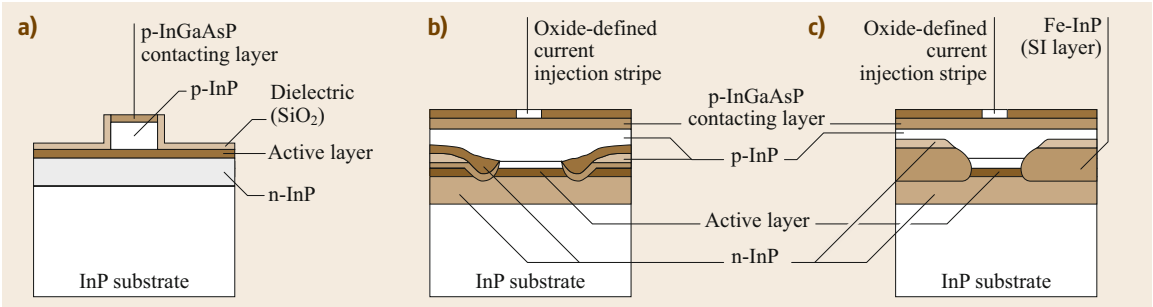

Fig. 35.12a–c Schematic diagrams of typical long-wavelength InP lasers **(a)** ridge structure, **(b)** double-channel planar buried heterostructure (DCPBH), and **(c)** semi-insulating planar buried heterostructure (SIPBH)

35.2.11 Laser Threshold and Efficiency

In Sect. 35.2.4, the condition for material transparency was derived. In a laser structure, the threshold is reached when the total gain is equal to the optical losses as the wave travels along the cavity plus the (useful) loss of light from the facets (mirror loss). If we consider the laser cavity shown in Fig. 35.8, the threshold gain condition, g_{th} is given by

$$g_{th} = \frac{1}{\Gamma}[\alpha_m + \alpha_i] = \frac{1}{\Gamma}\left[\frac{1}{2L_{cav}} \ln\left(\frac{1}{R_1 R_2}\right) + \alpha_i\right], \quad (35.30)$$

where R_1 and R_2 are the facet reflectivities, α_m is the mirror loss, and α_i is the internal loss per unit length in the *entire* structure, including scattering losses, free-carrier absorption, and inter-VB absorption [35.31]. Γ is the optical confinement factor, which is equal to the fraction of the optical field intensity that overlaps the active region. This therefore accounts for the fact that not all of the optical field will give rise to the gain. Note that g_{th} is the threshold gain per unit length of the device. For a typical 1000 µm long 1.5 µm QW device ($\Gamma \approx 0.02$) with as-cleaved facets ($R_1 = R_2 \approx 0.3$) and $\alpha_i = 10\,\mathrm{cm}^{-1}$, $g_{th} \approx 1100\,\mathrm{cm}^{-1}$. The carrier density required to reach g_{th} is termed n_{th}, and the corresponding current (density) is termed I_{th} (J_{th}). Figure 35.13 shows how the light output and carrier density increase as current is injected into the laser structure. Below threshold, increasing the current causes the Fermi-level splitting to increase, thereby increasing the electron and hole (carrier) densities in the active region of the laser. In this regime, the laser is acting as an LED and SE is produced. However, the electrical-to-optical conversion efficiency is relatively low ($\approx 1\%$). In practice, non-radiative recombination processes (as discussed in the next section) cause the carrier density to have a non-linear dependence on current below the laser threshold. At threshold, the stimulated lifetime decreases, causing each additional injected carrier to undergo stimulated emission. These carriers rapidly transfer to the VB with the production of a photon via stimulated emission giving rise to an abrupt increase in the light output. Thus, at threshold, the carrier density becomes pinned at n_{th} since every additional carrier quickly undergoes stimulated emission. Hence, above threshold, the intrinsic *differential* quantum efficiency, η_d, of the lasing process can be as high as 100% in an ideal laser. However, effects including carrier leakage, absorption, and self-heating can reduce the overall measured differential quantum efficiency.

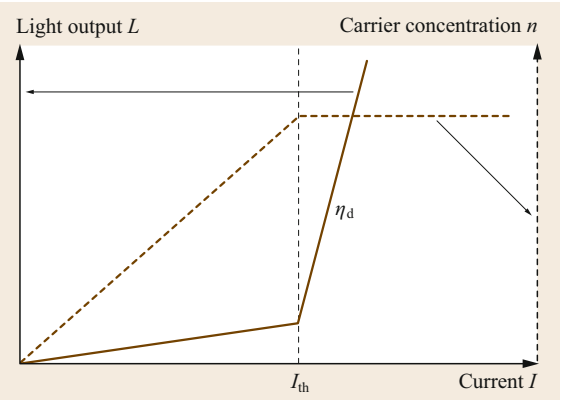

Fig. 35.13 Variation of the light output (*solid curve*) and carrier density (*dashed curve*) as a function of the injection current. Above threshold, the light output increases abruptly while the carrier density becomes pinned

The differential quantum efficiency, η_d, is defined as the ratio of the incremental number of photons emitted from the facets to the incremental number of carriers injected into the laser (above threshold), thus

$$\eta_d = \frac{dL}{dI}\frac{e}{h\nu}, \quad (35.31)$$

where L is the optical power emitted from both facets, e is the electronic charge, and $h\nu$ is the photon energy (the lasing energy). Thus, η_d can simply be determined from the light–current characteristic (providing that all of the stimulated light is collected), η_d can more generally be defined from

$$\eta_d = \eta_i\left(\frac{\alpha_m}{\alpha_i + \alpha_m}\right), \quad (35.32)$$

η_i is the *internal* quantum efficiency and accounts for the fact that, in a real laser, not all of the injected carriers will result in the production of a photon. This may be due to inefficient injection of carriers into the active region of the laser (dependent on both the laser materials and the geometry of the laser). It is convenient to rewrite (35.32) in terms of the inverse efficiency so that

$$\frac{1}{\eta_d} = \frac{1}{\eta_i}\left(\frac{\alpha_i + \alpha_m}{\alpha_m}\right) = \frac{1}{\eta_i}\left(\frac{\alpha_i}{\alpha_m} + 1\right) = \frac{1}{\eta_i}\left[\frac{2\alpha_i L_{cav}}{\ln\left(\frac{1}{R_1 R_2}\right)} + 1\right]. \quad (35.33)$$

If R_1 and R_2 are known (easily calculated), by measuring η_d for lasers with several different cavity length taken from the same wafer and plotting a graph of $1/\eta_d$ versus L_{cav}, one can obtain a value for both η_i (from the intercept) and α_i (from the slope/intercept).

From Fig. 35.13, it is clear that the *overall* efficiency of the laser will depend on both the differential quantum efficiency η_d, which we wish to maximize, and the threshold current I_{th}, which we would like to minimize. In the discussion thus far, the threshold current has been described only in terms of an SE current. In practice, there exist many other recombination paths that contribute to the laser threshold. These are discussed in the next section.

35.2.12 Carrier Recombination Processes

When carriers are injected into a semiconductor laser, there are many possible recombination paths. In an ideal semiconductor laser, above threshold, the carrier density pins, as illustrated in Fig. 35.13. Therefore, above threshold, any recombination path which depends upon n will also become pinned. However, the threshold current itself is determined by the different mechanisms by which carriers recombine in a real laser structure. In this section, the important radiative and nonradiative recombination mechanisms are briefly discussed. The threshold current of a semiconductor laser is defined as the current required to provide enough gain to reach the threshold gain level g_{th}. Due to differences between laser structures, it is frequently more useful to compare the threshold current density J_{th} between devices, which accounts for the overall area of the device that is being pumped, thereby allowing a useful comparison to be made between different device structures. In this chapter, both are used interchangeably when discussing laser characteristics. At threshold, the total current I can be expressed as the sum of the current paths as

$$I = eV(An + Bn^2 + Cn^3) + I_{leak}\,, \qquad (35.34)$$

where e is the electron charge, V is the active region volume, and n is the carrier density (where we assume that the electron (n) and hole (p) densities are equal, $n = p$).

The An term is due to recombination at defects and is considered to be negligible in high-quality material. It does however make significant contributions to some laser materials, most notably InGaAsN/GaAs where it can account for up to 50% of I_{th} even in the best 1.3 μm devices [35.32].

The Bn^2 term corresponds to the radiative recombination of electrons and holes giving rise to SE, as observed from LEDs, and semiconductor lasers operated below threshold. Radiative recombination occurs (for interband processes) when an electron in the CB recombines with a hole in the VB, resulting in the SE of a photon as illustrated in Fig. 35.14. For lasing to occur, it is necessary to have spontaneous recombination to initiate the stimulated emission process. However, because SE is a random process, emitting photons in all directions over a broad energy range, only a small fraction of the photons can couple with the laser gain. Hence, for efficient laser operation, it is desirable that the amount of unwanted SE is reduced.

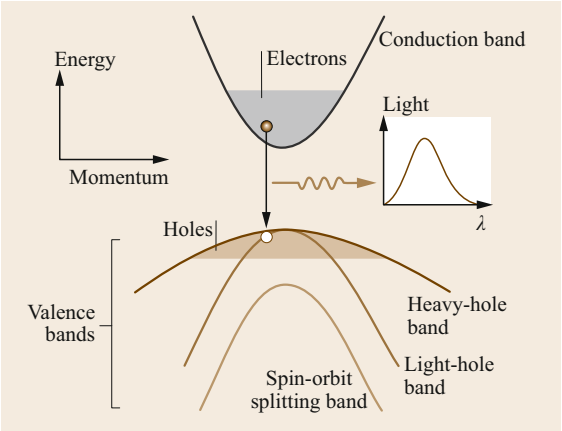

Fig. 35.14 Spontaneous emission in a bulk semiconductor

The Cn^3 term describes *nonradiative* Auger recombination. In an Auger recombination process, the energy of a recombining electron–hole pair that would normally produce a photon is instead given to a third carrier (electron or hole) which is excited further into its respective band. Thus, in an Auger recombination process, three carriers are involved, the initial electron–hole pair plus an additional electron or hole. The two main Auger recombination processes are illustrated in Fig. 35.15, where the closed circles represent electrons and open circles represent holes. In the conduction–hole–conduction–conduction (CHCC) process, the energy and momentum of a recombining CB electron and VB hole are transferred directly to a second CB elec-

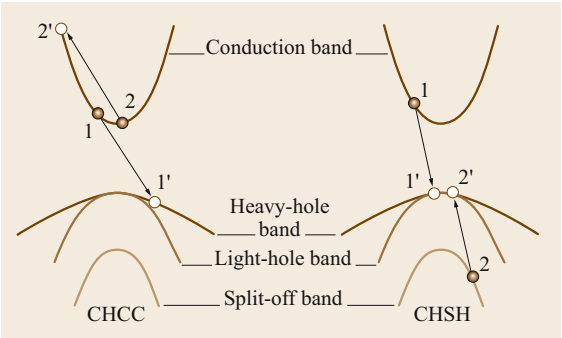

Fig. 35.15a,b The two primary Auger recombination processes: **(a)** CHCC producing hot electrons and **(b)** CHSH producing hot holes

tron, which is then excited into a higher energy CB state. In the direct conduction–hole–spin–hole (CHSH) process, the energy and momentum are transferred to a second VB hole, which is then excited into the spin split-off band. In addition to these direct Auger recombination processes, there may be phonon-assisted processes whereby the conservation of momentum and energy of the carriers is relaxed by the emission or absorption of a phonon. These are however of less importance in 1.3 and 1.5 μm lasers [35.33]. It should be noted that Auger-generated carriers are very energetic and initially lie many k_BT more than E_g above their respective band edges. While these carriers quickly scatter back to thermal equilibrium, there is a finite probability that they will scatter from the active region into the cladding layers, thus forming an additional Auger-generated leakage current.

