36. Liquid Crystals

Geoffrey Luckhurst, David Dunmur

This chapter outlines the basic physics, chemical nature and properties of liquid crystals. These materials are important in the electronics industry as the electro-optic component of flat-panel liquid-crystal displays, which increasingly dominate the information display market.

Liquid crystals are intermediate states of matter which flow like liquids, but have anisotropic properties like solid crystals. The formation of a liquid-crystal phase and its properties are determined by the shape of the constituent molecules and the interactions between them. While many types of liquid-crystal phase have been identified, this Chapter focuses on those liquid crystals which are important for modern displays.

The electro-optical response of a liquid crystal display (LCD) depends on the alignment of a liquid-crystal film, its material properties and the cell configuration. Fundamentals of the physics of liquid crystals are explained and a number of different displays are described.

In the context of materials, the relationship between the physical properties of liquid crystals and their chemical composition is of vital importance. Materials for displays are mixtures of many liquid-crystal compounds carefully tailored to optimise the operational behaviour of the display. Our current understanding of how chemical structure determines the physical properties is outlined, and data for typical liquid-crystal compounds are tabulated. Some key references are given, but reference is also made to more extensive reviews where additional data are available.

36.1 Introduction to Liquid Crystals

Liquid crystals have been known for almost 130 years but it is only in the last 40 years or so that their unique application in display devices has been recognised. Now they are seen as extremely important materials having made possible the development of thin screens for use with personal computers (PCs) and in televisions. In fact a wide range of different liquid-crystal (LC) display devices has been developed. The common feature for each of these is that the optical characteristics of the display are changed on application of an electric field across a thin liquid-crystal film. The process causing this change is associated with a variation

in the macroscopic organisation of the liquid crystal within the cell. The liquid crystal is, therefore, strictly behaving as a molecular material and not an electronic one. Nonetheless the display itself is closely integrated with electronic components. Since liquid crystals may be unfamiliar to those concerned with conventional electronic materials, this section begins with an introduction to liquid crystals and the compounds that form them. The following section describes the basic physics for liquid crystals which are needed to understand their use in display devices. The functioning of the most important displays is described in Sect. 36.3, which makes contact with the basic physics outlined in Sect. 36.2. The liquid-crystal materials used in display devices are discussed in the final section, where the necessary optimisation of a wide range of properties is addressed.

The majority of chemical compounds can exist in three states of matter, namely crystal, liquid or gas, each with its defining characteristics. There is a fourth state known as a liquid crystal and, as the name suggests, this state has characteristics of both crystals and liquids. Thus a liquid crystal flows when subject to a stress, like a liquid, but certain of its properties are anisotropic, like a crystal. This macroscopic behaviour, often used to identify the phase, implies that at the microscopic or molecular level the material has an element of long-range orientational order together with some translational disorder at long range. It is this combination of order and disorder that makes liquid crystals so fascinating and gives them their potential for applications, especially in the field of electro-optic displays.

A variety of different classes of materials are known to form liquid crystals at some point on their phase diagram [36.1]. These include organic materials where the liquid crystal is formed, on heating, between the crystal and isotropic liquid phases. Such materials are known as thermotropic liquid crystals and are the subject of this Chapter. Another class is formed by amphiphilic organic materials in which part of the constituent molecules favours one solvent, normally water, while the other part does not. When the amphiphile is

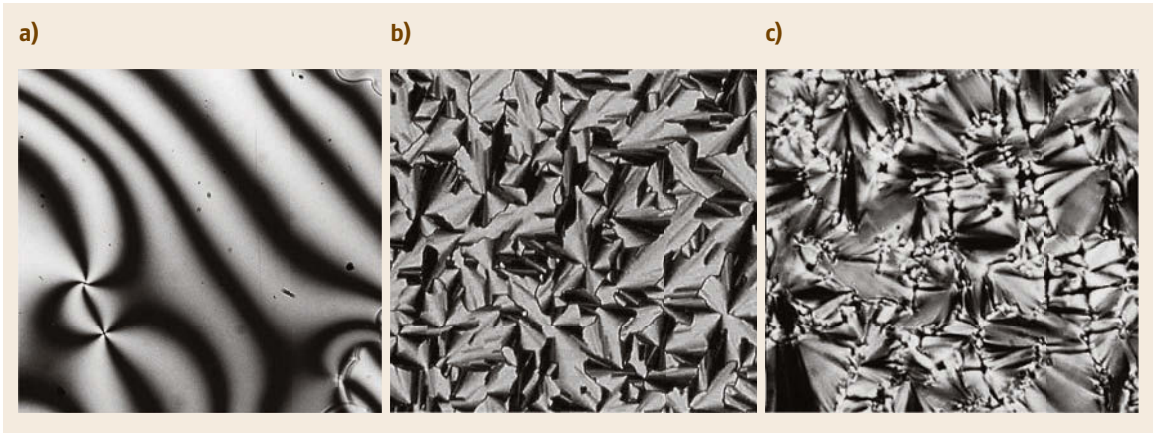

Fig. 36.3a–c Typical optical textures observed with a polarising microscope for **(a)** nematic, **(b)** smectic A and **(c)** columnar liquid-crystal phases