Auger recombination processes are very sensitive to the band gap, E_g, and are severely detrimental to laser performance. For emission wavelengths below 1 μm, the probability of an Auger recombination process occurring is small due to the near-vertical transitions that are required on an energy–momentum diagram, which decreases the probability of the process occurring (*inset* Fig. 35.16). However, as E_g decreases, the transitions become less vertical and the probability of finding a state for the *hot* Auger carrier increases. Auger recombination, therefore, begins to influence the performance of semiconductor lasers and by 1.5 μm it dominates their behavior at room temperature, forming ≈ 80% of the threshold current [35.28]. This is illustrated in Fig. 35.16 where the normalized variation of the measured threshold current with lasing energy was determined by performing high-pressure measurements on several lasers over the nominal wavelength range 1.3–1.6 μm. With increasing lasing energy (band gap), the threshold current decreases strongly due to the lowered contribution of Auger recombination. Thus, long-wavelength lasers are more susceptible to Auger recombination. Auger recombination is also largely responsible for the high-temperature sensitivity of the threshold current of 1.3 and 1.5 μm semiconductor lasers. In Fig. 35.17, we plot the temperature dependence of the threshold current (*circles*) for a 1.3 μm InGaAsP laser. The squares correspond to the measured radiative current as determined from SE measurements [35.28]. At low temperature, the threshold current follows the radiative current very closely, however, above ≈ 160 K, the threshold current increases strongly due to thermally activated Auger recombination. This is primarily due to the n^3 dependence of the Auger current and also because the Auger coefficient C is thermally activated [35.34]. Suppressing Auger recombination is challenging and work is ongoing on new semiconductor materials such as the III–V-bismides which have the potential to reduce or eliminate Auger recombination processes through band structure engineering, as discussed later in this chapter.

I_{leak} is associated with heterobarrier leakage and current spreading around the active region. With increasing temperature there is an increasing probability that electrons in the CB and holes in the VB will have enough thermal energy to escape from the QWs. This is termed heterobarrier leakage. Here, these carriers may

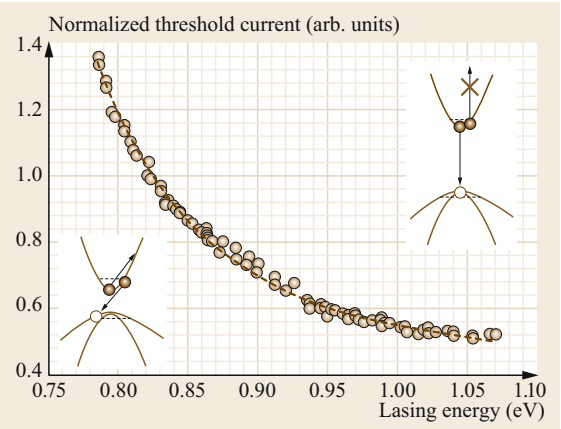

Fig. 35.16 Variation of the threshold current with lasing energy over the wavelength range 1.2–1.6 μm. With increasing wavelength (decreasing energy), the threshold current increases swiftly due to the increased probability of Auger recombination, as illustrated in the *insets*

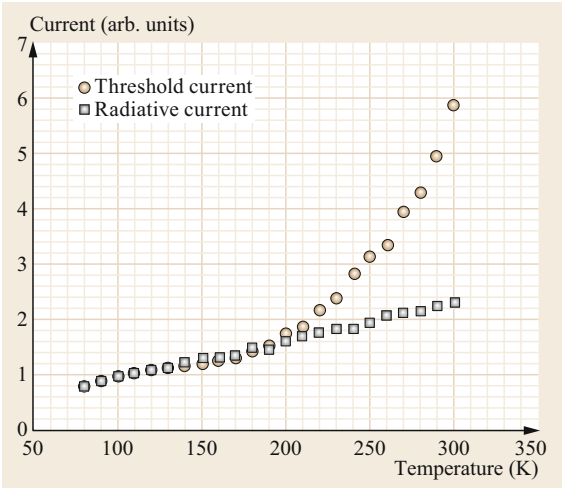

Fig. 35.17 Threshold current (*circles*) and radiative current (*squares*) versus temperature for a 1.3 μm InGaAsP laser. The threshold current increases more strongly with temperature than the radiative current due to the thermally induced onset of Auger recombination

recombine radiatively (at shorter wavelengths) or non-radiatively. If they have sufficient energy, they may even escape into the cladding layers. The probability of carriers escaping into the cladding layers depends upon the position of the quasi-Fermi levels with respect to the cladding band edge, as illustrated in Fig. 35.18. With increasing temperature, the thermal spread of carriers broadens and the population of unconfined carriers at threshold increases, thereby increasing the threshold current. For diffusion-driven leakage of electrons, the leakage current I_{leak} can be described via an activation energy E_a, equal to the difference in energy between F_c and the lowest (Γ, L, or X) CB edge of the cladding layer. Thus,

$$I_{\text{leak}} = I_0 \exp\left(-\frac{E_a}{k_B T}\right), \tag{35.35}$$

where k_B is the Boltzmann constant, T is the temperature, and I_0 is independent of temperature. As with Auger recombination, carrier leakage is strongly temperature dependent and can lead to a large change in the threshold current with temperature. For this reason, much effort has been put into designing lasers which minimize carrier leakage. In III–V semiconductors, due to the large hole effective mass, F_v moves toward the VB at a much slower rate than F_c moves toward the CB edge. For InGaAs(P)-based materials as used in 1.3 and 1.5 μm lasers, the QW to barrier/SCH band offset in the CB is much lower than the VB offset. Additionally, holes have a much lower mobility than electrons. Consequently, the overflow of electrons is generally considered to be more significant compared to the overflow of holes in this materials systems. Carrier leakage is a particular problem for visible semiconductor lasers for which the Al-containing layers may be close to, or indeed are, indirect, whereby the CB X-minima are at a lower energy than the CB Γ-minima. Thus, electrons may thermally escape from the separate confinement heterostructure (SCH) into the cladding, forming a leakage current. An example of this is shown in Fig. 35.19 where the threshold current is plotted as a function of temperature for a 670 nm Al(GaInP) laser. The strong increase in threshold current with temperature is due to the thermal leakage of electrons from the GaInP QW via the SCH region into the X-minima of the AlGaInP barrier layers. At room temperature, leakage accounts for ≈ 20% I_{th} at room temperature, rising to ≈ 70% at 80 °C at this wavelength [35.35]. Due to the smaller activation energy, shorter wavelength devices suffer still further from carrier leakage and this, in practice, sets the lower wavelength limit for lasers produced using this material system.

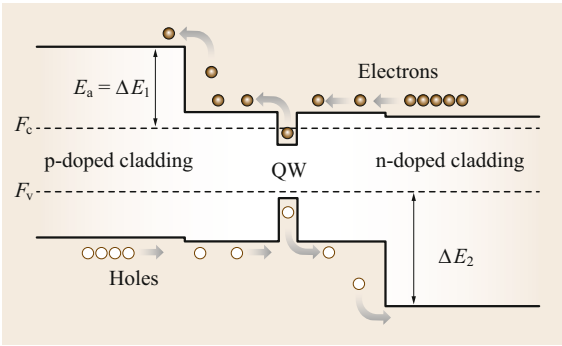

Fig. 35.18 Carrier leakage in a QW semiconductor laser

35.2.13 Temperature Sensitivity and T_0

As described in the previous section, the threshold current of lasers operating in the visible and in the 1.3–1.5 μm range is very sensitive to the ambient temperature. From a commercial perspective, this is very unsatisfactory as these lasers are required to provide a constant light output for a given drive current above threshold all year round. However, throughout the year, the ambient temperature can typically vary significantly. Hence, further cost results from having to use expensive temperature-control electronics to stabilize the temperature and hence light output of these lasers. This can be seen in Fig. 35.20 where the power–current curves are plotted for a 1.3 μm laser over the temperature range 20–70 °C. Clearly, by operating the laser at a constant bias current, the light output decreases considerably as the temperature decreases. In extreme cases, the current may no longer be sufficient

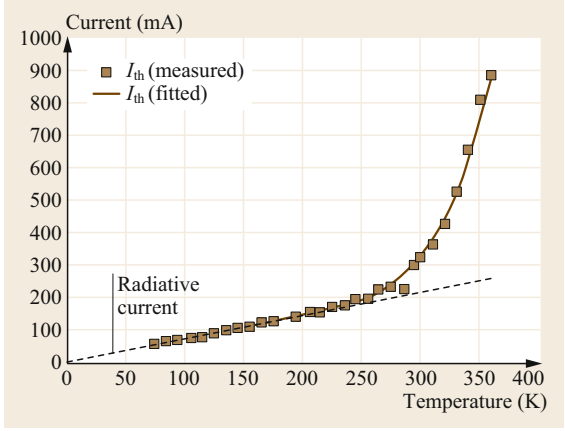

Fig. 35.19 Threshold current versus temperature for a 670 nm GaInP QW laser. The strong temperature sensitivity above 250 K is due to electron leakage into the X-minima of the AlGaInP barrier layers

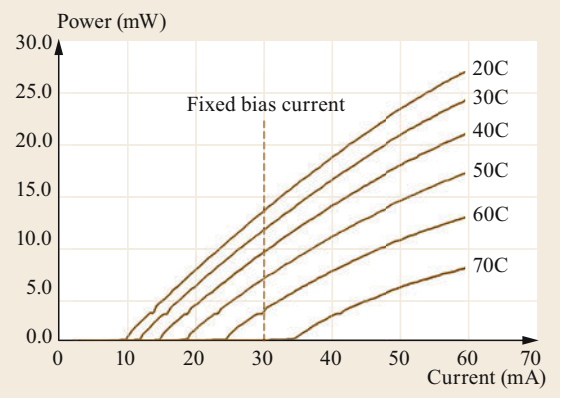

Fig. 35.20 Typical curves of power versus current for a 1.3 μm laser as a function of temperature. The large increase in threshold current with increasing temperature gives rise to a strong loss of power for a fixed bias current

to reach laser threshold, at which point the device will no longer lase and the output would only be SE (as shown in Fig. 35.20, for the 70 °C curve). In practical situations, this therefore necessitates the use of temperature-control feedback electronics. These add considerable cost (many times the cost of the laser itself) to the system. This has become known as the T_0 problem. Around room temperature and over a limited range of temperature, the threshold current of many semiconductor lasers was observed to increase approximately exponentially with temperature [35.36]. Hence, it is usual to write that $I_{th} = I_0 \exp(T/T_0)$, where I_0 is a constant and T_0 is the characteristic temperature of the threshold current given by

$$\frac{1}{T_0} = \frac{1}{I_{th}} \frac{dI_{th}}{dT} = \frac{d \ln(I_{th})}{dT} , \tag{35.36}$$

T_0 is usually expressed in units of Kelvin. It follows that a low value of T_0 corresponds to a high-temperature sensitivity and vice versa. Hence, a high T_0 is desirable. Experimentally, T_0 can be determined from measurements of I_{th} from

$$T_0 = \frac{T_2 - T_1}{\ln\left[\frac{I_{th}(T_2)}{I_{th}(T_1)}\right]}, \tag{35.37}$$

where $I_{th}(T_1)$ and $I_{th}(T_2)$ are the threshold currents at T_1 and T_2, respectively, and $T_2 > T_1$. In practice, over a wider temperature range, T_0 is itself temperature dependent due to the temperature dependence of the recombination mechanisms that occur in the lasers. However, T_0 is a parameter often used to investigate the temperature dependence of the threshold current. For a typical 1.3 or 1.5 μm QW laser, $T_0 \approx 50$–60 K. This is due to Auger recombination, as discussed above. It can be shown that, for an ideal QW laser, the maximum $T_0 = 300$ K around room temperature, where the threshold current is entirely due to radiative recombination [35.37]. Furthermore, by going to QD lasers, due to the 3-D-confinement effect, an infinite T_0 has been predicted [35.12]. Recently reported experimental work has shown that this may be possible by using p-doped QD layers, which exhibit temperature-insensitive operation around room temperature [35.38].

35.3 Single- and Multimode Lasers

35.3.1 DFB and Wavelength Tuneable Lasers

In an ideal laser, the output spectrum would be very narrow with no side modes. In practice, the output spectrum of Fabry–Perot devices such as those described earlier in this chapter consists of several competing modes. This is due to the comb of Fabry–Perot modes, which overlap with the laser gain spectrum (shown earlier in Fig. 35.9). There are a number of laser devices that can be operated with high spectral purity. Perhaps the most important of these is the DFB laser. In a Fabry–Perot laser, the end facets provide optical feedback to give rise to provide a sufficient gain to achieve threshold. Because the reflectivity of the end facets is only slightly wavelength dependent (for a given polarization), this gives rise to several longitudinal modes. These are clearly visible in the output amplified SE spectrum of a Fabry–Perot laser; indeed, this is one way in which the gain can be measured [35.39]. In contrast, in a DFB laser, there is an additional layer called the guiding layer (Fig. 35.21a,c) grown close to the active layer. The guiding layer is essentially a grating consisting of a corrugated layer of a dissimilar refractive-index semiconductor defined using lithographic and etching techniques. If the grating is defined only near the laser facets, it is called a distributed Bragg reflected (DBR) laser (Fig. 35.21b). The corrugations in the material provide a periodic variation in the refractive index along the laser cavity and hence the optical feedback is *distributed* along the length of the cavity.

Both DBR and DFB lasers essentially have the same operating principle. The optical radiation generated in the active layer satisfying the Bragg condition will be reflected back efficiently. This condition is set

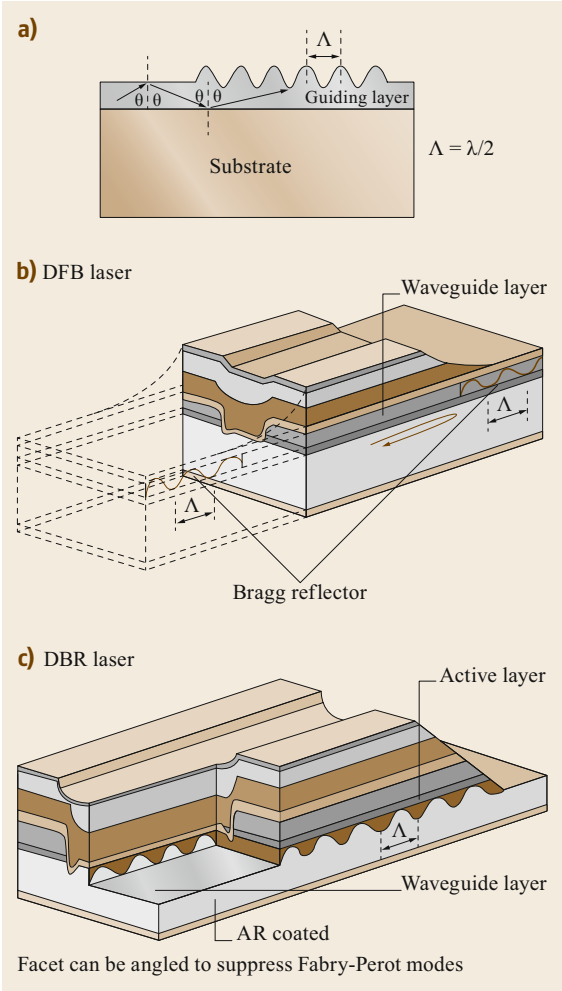

Fig. 35.21 **(a)** Schematic of a DBR based waveguide design on a substrate with grating period Λ, **(b)** a DBR laser design with a grating structure defined to selectively reflect the desired wavelength for oscillating in the active layer. **(c)** A DFB laser design where the grating covers the entire cavity. Both lasers shown have a buried heterostructure lateral current confinement design. (After [35.40, 41])

by waves scattering off successive corrugations reflecting and constructively interfering. For a guiding layer with the refractive index η, the Bragg condition is given by [35.40, 42]

$$2\Lambda \sin\theta = \frac{m\lambda_0}{\eta} \,. \tag{35.38}$$

The minimum requirement for a positive optical feedback within the cavity is scattering at $\approx 180°$ with respect to the direction of the propagating mode resulting in $\theta \approx 90°$. One can include the angular dependence in the definition of the modal effective index η_{eff} for the guided mode giving

$$\Lambda = \frac{m\lambda_0}{2\eta_{\text{eff}}} \,, \tag{35.39}$$

that is, the grating period required for the laser to operate λ_0 at depending on the order of diffraction m.

The grating structure can be produced via photolithography in which holographic techniques are used for projecting a periodic interference pattern on the surface to be etched [35.40–42]. For many near-infrared lasers, the requirement for the first-order grating period is in the 100–300 nm range, requiring resolutions available only with advanced lithographic equipment. To make fabrication easier, higher order diffraction grating structures have been investigated, although their efficiency tends to be lower due to lower order diffraction loss. It can be shown that a DFB laser has two resonant frequencies around the desired cavity resonance where the cavity oscillations can occur [35.43]. This is undesirable and is generally remedied by using a $\lambda_0/4$ phase-shifted design [35.44]. DBR lasers can also provide single-frequency operation with a high degree of stability and tunability. As the gain and Bragg reflection regions are separate, independent control of the carrier density in the grating region is possible which can be used to alter the effective index of the waveguide using the free-carrier plasma effect [35.42], for fine frequency tuning.

An added benefit of the grating in a DFB laser is that it may be used to artificially reduce the temperature sensitivity of the laser threshold current and lasing wavelength. Unlike Fabry–Perot lasers, which primarily emit at the mode closest to the gain peak, as discussed above, DFB lasers can be made to emit at one fixed mode. The peak of the gain spectrum moves approximately at the same rate as that of the band gap ($\approx 0.5\,\text{nm/K}$), while the temperature dependence of the DFB mode follows the thermally induced change in the refractive index ($\approx 0.1\,\text{nm/K}$) which is much less temperature sensitive. Thus, DFB lasers are far less susceptible to thermally induced mode hops. Furthermore, by carefully designing the peak of the gain spectrum to lie at a shorter wavelength than the DFB wavelength, one can effectively *tune* the DFB laser with increasing temperature resulting in, over a limited temperature range, a relatively temperature-independent threshold current. This has been demonstrated as a means of achieving cooler-less 1.3 μm lasers, albeit at the expensive of higher threshold currents.

DFB lasers are the mainstay of optical communications systems due to their single-mode behavior with high side-mode suppression and narrow line widths ($< 0.1\,\text{nm}$). In an optical-fiber communication system, this allows for the simultaneous transmission of sev-

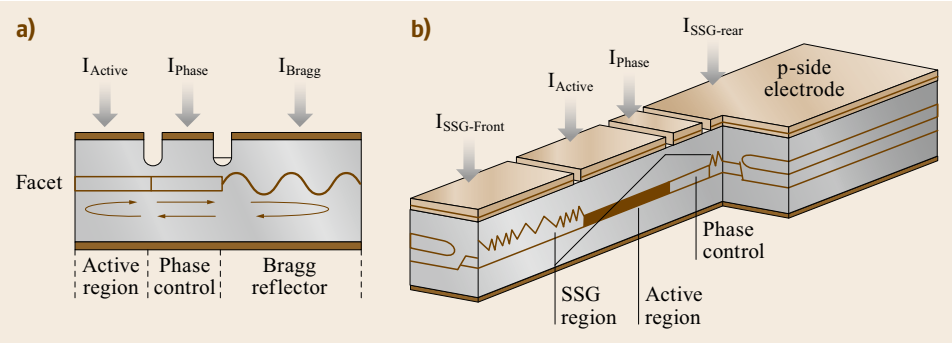

Fig. 35.22

eral data channels with closely spaced wavelengths around the fiber attenuation minimum of 1.55 μm. This is known as dense wavelength-division multiplexing (DWDM).

The DBR design can be adapted to design efficient and widely tuneable lasers on a single semiconductor chip. Figure 35.22a shows a three-section laser design where each section can be pumped independently. This allows wavelength tuning via phase tuning or tuning of the effective grating period (both via refractive-index tuning) by independent electrical pumping of the respective sections. A combination of both allows a continuous tuning of about 1% around the central wavelength [35.45, 46]. This limitation of tuning range is imposed by the extent to which the effective refractive index can be altered via current injection, that is, (mainly) via the free-carrier plasma effect. In this effect, the free carriers under mutual Columbic interaction alter the dielectric polarization of the material, thereby altering its refractive index [35.45, 47]. An order of magnitude increase in the tunability range can be achieved by using a superstructure grating (SSG) design, Fig. 35.22b. An SSG can be approximated as an array of frequency-independent scattering centers spaced at Λ. The SSG-DFB laser works using the Vernier effect between the reflection peaks of the two SSGs which are designed to have slight offset in their reflection peaks [35.45, 47]. SSG-DFB lasers and related design variations are used as local oscillators in modern coherent detection systems forming an integral part of today's optical communication networks.

35.3.2 Vertical Cavity Surface-Emitting Lasers (VCSELs)

We note from the discussion in Sect. 35.2.7 that if the frequency spacing between the adjacent longitudinal modes is wider than the gain bandwidth, single longitudinal mode operation is possible. Equation (35.29) suggests that this can be achieved by having a very short cavity. In a VCSEL, the cavity length is made very short and the laser beam is emitted perpendicular to the wafer, that is, in the same direction as that of the injected current. Because the VCSEL emits from its surface, the optical cavity over which the optical field may experience the gain is very short. Consequently, in order to reach the threshold gain level, the optical field needs to make several passes through the active region. This requires highly reflective end mirrors. At a typical III–V semiconductor–air interface, the refractive-index contrast gives rise to a reflectivity of $\approx 30\%$. This is enough to achieve a sufficient gain to reach threshold in an edge-emitting laser, which is typically many hundreds of micrometers long. However, in a VCSEL, the cavity length is typically of the order of the wavelength of light in the material, requiring mirror reflectivities $> 99\%$. This is achieved by sandwiching the active region between two multilayer dielectric (Bragg) mirrors. The short cavity and small active volume require a high-Q cavity to keep the lasing threshold current low [35.40, 48].

The active layer in a VCSEL is sandwiched between a stack of Bragg mirrors, that is, alternate layers of high and low refractive-index materials, each of which is designed to be a quarter wavelength thick at the desired laser wavelength, Fig. 35.23a,b. The Bragg mirrors provide very high reflectivity of the light back into the active region, allowing the VCSEL to generate a sufficient gain in spite of the small gain region optical path length. Constructive and destructive interferences within the Bragg stack result in a Bragg resonance, which gives rise to a reflectivity that increases with the number of layer pairs (one high index high η_{high} and one low index low η_{low}). The resultant reflectivity for the intra-cavity field can be approximated by

$$r_{Bragg} \approx \tanh\left[2m\left(\frac{\eta_{high}-\eta_{low}}{\eta_{high}+\eta_{low}}\right)\right] = \tanh\left[\frac{2m\Delta\Lambda}{\lambda_0}\right], \quad (35.40)$$

if the entry and exit materials for the radiation are considered the same [35.49], where m is the number of

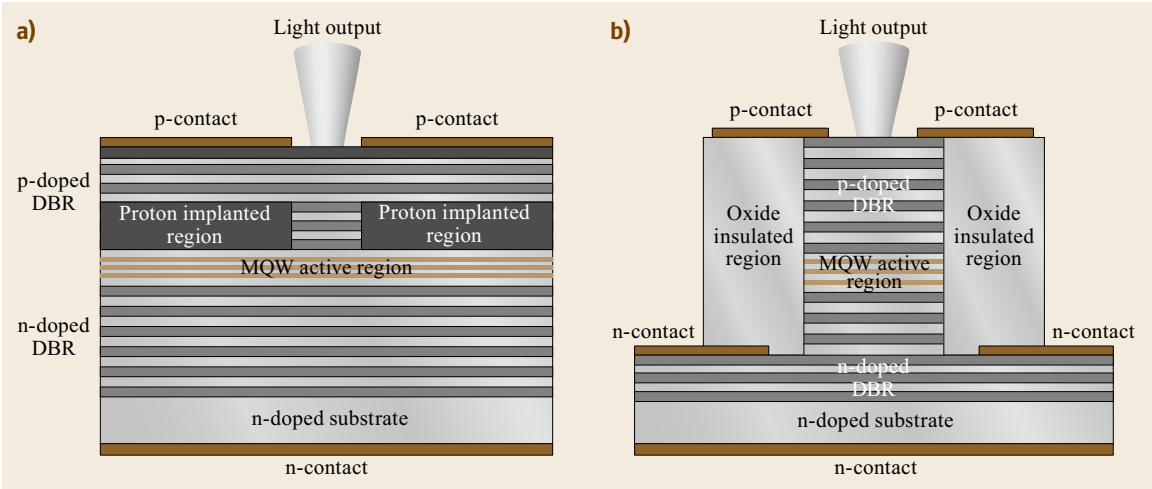

Fig. 35.23a,b Cross-sections of two common cylindrical VCSEL designs for lateral current confinement **(a)** a proton-bombarded top-bottom contact design and **(b)** an oxide confined side-contact design. The MQW active region sandwiched between the DBR stacks forming the cavity is also shown. The VCSEL being a cylindrical design emits a circular beam profile

layer pairs. For $\eta_{\text{high}} - \eta_{\text{low}} = 0.3$, greater than 98% intensity reflectance ($R = r^2_{\text{Bragg}}$) can be achieved for 30 layers in an AlGaAs/GaAs-based Bragg stack for resonance wavelength around $\approx 850\,\text{nm}$. For longer wavelengths, a higher number of (thicker) layer pairs are generally required [35.49]. A Bragg stack with a sufficient number of layer pairs results in a flat and broad reflectivity spectrum (called a stop band) with a width $\Delta\Lambda$ around the cavity resonance wavelength λ_0 it is designed for, see Fig. 35.24b. The top Bragg stack usually has lower number of layer pairs for the output coupling of the generated laser beam.