dissolved in the water, the molecules form aggregates which then interact to give the liquid-crystal phase, the formation of which is largely controlled by the concentration of amphiphile. These are known as lyotropic liquid crystals; they underpin much of the surfactant industry, although they are not used in displays and so will not be considered further. Colloidal dispersions of inorganic materials such as clays can also form liquid-crystal phases depending on the concentration of the colloidal particles. Solutions of certain organic polymers also exhibit liquid-crystal phases and, like the colloidal systems, the solvent acts to increase the separation between polymer chains but does not significantly affect their state of aggregation. A prime example of such a system is the structural polymer Kevlar, which for the same weight is stronger than steel; it is formed by processing a nematic solution of the polymer.

The following sections return to thermotropic liquid crystals and describe the molecular organisation within the phases, mention some of their properties and briefly indicate the relationship between the phase and molecular structures.

36.1.1 Calamitic Liquid Crystals

In view of the anisotropic properties of liquid crystals, it seems reasonable that a key requirement for their formation is that the molecules are also anisotropic. This is certainly the case, with the majority of liquid crystals having rod-like molecules, such as those shown in Fig. 36.1. One of the simplest nematogenic rod-like molecules is *p*-quinquephenyl (Fig. 36.1a), which is essentially rigid. However, flexible alkyl chains can also be attached at one or both ends of the molecule (Fig. 36.1b,c) or indeed in the centre of the molecule (Fig. 36.1d), and rigid polar groups such as a cyano (Fig. 36.1d–f) may be attached at the end of the molecule. The rigid part is usually constructed from planar phenyl rings (Fig. 36.1a–e) but they can be replaced by alicyclic rings (Fig. 36.1f) which enhance the liquid crystallinity of the compound. The term calamitic, meaning rod-like, is applied to the phases that they form. There are, in fact, many different calamitic liquid-crystal phases but we shall only describe those which are of particular relevance to display applications.

At an organisational level the simplest liquid crystal is called the nematic and in this phase the rod-like molecules are orientationally ordered, but there is no long-range translational order. A picture showing this molecular organisation, obtained from a computer simulation of a Gay–Berne mesogen [36.2] is given in Fig. 36.2b. The molecular shape is ellipsoidal and the symmetry axes of the ellipsoids tend to be parallel to each other and to a particular direction known as the director.

In contrast there is no ordering of the molecular centres of mass, except at short range. The essential difference between the nematic and isotropic phases (Fig. 36.2a) is the orientational order, which is only short range in the isotropic liquid. At a macroscopic level the nematic phase is characterised by its high fluidity and by anisotropy in properties such as the refractive index. The anisotropic properties for a nematic have cylindrical symmetry about the director, which provides an operational definition of this unique axis and is the optic axis for the phase. The anisotropy in the refractive index combined with the random director distribution results in the turbidity of the phase, which contrasts with the transparency of the isotropic liquid. This on its own would not be sufficient to identify the liquid crys-

tal as a nematic phase but identification is possible from the optical texture observed under a polarising microscope. These textures act as fingerprints for the different liquid-crystal phases. An example of such a texture for a nematic phase is shown in Fig. 36.3a; it is created by the anisotropy or birefringence in the refractive index combined with a characteristic distribution of the director in the sample.

The next level of order within liquid crystal phases is found for the smectic A phase. Now, in addition to the long-range orientational order, there is translational order in one dimension, giving the layered structure shown in Fig. 36.2c [36.2]. The director associated with the orientational order is normal to the layers. Within a layer there is only short-range translational order as in a conventional liquid. In this structure the layer spacing is seen to be comparable but slightly less than the molecular length, as found experimentally for many smectic phases.

At a macroscopic level the layer structure means that the fluidity of a smectic A phase is considerably less than for a nematic phase. The properties are anisotropic and the birefringence is responsible for the turbidity of the phase, as found for a nematic. However, under a polarising microscope the optical texture is quite different to that of a nematic, as is apparent from the focal conic fan texture shown in Fig. 36.3b.

A variant on the smectic A is the smectic C phase. The essential difference to the smectic A phase is that the director in the smectic C phase is tilted with respect to the layer normal. The defining characteristic of the smectic C phase is then the tilt angle, which is taken as the angle between the director and the layer normal. This tilt in the structure reduces the symmetry of the phase to the point group C_{2h} in contrast to $D_{\infty h}$ for nematic and smectic A phases. This lowering in symmetry naturally influences the symmetry of the properties. The fluidity of the smectic C phase is comparable to that of a smectic A phase. However, the optical texture can be quite different and it has elements similar to a nematic phase and to a smectic A; the focal conic fan structure is less well defined and is said to be broken. The nematic-like features result from the fact that the tilt direction of the director is not correlated between the smectic layers and so it adopts a distribution analogous to that of the director in a nematic phase.