This emission wavelength from a VCSEL (or for that matter any single-frequency laser) is selected via a dynamic competition between the cavity resonance and material gain peak. For a high-Q cavity, the emission wavelength is closer to the cavity resonance than the gain peak (mode/frequency pulling [35.50]). Thus, in general, the VCSEL cavity is designed so that there is a fixed detuning between the material and the cavity resonances at room temperature so that at the operating temperature the cavity resonance aligns with the peak gain and the desired wavelength is emitted with the maximum gain available at the cavity resonant mode [35.51–53].

In addition to the advantage of being an inherently single-frequency laser, VCSELs offer several other advantages, including ease of fabrication and on-wafer testing of single chips, ease of fabrication of planar arrays (hence lower costs), and their symmetric circular beam profile which makes coupling of the generated light to an optical fiber easier and more efficient (lower coupling loss) compared to edge-emitting lasers. VCSELs can be fabricated using conventional planar integrated circuit fabrication techniques and can provide emission over a wider aperture if high order spatial modes can be tolerated in the application. Optical interconnects based on narrow-aperture VCSELs are used in many levels of modern light-wave communication systems. Note that the resonant cavity LED (RCLED) is a related device that provides surface emission in a VCSEL-like structure. However, such devices have a lower number of DBR layer pairs in the Bragg stack and do not achieve a lasing threshold and thus emit narrow-band SE. RCLEDs are, however, useful for applications such as plastic optical fiber (POF)-based visible light data links [35.54].

Other forms of surface-emitting laser have also been designed where an angled facet is used to direct the laser beam perpendicular to the plane of the epistructure while using conventional current injection designs as in edge-emitting semiconductor lasers [35.40, 41, 55]. Laser designs based on photonic band-gap materials (i. e., photonic crystal lasers [35.56]) also employ vertical emitting designs (Photonic Crystal Surface Emitting Lasers, PCSELs) with carrier injection schemes similar to conventional VCSELs.

High-quality VCSELs have already been produced for emission at 650 and 850 nm (for plastic and silica fiber communications), for oxygen sensing using 760 nm VCSELs and high-power devices for emission at 980 nm [35.57]. However, there has been considerable difficulty in producing VCSELs at the telecommunication wavelengths of 1.3 and 1.55 μm. This is

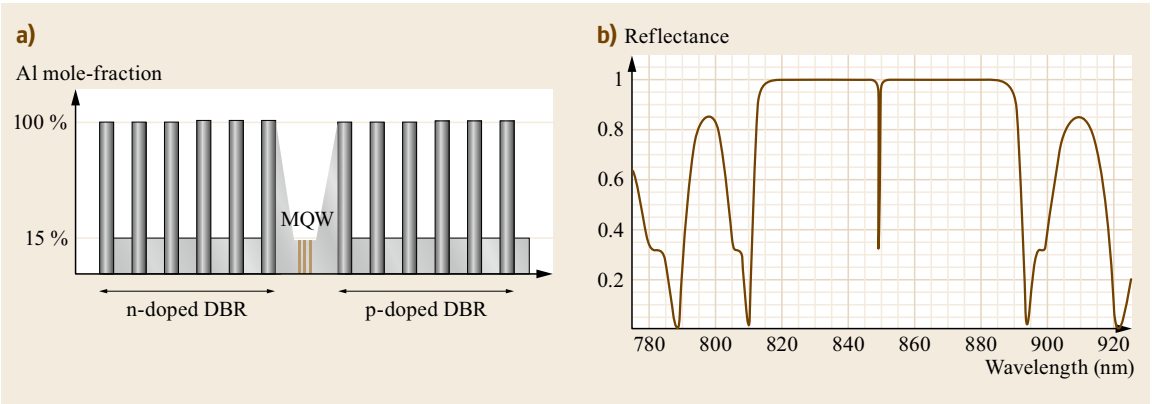

Fig. 35.24 **(a)** MQW active region in a AlGaAs/GaAs-based VCSEL sandwiched between two AlGaAs/GaAs Bragg stacks which are differently doped for efficient carrier transport. **(b)** Typical stop-band characteristics in a VCSEL around the resonance wavelength

primarily due to the fact that GaAs/AlGaAs is the preferred system for making highly reflective DBRs due to the high refractive-index contrast between GaAs and AlAs. Such DBRs are therefore compatible with the GaAs substrates as used in devices below $\approx 1\,\mu m$. However, for longer wavelength devices, which are primarily based on InP substrates, it is difficult to form highly reflective DBRs using InGaAsP/InP due to their low refractive-index contrast. Alternative methods of producing long-wavelength VCSELs are inherently process-intensive, using techniques such as wafer fusion in which the active layer and InGaAsP/InP DBR are first grown on an InP substrate, while a GaAs/AlAs DBR is grown separately on a GaAs substrate. The active layer is then fused onto the GaAs/AlAs DBR, and the InP substrate is then removed [35.58]. The wafer fusion process is understandably both costly and difficult, and therefore methods of growing monolithic 1.3 and $1.55\,\mu m$ VCSEL structures using only a single GaAs substrate are particularly attractive. This has stimulated a great deal of research into producing GaAs-based active regions emitting at these wavelengths. In recent years, there has been some success in achieving this by two approaches. The first approach is to use InAs/GaAs QDs as the active region. QD lasers with very low threshold current density ($< 20\,A/cm^2$) emitting at $1.3\,\mu m$ have already been realized [35.13]. However, there are few reports in the literature on QD-based VCSELs. This is largely due to the difficulty in achieving a sufficient gain from the QDs and can result in the need for several layers of QDs. In spite of this, QDs are showing promise for use in temperature-insensitive edge-emitting lasers and high-power lasers.

The second approach has been in the use of the so-called dilute nitrides. In 1997, *Kondow* et al. originally proposed the use of InGaAsN/GaAs as an active material to achieve long-wavelength emission on GaAs [35.59]. This is due to the unusual band-gap bowing that occurs when small concentrations (≈ 2–5%) of nitrogen are added to GaAs. By growing the alloy InGaAsN, one may achieve long-wavelength emission while maintaining a low or zero strain. Although material quality remains an issue, there have been several successful demonstrations of edge-emitting lasers and VCSELs based upon this material emitting at $1.3\,\mu m$ [35.60–62]. The push towards $1.55\,\mu m$ emission has been largely hampered by material quality issues although at the time of writing this chapter, there have been the first reports of low-threshold $1.5\,\mu m$ edge-emitting lasers based upon InGaAsN/GaAs [35.63]. Other researchers have produced close-to-$1.5\,\mu m$ edge-emitting and VCSEL devices with the pentenary material InGaAsNSb/GaAs [35.64]. It is speculated that antimony may act as a surfactant to improve the quality of growth. The dilute nitride approach does at present appear to offer the best possibility of obtaining monolithic VCSELs emitting at the technologically important wavelength of $1.55\,\mu m$.

35.3.3 High Power Lasers

Direct and efficient conversion of electrical energy into coherent light provides a wealth of applications such as in solid-state and fiber laser pumping, medical applications, optical communication via free-space energy transfer, and high quality material processing (cutting and welding) allowing the process to be controlled with high spatial and temporal resolution. Thus, interest in scaling the output power to the kilowatt range and beyond has been there from the very beginning of semiconductor lasers. There is a limit to the max-

imum optical power that can be extracted from an edge-emitting stripe-geometry laser. This limit is set by the *thermal runaway* power load and secondly the optical power load at the facet which can be up to few $\approx$ MWcm^{-2}, beyond which the facet succumbs to the generated heat and undergoes catastrophic optical damage (COD) [35.65, 66]. With an increase in carrier injection (pumping), the optical output power from the laser increases until the generated heat (via unused injected power) causes thermal escape of the carriers from the active region (thermal runaway [35.46]), resulting in a drop in the optical power upon further current injection. At sufficiently high injection, the device no longer lases owing to the fact that the threshold current itself increases (due to joule heating) with injection until such point that the threshold current exceeds the injected current level. Thermal runaway is a reversible phenomenon, unlike COD, which irreparably damages the laser [35.46]. COD is sensitive to the quality of the facet and modern facet passivation approaches mean that COD is less problematic than it once was. Thermal runaway generally occurs at a much lower power load than facet damage in diode lasers and thus, under some circumstances, self-limits the device from undergoing COD. High-power diode lasers consequently require wide aperture designs, firstly to achieve a higher gain volume for high-power generation, and secondly to withstand and efficiently dissipate the heavy thermal load generated by the device. Additionally, they are often operated under quasi-CW conditions (100 µs–1 ms pulse length) to limit thermal effects and to extract the maximum possible power.

The distinction between low- and high-power semiconductor lasers is not very well defined. It may depend on the type of diode laser and the application for which it has been designed. Generally, 50 mW (or more) CW for single-mode, single-frequency lasers and 500 mW (or more) CW for broad-area multimode lasers and laser arrays is generally considered to be high power [35.46]. For many applications, however, the power requirement from diode lasers is quite low. For example, CD players use a 3 mW range GaAs laser emitting at $\lambda = 780$ nm, supermarket scanners use visible ($\lambda = 670$ nm) 3 mW AlGaInP lasers, and in optical fiber telecommunications 10–50 mW (in-fiber) InGaAsP lasers ($\lambda = 1.3$ or 1.55 µm) are generally used, all emitting in single mode. However, an important class of applications requires much higher output powers either in pulsed or CW operation. Operation in a single spatial mode or at a single frequency is often desirable, but raw power can also be very useful. One example where raw power is most important is in diode-pumped yttrium–aluminium garnet (YAG)-based solid-state lasers, where the pumping laser array fabricated from AlGaAs material emits kilo-watts of incoherent quasi-CW pulses. The wavelength of the AlGaAs laser array is well tuned to the absorption spectrum of the YAG crystal (806–810 nm), providing much higher overall efficiency than flash-lamp pumping. Applications where both high-power and near-diffraction-limited beam quality (i. e., coherent emission) are required include many communication and most scientific applications, where transmission over long distances and/or the ability to focus the light to a small spot of high power density is desired, such as pumping erbium-doped fiber amplifiers (EDFAs). In general, the power available from incoherent sources exceeds the power available from coherent sources by more than an order of magnitude. However, the brightness or radiance (power/beam divergence) of coherent, diffraction-limited sources is significantly higher. Tremendous advances have been made in scaling the output power of diode lasers and arrays, thanks to modern crystal growth, device cooling, and facet passivation technologies.

Over the last two decades, the output power from diode lasers has increased by an order of magnitude [35.46, 67]. The electro-optic (wall-plug) conversion efficiency measured under laboratory conditions is now $> 70\%$ in GaAs-based lasers, which has reduced the thermal load immensely [35.68–70]. Under pulsed conditions, more than 150 W of optical power output has already been demonstrated from a 100 µm emitting stripe geometry laser [35.69]. Under CW operation, optical power in the range of tens of watts has been demonstrated before thermal runaway occurs [35.46]. Further improvements are being reported each year [35.49, 70]. Multi-kW level raw power delivery is already possible from modern stacked laser diode arrays [35.71].

A diode laser array is essentially a multistripe semiconductor laser with stripes fabricated in close proximity to each other (Fig. 35.25). Lateral current confinement can either be achieved via a mesa-stripe (gain guided) or via proton-bombarded (index-guided) design [35.71–73]. It is common to have 1 cm wide arrays (called diode laser bars) in array stacks. The proximity of the individual stripes results in an overlap of oscillating intracavity field distributions from adjacent emitters (Fig. 35.25b) and with appropriate design these can be phase locked, resulting in a combined, coherent wavefront being emitted from the whole facet [35.71–73]. Vertical stacks of the cm bars operate under active, for example, liquid-based cooling (Fig. 35.25c).

Optically pumped semiconductor slab/disk lasers (also known as VECSELs or OPSELs, see below) [35.74] are the only technology competing with stacked diode laser arrays. Vertical external cavity

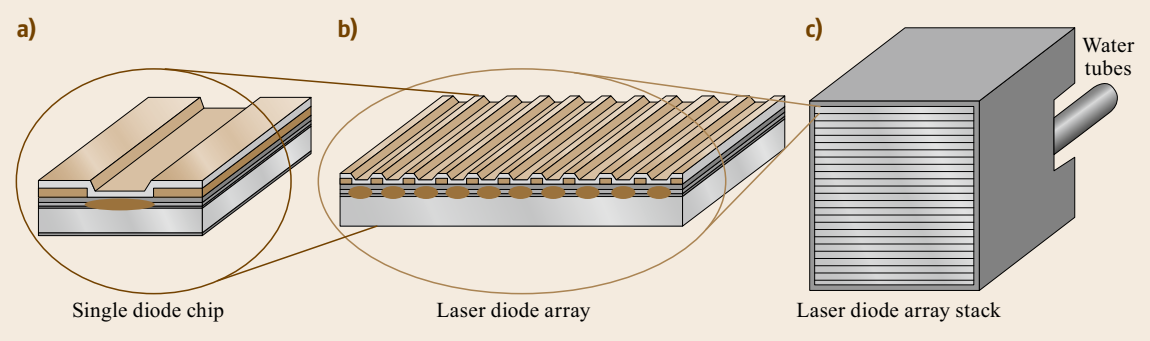

Fig. 35.25a–c Schematic for a high-power diode laser: **(a)** single chip, **(b)** array of diode lasers, **(c)** a two-dimensional stack (requires active cooling)

lasers or VECSELs are essentially optically pumped large aperture VCSELs which are designed with a pump absorbing layer in place of the top DBR stack (output coupling side), see Fig. 35.26a. Hence, they are also called optically pumped surface emitting lasers (OPSELs) or just disk or slab lasers. Diode laser array stacks are used for optical pumping while an external mirror completes the cavity [35.75].

The advantage of VECSELs over a stack of edge emitting laser bars is a symmetric beam profile, a narrow line width and the possibility of intracavity frequency doubling [35.75]. The scalability of the aperture allows the generation of high powers while maintaining the circular beam shape and narrow line width. However, efficient thermal management is essential for VECSEL operation due to the generally poor thermal conductivity of the bottom DBR.

Despite the developments in high-power diode laser technology, achieving high spatial coherence (beam quality) still remains an open challenge. Beam quality of high-power diode lasers (both edge emitting and large aperture VECSELs) is affected by nonlinear filamentation of the spatial modes and is far behind from what is achievable from modern solid state and gas lasers. Poor beam quality affects the focusing ability (brightness) of the beam and the coupling efficiency to optical fibers. A nonzero positive phase–amplitude coupling in the semiconductor gain medium is the primary reason behind the filamentation instability [35.46, 73]. Thermal effects also play a key role [35.46, 73, 74, 76, 77]. Currently, a master oscillator power amplifier (MOPA) design or a derivative of it offers some promise in achieving high-spatial and temporal coherence from a broad area diode laser [35.46, 73]. However, the coherence properties start deteriorating at higher pumping due to thermal effects [35.74, 76–80]. The working principle behind a MOPA design is as follows. The MOPA design consists of a narrow aperture ridge waveguide section with an in-built grating (a DBR laser-type design) acting as the master oscillator which injects a spatially and spectrally filtered beam into an adiabatically tapered section that amplifies and scales the optical power, see Fig. 35.26b. Some variants of the MOPA design do not use a grating when spectral purity is not important for the application. Beam spoiling grooves are sometimes used to attenuate any backward

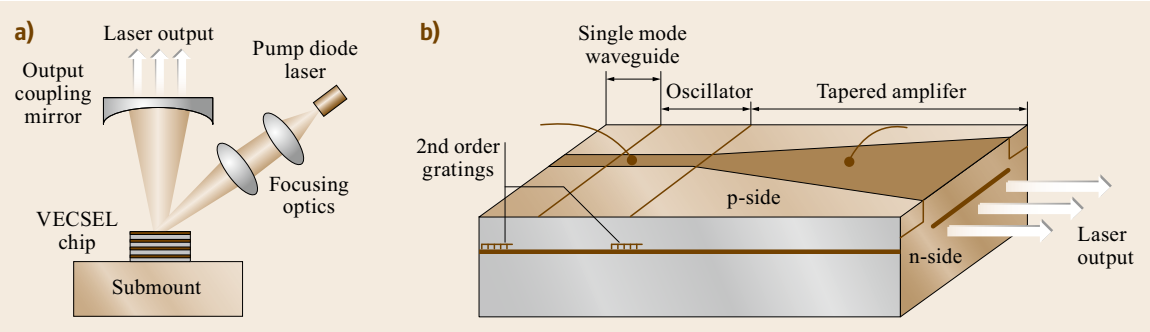

Fig. 35.26 **(a)** Schematic of a vertical external cavity surface-emitting laser (VECSEL) showing the VECSEL chip, the external cavity and the pumping scheme **(a)** a master oscillator power amplifier (MOPA) laser design for high brightness (see text for details)

propagating wave in the tapered region for enhancing the beam stability [35.46, 73].

High brightness, high-power diode laser sources are gaining interest for applications previously dominated by solid-state lasers, because of their efficiency, compactness, and high reliability. Among others, laser projection displays, free-space communication, frequency doubling, and direct material processing are rapidly emerging areas, where high output power together with diffraction-limited beam quality is either the key requirement or strongly enhance system performance. Production of high-power diode lasers with improved brightness will allow them to compete with the very best solid state and gas lasers at much lower cost [35.46, 67], and may enable future generations of compact, inexpensive, and portable laser systems.

35.3.4 Quantum Cascade Lasers

The semiconductor lasers that we have discussed so far emit wavelengths largely determined by the band gap of the available (direct-band gap) semiconductor materials since the devices rely on so-called interband transitions. This restricts the use of semiconductors as a lasing medium in large parts of the mid- to far-infrared spectrum, not covered by conventional direct semiconductor materials or for which processes, such as Auger recombination, which become increasingly important for narrow band gaps, are problematic and limit device performance [35.81, 82]. A QCL uses intraband transitions (instead of interband transitions used by conventional lasers) to generate photons in the mid- and far-infrared spectrum, including in the terahertz (THz) range. These intraband transitions are electronic transitions within the QWs, and the emitted photon energy depends on the QW width and heterojunction band offsets. Therefore, the desired emission wavelength can be varied just by varying the well width. Thus, QCLs are uni-polar lasers unlike conventional semiconductor lasers which are bi-polar devices. Almost all III–V semiconductor-based QCLs use electrons in the CB as the charge carriers; however, it is also possible to use holes as charge carriers in a VB-based device, as is the case of SiGe/Si-based QCLs [35.83]. The QCL structure was originally proposed in 1971 [35.84] and was first demonstrated only in 1994 [35.85], mainly due to the complex structure and accurate growth technology required to implement a QCL design in practice. Since QCLs are intraband and unipolar devices, the physics of gain and lasing is different from what we have discussed above for interband lasers and a detailed discussion is beyond the scope of this chapter. Nevertheless, QCLs form an important class of modern semiconductor lasers so we will present a qualitative outline of their working principles.

The cavity and waveguide design used in both conventional semiconductor lasers and QCLs are essentially similar except for the doping (both cladding layers are n-doped in the majority of QCLs) [35.56, 85, 86]. The main difference in QCLs lies in the active layer which employs intraband transitions only in one band. Since-electron charge carrier in CB-based devices form the vast majority of QCLs, we will focus on these. This can be seen in Fig. 35.27 which shows a section of the active layer which employs MQWs in two stages: an injector region and an active region all under an electric field. The closely spaced QWs and narrow barriers in the injector region result in the formation of mini bands in a superlattice [35.56, 85, 86]. Quantum-mechanical tunneling-assisted transport of the injected electrons through the minibands into the adjacent active region creates an effective population inversion in the active QW. This leads to an intraband transition of the electron from the upper level to lower level of the QW resulting in photon emission. Subsequently, the electron thermalizes to a lower state and tunnels into the next injector region cascading through the structure (hence the name of the laser) producing many more photons. A typical QCL has 20–80 such stages, each having several MQW structures. Typically, there are several hundred to over a thousand epi-layers in QCLs. QCLs have been demonstrated from just below 3 up to 67 μm, opening-up the THz range and its associated applications [35.86, 87]. High-power and DFB QCLs have also been demonstrated [35.56, 86]. It is interesting to note that the *quantum* efficiency of QCLs can be far above 100% owing to the fact that one electron produces many photons. However, this is not breaking any law of physics, as the power (wall-plug) efficiency is typically $< 50\%$ owing to the large voltages that are required to produce the electric field across the relatively thick structure which allows the cascading process to occur.

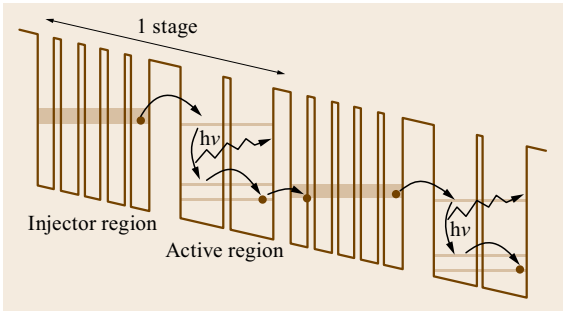

Fig. 35.27 Schematic of the CB design for two successive stages inside the active region of a quantum cascade laser (QCL)

35.3.5 Emerging Semiconductor Materials for Modern Semiconductor Lasers

The lasing characteristics and reliability of semiconductor lasers largely depend on materials used in their design. The band gap and the lattice constant both play a vital part and the maturity of the growth technology of the chosen semiconductor. While the band gap for most types of laser largely determines the emission wavelength, the lattice constant determines whether the semiconductor material can be grown lattice matched on the substrate of choice, hence reducing the density of defects. The latter directly affects the performance and reliability of the device. As discussed earlier, a small amount of strain can be beneficial if kept within a thin QW layer [35.40, 55]. However, in general, the overall semiconductor laser structure should be relatively strain free to minimize defect formation. A simple SQW-SCH active region design requires a minimum of five epi-layers on the substrate to make a laser structure (typically, there are more than 10 layers). One can see that this immediately limits the number of semiconductor alloys with the desired band gap and lattice constants which can be used in a typical laser design. While many new semiconductor alloys have been proposed in recent years to fill the existing gaps, there are only a few with mature enough growth technology which can be used for commercial devices that require high reliability. Figure 35.28 lists some semiconductor alloys with their band gaps and lattice constants [35.88, 89].

Materials falling on a vertical line are lattice matched to each other. There is a great impetus toward achieving efficient semiconductors active regions grown on silicon substrates which will allow on-chip integration of lasers with silicon-based optical waveguide components for all-optical communications and data processing. Being an indirect-band-gap semiconductor, silicon itself is a poor emitter of light; hence, the integration of high optical quality direct-band gap semiconductors on cheap silicon substrates is highly desirable. The primary limiting issue to achieve this is the lattice mismatch between silicon and standard III–V materials such as InP- or GaAs-based alloys (Fig. 35.28), which makes it difficult to grow high-Q alloys directly on silicon.

There have been tremendous advancements in hybrid approaches to this where strain relaxed (metamorphic) growth techniques have been used to grow relatively defect-free working laser structures [35.90, 91], through the use of QD [35.92] and exotic QW [35.93] active regions and through wafer fusion approaches [35.91]. This remains an active area of ongoing research as noted in a number of reviews on this topic [35.94, 95]. Entirely new materials for semiconductor lasers continue to being investigated to help push the wavelength limits of semiconductor lasers and to improve the efficiency and temperature sensitivity of devices. Recently, for example, GaAsBi-based semiconductor lasers have been demonstrated [35.90, 94–99]. Such alloys provide a route to overcome the ill-effects of Auger recombination which have limited the maximum achievable power and efficiency of near- and mid-infrared semiconductor lasers and have the potential to significantly reduce the energy demands of optical fiber communications [35.90, 94–98].

Table 35.1 lists some of the common active and cladding layer compositions used in modern semiconductor lasers together with the substrate material and the emisson wavelength range. The list is incomplete as many materials and compositions still under research are not included [35.100]. The values of mole fractions indicated in Table 35.1 are either for direct-band gap or strain balanced designs. Semiconductor lasers emitting in the range 0.35−0.92 μm find applications in holographic storage, image recorders, fax machines, printers, solid state and fiber laser pumping, barcode readers, blu-ray disks and other disk read–write devices, material processing, medical therapeutics, range finders and aerospace. 0.9−1.10 μm semiconductor lasers are used as optical fiber amplifier pumps, in material processing and medicine. Approximately, 1.1−1.65 μm lasers find their use in optical fiber communication sys-

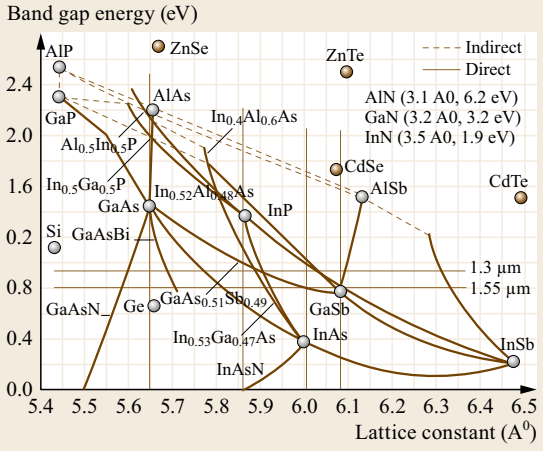

Fig. 35.28 Band gap energies and lattice constants of common semiconductor alloys used for making semiconductor lasers (After [35.88]). Open symbols refer to indirect-band gap materials while closed circles are direct-band-gap materials. AlN, GaN, and InN indicated separately. Alloys are indicated by the connecting curves (*solid* are direct-band-gaps and *dashed* are indirect-band gaps)

Table 35.1 List of some example active and cladding layer compositions used in modern semiconductor lasers. The substrate material and approximate emisson wavelength range is also indicated. (After [35.40, 42])

Cladding layer/Active layer	Substrate	Emission wavelength range (μm)
$GaN/In_xGa_{1-x}N$	Sapphire, GaN, SiC	≈ 0.35–0.50
$Al_xGa_{1-x}N/In_xGa_{1-x}N$	Sapphire, GaN, SiC	≈ 0.40–0.60
$Cd_xZn_{1-x}S/CdS$	CdS	≈ 0.35–0.50
$(Al_xGa_{1-x})_{0.5}In_{0.5}P/Ga_yIn_{1-y}P$	GaAs	≈ 0.60–0.72
$Al_xGa_{1-x}As/GaAs$	GaAs	≈ 0.60–0.92
$Al_xGa_{1-x}As/In_yGa_{1-y}As$	GaAs	≈ 0.90–1.10
$InP/Ga_xIn_{1-x}As_yP_{1-y}$	InP	≈ 1.1–1.65
$Al_xGa_{1-x}As/In_yGa_{1-y}As_{1-x}N_x$	GaAs	≈ 1.24–1.30
$Al_xGa_{1-x}Sb_{1-y}As_y/In_xGa_{1-x}Sb_{1-y}As_y$	GaSb or InAs	≈ 1.7–4.0

tems, transceivers, and Raman amplifiers. Lasers of the range 1.24–1.30 μm are also used in aerospace and military range finders, and 1.7–4.4 μm lasers are used in spectroscopic sensing of humidity, gas impurities, drugs and optical fiber, and free-space communications [35.56].

35.4 Optical Amplifiers

35.4.1 An Introduction to Optical Amplification

As a light pulse propagates through an optical communication system, the pulse becomes attenuated until eventually it is necessary to regenerate the pulse to keep the signal above the background noise level. This was initially achieved by detecting the pulse using a photodetector, and then using the detected electronic pulse to trigger a laser giving a fresh output pulse. An alternative technique is to use direct optical amplification. This has been achieved for instance by doping optical fibers with rare-earth elements, such as erbium, forming an EDFA. Population inversion is achieved by exciting the erbium atoms at 980 nm or 1.48 μm, where the excited carriers decay to a level from which they can recombine to give stimulated emission at 1.55 μm, amplifying weak signals in the fiber. Amplification can also be achieved within conventional silica fibers using the Raman effect; by pumping the fiber with a high-power pump laser (total power ≈ 1 W) at a fixed frequency above the signal frequency, Raman scattering gives rise to gain at a lower frequency (the difference is the phonon energy). Thus, by pumping an optical fiber at 1.45 μm, one may achieve gain at 1.55 μm. The main advantage of Raman amplification compared with EDFAs is the fact that the gain curve may be dynamically tuned by judiciously using different wavelength pump lasers. The disadvantages of Raman amplification that the overall gain is generally lower than an EDFA and its cross-amplification can be a problem. For some applications, semiconductor optical amplifiers (SOAs) may be preferred.

35.4.2 Semiconductor Optical Amplifiers (SOAs)

The structure of an SOA is very similar to that of a laser, but with one significant difference: the reflectivity of the end facets, $R \approx 0$. This is achieved through the use of multilayer antireflection coatings together with angled facets or cavities. This suppresses lasing within the cavity and eliminates reflected signals in the optical system. The signal emerging from an optical fiber is, in general, randomly polarized and therefore it is very desirable that any optical amplifier provides the gain that is independent of the direction of polarization of the light. In a bulk heterostructure device, the TE and TM material gain are equal. However, the optical confinement factor Γ for TE light polarized in the plane of the heterostructure is slightly larger than that for TM light polarized perpendicular to the heterostructure plane, leading to a larger overall TE gain. As discussed earlier in this chapter, in a normal QW system, the quantum confinement brings the heavy-hole band to the top of the VB and light polarized in the TE mode is amplified considerably more strongly than light polarized in the TM mode. This problem can be overcome using strained-layer techniques. It is possible to grow the wells or the barriers with a small amount of tensile strain. This raises the light-hole band and the strain can be adjusted to increase the device TM gain until it is just equal to that of the TE gain. Work to date indicates that the relative gains in the two modes are sensitive to the magnitude of the amplifier current and so the gains are equal over a limited range.

Strained SOAs

Another more promising approach is to introduce both compressive- and tensile-strained wells alternately into the active region. The compressive wells provide gain predominantly to the TE mode and the tensile wells predominantly to the TM mode. The structure can then be designed to make the two gain modes equal. The initial work by *Tiemeijer* et al. from Philips concentrated on 1.3 μm devices [35.101]. They found that a combination of four compressive wells and three tensile wells each with 1% strain gave the TE and TM gains within 1 dB of each other over a wide wavelength band and over an order of magnitude change in the amplifier current. This structure is an excellent example of the flexibility in device design that is afforded by the introduction of strained-layer techniques. Other applications of such a structure include two-polarization or two-frequency lasers, polarization control elements, and nonabsorbing strain-overcompensated mirrors in high-power lasers.

35.5 Modulators

35.5.1 Modulator Theory

Although it is possible to modulate the output from a semiconductor laser by directly modulating the injected current, in some applications requiring high-speed or low-power switching, it is advantageous to run the laser source CW and modulate the light subsequently [35.102]. This is basically because, unlike lasers, semiconductor modulators are diodes operated in the reverse bias. They therefore draw little current and, because there is no carrier injection, there is much less chirp.

Electroabsorption modulators make use of the fact that the presence of a large electric field adds a perturbation to the Schrödinger equation, which leads to a decrease in the band-gap energy E_g. Thus, photons with energies just below the band gap become more strongly absorbed when a field is applied, leading to a decrease in light intensity. Electroabsorption modulators can benefit enormously from the use of multiple QWs, where the electroabsorption effect is more than one order of magnitude greater than that in comparable bulk structures.

In QWs the modulation of the energy levels by an electric field applied perpendicular to the plane of the wells is called the quantum-confined Stark effect (QCSE). For a given applied voltage, it causes more change, $\Delta\alpha$, to the absorption coefficient α close to the band edge than in equivalent bulk structures for three main reasons. Due to the quantum confinement, there is a step-like increase in the density of states at the band edges, as described above, and so a faster rate of increase in absorption coefficient with energy. Thus, $\Delta\alpha/\Delta E_g$, the change in absorption coefficient with the band gap, is larger. Secondly, the steep rise in the absorption coefficient with energy at the band edge is further enhanced in QW structures due to excitonic effects. An exciton consists of an electron–hole pair bound together by electrostatic attraction and has associated with it a sharp line absorption spectrum which is superimposed on the QW absorption. Figure 35.29 shows the measured photocurrent spectra at low temperature as a function of the applied reversed bias for two long-wavelength modulator structures. The exciton peak is clearly visible at the absorption edge, particularly for low bias values. Excitons also exist in bulk material at low temperatures but not at room temperature. In QWs, however, the electrons and holes are confined into the same region of space by the well and so the electrostatic binding energy is sufficiently large that they are still able to exist at room temperature. Finally, the actual energy of the band edge is largely determined by the effect of quantum confinement, which depends not only on the width of the QW but also on its shape. Since the shape of the well can be strongly modified by an applied electric field, so can the electronic energies at the band edges, as can be seen from the shift in absorption edge with the applied bias, as shown in Fig. 35.29. Thus, ΔE_g is enhanced by quantum confinement.

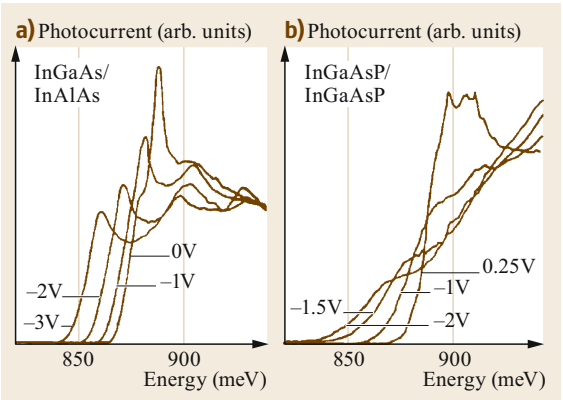

Fig. 35.29a,b Measured photocurrent spectra at 2 K of an InGaAs/InGaAlAs **(a)** and an InGaAsP/InGaAsP **(b)** electroabsorption modulator at several bias voltages. (After [35.58])

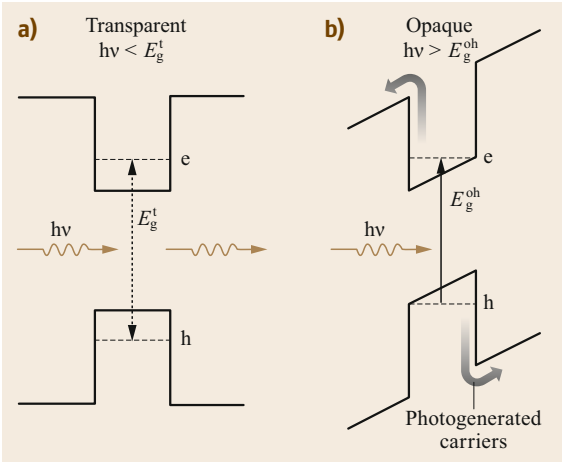

Fig. 35.30a,b The band alignment of a QW in **(a)** flat band (*zero field*) where the optical gap equals $E_g^t > h\nu$ (*transparent*) and **(b)** for a large field across the QW, where the optical gap equals $E_g^0 < h\nu$ (*opaque*)

The effect of an electric field applied perpendicular to the plane of a QW is to change the shape of the well from the rectangular well, as shown in Fig. 35.30a, to the triangular shape, as shown in Fig. 35.30b. Solutions to the Schrödinger equation show that the lowest confined states are closer together in the triangular situation than the rectangular one and so the effective absorption edge is moved to lower energies. Because the electron ground state is shifted toward one side of the QW, and the hole ground state toward the opposite side, the overlap of the electron and hole wavefunctions is decreased by the application of an electric field. The result is to decrease the absolute value of the absorption coefficient and to decrease the exciton absorption peak, as shown in Fig. 35.29. However, if one considers an energy just below the band-edge exciton energy at the zero field, at about 850 meV in Fig. 35.29, the absorption coefficient at that energy can be greatly increased by the application of an electric field.

For a modulator, a very important parameter is the ratio of the light intensity transmitted in the *on* state to that transmitted in the *off* state when the field is applied. This is given simply by

$$P = \exp(\Delta\alpha L)\,, \tag{35.41}$$

where L is the distance the light travels through the absorbing medium. In QW structures, although $\Delta\alpha$ is relatively large, if the light travels in a direction perpendicular to the plane of the wells, the length L is small; of the order of tens of nm. One way to overcome this problem is to use the QCSE modulator in the waveguide configuration; that is, to pass the light parallel to the plane of the QWs in a waveguide structure similar to that for a laser as described previously. In this case, the effective absorption per unit length will be decreased by the optical confinement factor (Γ) to $\Gamma\alpha$, but L can easily be increased much more; to tens or even hundreds of μm. Such a waveguide configuration can achieve a large on–off ratio, but it has two potential problems. First, it can have a large insertion loss because it is difficult to launch the light into the waveguide unless it is integrated with the laser source and also there can be light scattering and absorption along the length of the guide even in the on state. Second, the modulator will be dependent on the polarization of the light beam traveling along the waveguide, as described below.

35.5.2 Polarization-Insensitive Modulators

As was explained when considering strained-layer electronic properties, the degeneracy of the heavy- and light-hole bands, which exists in bulk material, is split by confinement effects in a QW. This is because the quantum confinement energy is proportional to l/m^* and so the first light-hole VB lh_1 lies below the first heavy-hole VB hh_1. As a consequence, the wavefunctions that make up the edge of the VB are derived from the heavy-hole band and so only interact with TE-polarized photons as described above. Thus, while photons of energy close to the band edge and polarized in the TE mode are modulated as the band edges move together with the applied electric field, photons of the same energy, but polarized in the TM mode, are relatively unaffected. This is in general unacceptable if the photons are arriving from a system, such as an optical fiber, which may deliver photons of any polarization in a manner which is sensitive to extraneous influences.

The problem of polarization sensitivity in modulators, as with the polarization-insensitive amplifier, may be dealt with by engineering the band structure with a judicious use of in-built strain within the QWs. As described above, the light-hole band may be raised in energy with respect to the heavy-hole band by the introduction of tensile strain. Thus, with tensile strain, it is possible to shift the heavy- and light-hole bands until the confined states are once again degenerate, as shown in Fig. 35.31a. Such a system, although it may be polarization insensitive at zero net field, can again become polarization sensitive as a net field is applied, as is shown by the movement of the band edges in Fig. 35.32a. This effect arises since the heavy-hole confined level, being closer to its band edge, is more sensitive to the distortion of that band edge by the applied field. Once again, however, it is predicted that this effect can be compensated by further band-structure

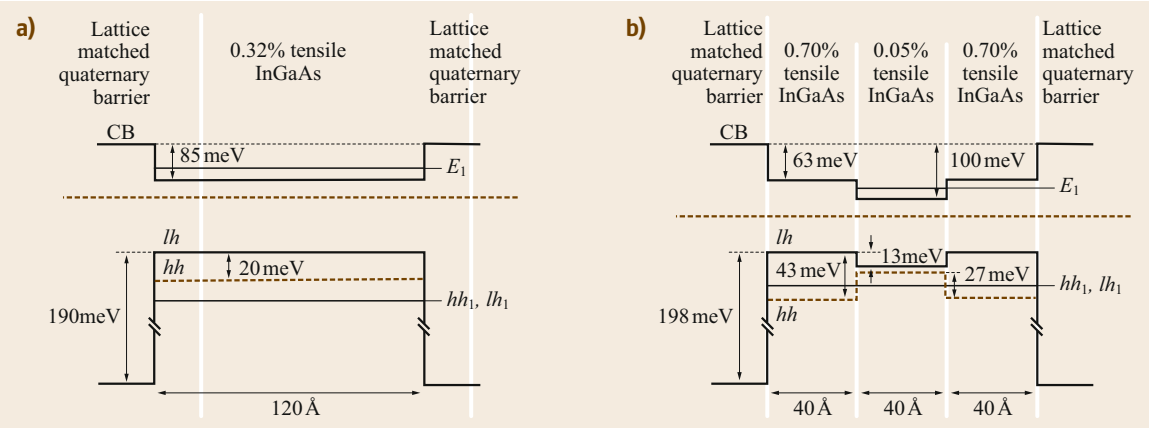

Fig. 35.31a,b Calculated CB and VB profiles for **(a)** conventional tensile QW and **(b)** multi-strain-stepped QW. (After [35.41])

refinements brought about by employing three zones of different strain within the same well. This is illustrated in Fig. 35.25b. In this multistrain well, the tensile strain is larger in the outer thirds of the well. Thus, when a field is applied and the hole wavefunctions are moved toward the edge of the well, the heavy-hole level sees a smaller effective well width and its change in energy can be made the same as for the light hole. Figure 35.32b shows that excellent matching of the movements of the heavy- and light-hole bands can be achieved with the three-zone well over the full range of practical electric fields, up to 100 kV/cm.

35.5.3 High-Speed High-Power QCSE Modulators

Strained-layer QCSE modulators have been successfully integrated with strained-layer lasers to produce high-speed low-chirp sources operating at 1.55 μm for optical communications. The laser and the modulator consist of the same wave-guide structure but are used in the forward and reverse bias, respectively. In this case, there are no polarization problems because if, for example, compressively strained wells are used the laser will produce the TE-polarized output, which is efficiently modulated by the modulator. One problem that is encountered, however, is that while the modulator is in the absorbing state, a significant density of photogenerated carriers may accumulate in the QWs. This has two effects. Firstly, the carriers tend to fill the band-edge states, thus reducing the field in the well, and in addition bleaching the absorption process. Secondly, they may take a long time to escape, so that efficiency of switching to the nonabsorbing state is dependent on how long the modulator was absorbing and what carrier density had accumulated. In practice, it is found that the escape rate of photogenerated holes

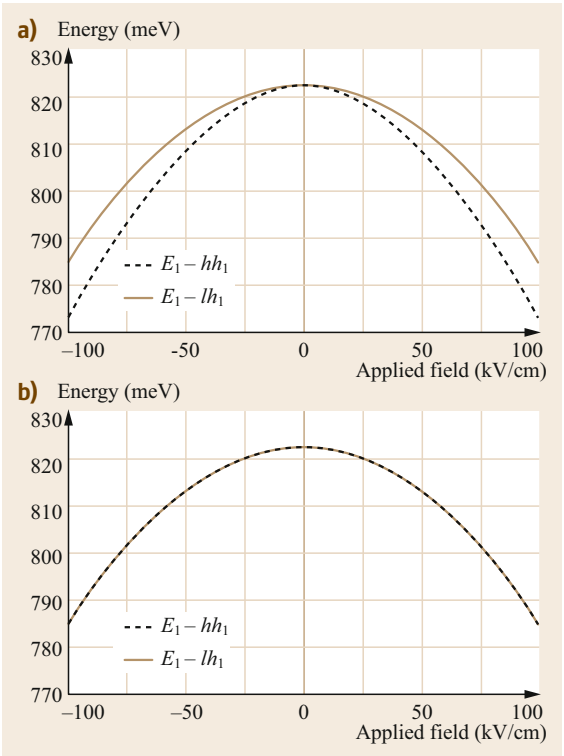

Fig. 35.32a,b Calculated quantum confined Stark shifts of the E_1–hh_1 (*dashed lines*) and E_1–lh_1 (*solid lines*) transitions for structures **(a)** and **(b)** in Fig. 35.25. (After [35.41])

from the QWs is slower than that for electrons and is the limiting process. This problem may be addressed by changing from the standard InGaAsP material system to InGaAlAs, which has a much smaller VB offset than in the equivalent InGaAsP layers [35.101]. Alternatively, the problem may be reduced by band-structure engineering in InGaAsP using strain.

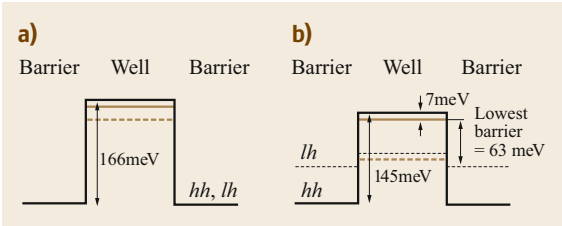

Fig. 35.33a,b Calculated VB edge energies and band alignments for **(a)** lattice-matched modulator and **(b)** strained modulator, as in Fig. 35.28. The *thick horizontal lines* indicate the highest hh confined state

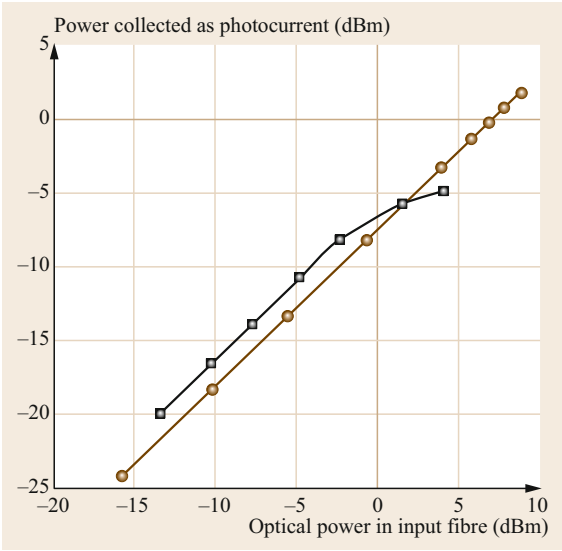

Fig. 35.34 Total power absorbed in lattice-matched (*open squares*) and strained (*closed squares*) electroabsorption modulator as a function of power in the input fiber. (After [35.43])

Figure 35.33a shows the VB structure of a lattice-matched InGaAsP-based electroabsorption modulator designed to operate around 1.5 μm. The heavy-hole well was calculated to be 166 meV deep, and the structure showed power saturation, as illustrated by the open squares in Fig. 35.34. However, when a 1% compressive strain was introduced into the well and 1% tensile strain into the barriers between the wells, the calculated excitation energy from the heavy-hole states in the well to light-hole states in the barrier was reduced to 63 meV, as illustrated in Fig. 35.33b. Since the strain in the barrier has little effect on the well depth for heavy holes, the heavy-hole wavefunctions and quantum confined Stark effect should be comparable in both structures, but now thermal excitation out of the well by phonon scattering to the light-hole level in the barrier is greatly enhanced. The improvement in the power-saturation characteristics of the strained modulator is shown by the solid squares in Fig. 35.34; a considerable improvement in the 10 GHz switching performance was also observed.

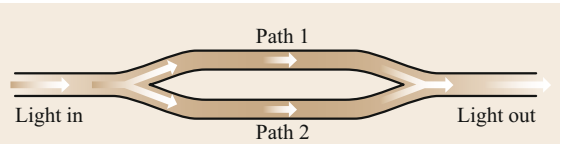

Fig. 35.35 Schematic of a Mach–Zender interferometer

35.5.4 The Electro-Optic Effect

The real part of the refractive index can be described in terms of virtual transitions between the VB and CB and is therefore related to the imaginary part of the refractive index. Hence, when an electric field applied to a semiconductor leads to a change in the absorption characteristics as described above, there is also an accompanying change in the real part of the refractive index. This results in a phase change of the light reaching the end of the active region of the modulator. While this causes unwanted chirp in the electroabsorption modulators described above, it can be used to advantage in modulators and switches that employ interference effects. A good example of such a device is the modulator based on a Mach–Zender interferometer. In this structure, the incoming wave is divided into two equal components at a Y-junction and then recombined at a similar junction, as shown in Fig. 35.35. If the two arms of the interferometer are exactly equivalent then the two beams will arrive in-phase and constructively recombine at the output. However, if the refractive index for light traveling down one path is increased by the electro-optic effect so that its phase at the output is changed by π, then the two beams will destructively interfere at the output and no light will be transmitted. Band-structure considerations for the electro-optic effect are ones with which we are already familiar. The linewidth enhancement factor α_1 is defined by

$$\alpha_1 = -\frac{4\pi}{\lambda}\left(\frac{\frac{dN}{dg}}{\frac{dg}{dn}}\right), \qquad (35.42)$$

and provides a measure of the ratio of the change in the real part N of the refractive index to the change in the imaginary part g of the refractive index, each as a function of carrier density n. Thus, for modulators based on the electro-optic effect, we would wish to have a band structure that results in a large α_1, while for electroabsorption modulators, we require α_1 to be as small as possible.

35.6 Photodetectors

In the first part of this chapter, we dealt with optoelectronic devices designed to produce light for use in applications including displays, indicators, data storage, and communications. The latter two of these applications also require the ability to detect the light once it has been created. Much of the explosion of interest in semiconductor optoelectronic devices over the past 20 or so years has been particularly aimed at the communications market. This has put high demands on the ability to detect small optical signals being transmitted at very fast data rates ($> 40\,\mathrm{Gbit/s}$). In this section, we consider the important aspects for detectors and describe some of the approaches that have been used.

35.6.1 Photodetector Requirements

There are many attributes important to the design of photodetectors. These can broadly be split into the following categories:

- Sensitivity
- Speed
- Noise
- Physical size (footprint)
- Reliability
- Temperature sensitivity
- Ease of use
- Finally cost.

When deciding on a particular photodetector, one must decide which of these factors is of most importance to the particular application of interest.

35.6.2 Photodetection Theory

The primary requirement of the band structure of semiconductor optical detectors is that the band gap of the active region is less than the photon energy to be absorbed. The electron–hole pair formed when the photon is absorbed is then separated by an applied or built-in field that exists in the active region. If, under the influence of the field, the electron and hole move apart by a distance, x, then the charge induced to flow in the external circuit connected to the detector is x/l. In a simple photoconductive detector consisting of a bulk semiconductor with conducting electrodes, l is the distance between the electrodes. In a p–n or p–i–n diode detector, l is the width of the depletion region.

Several factors need to be taken into account when considering the band structure of a detector. Firstly, the absorption depth of the light to be detected must be matched to the width of the active region, so that there is a high probability that the photogenerated carriers will be produced within the active region or less than the minority-carrier diffusion length from it. Figure 35.36 shows the absorption coefficient as a function of energy for direct-gap GaAs and for indirect-gap Si. An absorption coefficient of $10^3\,\mathrm{cm}^{-1}$, typical for Si, corresponds to an absorption depth of $10\,\mu\mathrm{m}$, while $10^4\,\mathrm{cm}^{-1}$ for GaAs corresponds to a $10\,\mu\mathrm{m}$ absorption depth. One must also consider the effect of the band structure on the dark current in the device, since this sets the lower limit on the strength of the signal that can be detected. There are three important effects that can give rise to the generation of electron–hole pairs even when no light is falling on the device. These are:

(a) Thermal generation
(b) Band-to-band tunneling
(c) Avalanche breakdown.

Processes (a) and (b) are illustrated in Fig. 35.37. Thermal generation, which occurs even at the zero elec-

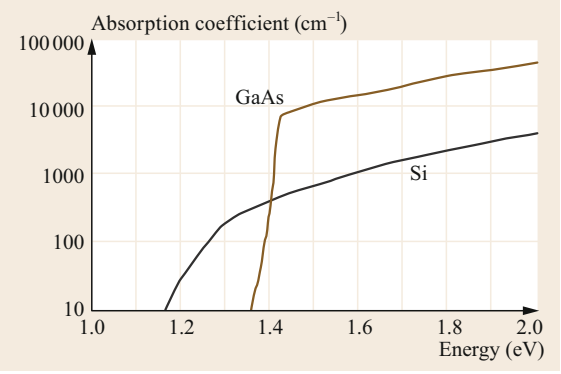

Fig. 35.36 Absorption coefficient as a function of energy for direct-gap GaAs and indirect-gap Si

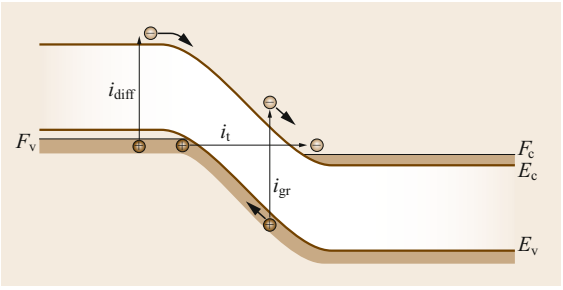

Fig. 35.37 Mechanisms contributing to the dark current in a reverse-biased p–i–n diode. Thermal generation has contributions from diffusion of minority carriers into the field region i_{diff} and from thermal generation within the field region i_{gr}. Zener (band-to-band) tunneling is indicated by the horizontal arrow i_t

tric field, can itself be conveniently divided into two parts. First, there is the part i_{diff} due to the diffusion of minority carriers into the field region. Second, there is the current i_{gr} due to thermal generation within the field region. The thermal generation current increases strongly with temperature but is relatively independent of the applied field, although i_{gr} increases slightly with a reverse bias since this causes the depletion width to increase. Process (b), band-to-band tunneling, is indicated by the horizontal arrow i_t in Fig. 35.37. At large reverse fields, electrons at the top of the VB see a triangular-shaped potential barrier through which it is possible for them to tunnel into the CB. This quantum-mechanical tunneling is relatively independent of temperature but is strongly dependent on the applied field. Process (c), avalanche breakdown, which occurs at very large electric fields, has to be avoided except in avalanche photodetectors (APDs), which will be described in some detail below. Avalanche breakdown involves carriers with initial kinetic energies greater than the band-gap energy E_g away from the CB minimum. This means that electrons in wide-band gap III–V semiconductors will be at energies such that they are scattering between the central Γ minimum, the three X minima at the edges of the Brillouin zone in the ⟨100⟩ directions, and the four L minima at the edges of the Brillouin zone in the ⟨111⟩ directions. Hydrostatic pressure measurements [35.103] showed that the effective ionization energy ⟨E⟩ could be related to the average CB energy simply by

$$\langle E\rangle = \frac{1}{8}(E_\Gamma + 3E_X + 4E_L)\,, \qquad (35.43)$$

where E_Γ, E_X, and E_L are the energies of the Γ, X, and L minima above the top of the VB, respectively.

The first two effects giving rise to a dark current, described in (a) and (b) above, increase almost exponentially with decreasing band gap E_g. Therefore, there exists an optimum value for the band gap E_g to be used to detect photons of a particular energy E_{ph}. Considering E_g to be the adjustable parameter, which can be determined by the alloy composition, as E_g is reduced below E_{ph}, the absorption coefficient increases and light becomes more efficiently absorbed within the active region, of the diode. However, once all the photons are absorbed, reducing E_g further adds nothing to the photocurrent but does continue to increase the dark current. Therefore, it is clear that the optimum band gap is just below that of the photon energy to be detected. The exact difference E_{ph}–E_g depends upon the shape of the absorption edge of the material, the thickness of the active region and its position within the device.

35.6.3 Detectors with Internal Gain

In a photoconductive detector, a gain can actually be achieved by adding impurities that trap one type of carrier, forming a center with a low-capture cross-section for the other type of carrier. Assuming the trapped carrier is a hole, as the free electron reaches the anode, another will be injected from the cathode, and this process will continue until an electron recombines with the trapped hole. Under these circumstances, x exceeds l and a gain of x/l is achieved: $x/l = \tau_r/t_t$, where t_t is the transit time of the electron between the electrodes and τ_r is the electron–hole recombination lifetime. The response time of such a system is $\tau_r = t_t x/l$ so that, as the gain increases, the speed of the device decreases. A related effect is obtained in a phototransistor. If, for example, we consider a photon being absorbed in the base or collector region of an n–p–n transistor, then the presence of the hole, which will be effectively trapped in the base region, will cause the transit of electrons between the emitter and the collector for the recombination lifetime of the hole. The gain of the system is then equal to the gain of the transistor, which is related to τ_r/t_t, where t_t is now the transit time of the electron from the emitter to collector.

35.6.4 Avalanche Photodetectors

Interestingly, silicon as well as direct-band gap materials can be used to produce efficient detectors, but for different reasons. In the direct-band gap materials, photons with energies greater than the band gap are strongly absorbed by the creation of electron–hole pairs, leading to the generation in the detector of a primary photocurrent or photovoltage. In silicon, photons with energies just above the band gap are relatively weakly absorbed, but the electrons generated can be greatly amplified by the process of avalanche multiplication. This occurs when a large reverse voltage is applied to the p–n or p–i–n junction of the detecting diode. Electrons drifting in the field can gain kinetic energy in excess of the band-gap energy E_g. It is then possible for the hot carrier to give up its energy and momentum in an impact ionization process, resulting in the generation of an electron–hole pair. The generated carriers can, in turn, drift in the electric field and themselves generate further carriers. The band structure of silicon is particularly well suited for avalanche multiplication since impact ionization can occur for hot electrons with conservation of energy and momentum when the electron's kinetic energy is almost exactly equal to E_g [35.104]. By contrast, a hot hole in silicon requires an energy close to $3E_g/2$ before it can generate an electron–hole pair. Thus, in silicon, a large avalanche multiplication can be

achieved with each electron that is optically generated and swept across the avalanche region. This situation is illustrated in Fig. 35.38a. Very large gains can be obtained, but all of the carriers are swept out of the active region in a time equal or less than $t_e + t_h$, where t_e and t_h are the transit times taken by electrons and holes, respectively, to cross the active region.

In contrast, it is found that, in the majority of direct-band gap materials, holes and electrons are able to produce impact ionization at the same electric field. As a result, above this field, avalanching occurs for both types of carrier as they move in opposite directions and the carrier density escalates uncontrollably, leading to complete avalanche breakdown. This situation is illustrated in Fig. 35.38b. Gain, but also breakdown, occurs when the field is large enough to create an impact ionization process just as the electron is about to leave the active region. If exactly the same happens for the hole, the situation can continue ad infinitum, leading to an infinite gain, but a current pulse that does not switch off. Of course, in fact, impact ionization is a statistical process and the current pulse might stop after one electron transit or run away as described, leading to an unstable noisy detection system.

Silicon is therefore clearly a very useful material for the production of APDs. Unfortunately, however, the detection bandwidth of silicon limits it from the visible spectrum up to $\approx 1\,\mu m$ in the near-infrared IR. It is of significant technological importance to have fast high-gain low-noise detectors above this wavelength, in particular in the range $1.3-1.6\,\mu m$ for optical communications. The mid-infrared is also of importance due to the large number of gas absorption bands in this range. Due to the effects discussed above, the performance of APDs in the near-mid-infrared region is poor when compared with silicon APDs. Recently, *Adams* proposed that APDs based upon InGaAsN may give rise to improved characteristics for detection in the near- and mid-IR [35.105]. As discussed earlier in this chapter, InGaAsN is already showing great promise for long-wavelength lasers due to the unusually large band-gap bowing brought about by small concentrations of nitrogen in GaAs. This clearly makes it a potential candidate

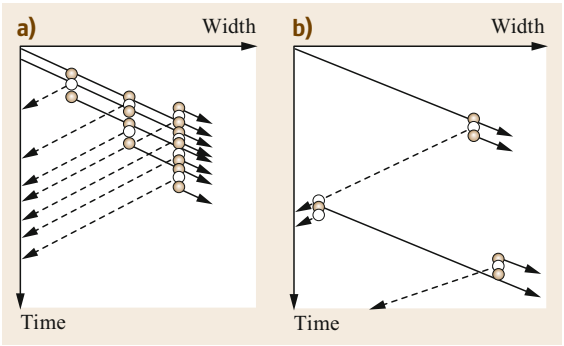

Fig. 35.38a,b Avalanche multiplication as a function of position and time where **(a)** the electron multiplication rate (*solid line*) is much greater than that for holes (*dashed line*). **(b)** When the electron and hole multiplication rates are equal, the current pulse continues for a long time

for the manufacture of long-wavelength detectors. However, in addition to the large band-gap bowing, InGaAsN has an unusually large CB effective mass derived from the dilute amount of nitrogen in the lattice. This has several effects of benefit to APDs. Firstly, the high effective mass inhibits electrons from gaining kinetic energy under an applied field. Secondly, the increased mass, and hence increased density of states, will increase the probability of electron scattering. As the electrons heat up and their energy approaches that of the N levels, they will be strongly scattered. Furthermore, if any electrons manage to reach the top of the E^- band, they have to be scattered across, or tunnel through, the energy gap to the next conduction (E^+) band before they can gain more energy. All of these effects prevent electrons from avalanching. However, since the VB is largely unaffected by the presence of nitrogen, the *holes* may be accelerated by the field and avalanche. It has been proposed that such devices will have a multiplication of $\approx 10^4$ compared with < 10 in the best currently available APDs at these wavelengths. Furthermore, it is also predicted that the noise factor of these devices could be reduced by two orders of magnitude. Although yet to be demonstrated in practice, InGaAsN may in the future provide both *high-Q detectors* and emitters in the infrared.

35.7 Conclusions

This chapter introduced some of the most important optoelectronic devices in use today. It has discussed how these devices were developed based upon highly innovative work which has transformed semiconductor growth technology over the past 40 years. The requirements for lasing action in semiconductors were discussed as well as the ways in which low-dimensional structures and strain may be used to improve the properties of devices such as lasers (both edge-emitting and surface-emitting), modulators, amplifiers, and detectors. The chapter considered current state-of-the-art semiconductor laser devices and discussed emerging future directions in semiconductor optoelectronic materials and devices.

Acknowledgments. It is a pleasure to acknowledge the many people with whom the authors have worked with over the years. In particular, we would like to thank the staff and students, past and present, at the University of Surrey, and at our UK and international academic and commercial partners.