The molecular factors which influence the ability of a compound to form a liquid-crystal phase have been well studied both experimentally [36.3] and theoretically [36.4]. Consider the simple nematic as formed, for example, by *p*-quinquephenyl (Fig. 36.1a); this melts at 401 °C to form the nematic phase, which then undergoes a transition to the isotropic phase at 445 °C; the transition temperatures are denoted by T_{CrN} and T_{NI}, respectively. The very high value of T_{NI}, which is a measure of the stability of the nematic phase, is attributed to the large length-to-breadth ratio of *p*-quinquephenyl. In contrast *p*-quaterphenyl, formed by the removal of just one of the five phenyl rings, does not exhibit a liquid-crystal phase at atmospheric pressure, even though its shape anisotropy is still relatively large. This occurs because, on cooling, the isotropic liquid freezes before the transition to the nematic phase can occur. Indeed many compounds with anisotropic molecules might be expected to form liquid-crystal phases, but do not because of their high melting points. As a consequence the molecular design of liquid crystals needs to focus not only on increasing the temperature at which the liquid crystal–isotropic transition occurs but also on lowering the melting point. One way by which this can be achieved is to attach flexible alkyl chains to the end of the rigid core (Fig. 36.1). In the crystal phase the chain adopts a single conformation but in a liquid phase there is considerable conformational disorder, and it is the release of conformational entropy on melting that lowers the melting point. The addition of the chain also affects the nematic–isotropic transition temperature, which alternates as the number of atoms in the chain passes from odd to even. This odd–even effect is especially dramatic when the flexible chain links two mesogenic groups (Fig. 36.1d) to give what is known as a liquid-crystal dimer [36.5]. The odd–even effect is particularly marked because the molecular shapes for the dimers with odd and even spacers differ significantly on average, being bent and linear, respectively.

The attachment of alkyl chains to the rigid core of a mesogenic molecule has another important consequence, as it tends to promote the formation of smectic phases (Fig. 36.1b,c). The reason that the chains lead to the formation of such layered structures is that, both energetically and entropically, the flexible chains prefer not to mix with the rigid core, and so by forming a layer structure they are able to keep apart. Indeed it is known that biphenyl (a rigid rod-like structure) is not very soluble in octane (a flexible chain). The lack of compatibility of the core and the chain increases with the chain length and so along a homologous series it is those members with long alkyl chains that form smectic phases. For example, 4-pentyl-4′-cyanobiphenyl (Fig. 36.1e) forms only a nematic phase whereas the longer-chain homologue, 4-decyl-4′-cyanobiphenyl only exhibits a smectic A phase. To obtain a tilted smectic phase such as a smectic C there clearly needs to be a molecular interaction which favours an arrangement for a pair of parallel molecules that is tilted with respect to the intermolecular vector. Such a tilted structure can be stabilised by electrostatic

interactions; for example by off-axis electric dipoles (Fig. 36.1b,c) [36.6] or with a quadrupolar charge distribution.

The ability of a compound to form a liquid crystal is not restricted to just one phase. The delicate balance of the intermolecular interactions responsible for the various liquid-crystal phases means that transitions between them can result from modest variations in temperature. This is apparent for the 4,4′-dialkyl-2′,3′-difluoroterphenyl shown in Fig. 36.1c, which on cooling the isotropic liquid forms nematic, smectic A and smectic C phases; such a compound is said to be polymorphic. Materials which form even more liquid-crystal phases are known [36.1]. The occurrence of several liquid-crystal phases in a single system can be of value in processing the material for display applications.

36.1.2 Chiral Liquid Crystals

The mesogenic molecules that have been considered so far are achiral in the sense that the molecule is superimposable on its mirror image. Molecules may also be chiral in that they are not superimposable on their mirror images; this chirality can result from the tetrahedral arrangement of four different groups around a single carbon atom. This is illustrated in Fig. 36.4a which shows such an arrangement together with its mirror image; these are known as enantiomers. The presence of a chiral centre will certainly change the nature of the interactions between the molecules and it is relevant to see whether the chiral interactions might not influence the structure of the liquid-crystal phases exhibited by the material. From a formal point of view it might be expected that the molecular chirality of a mesogen should be expressed through the symmetry of the liquid-crystal structure. This proves to be the case, provided no other interactions oppose the chiral deformation of the liquid-crystal phase. In fact the first liquid crystal to be discovered [36.7] was chiral; this was cholesteryl benzoate where the cholesteryl moiety contains many chiral centres. The structure of the liquid crystal is nematic-like in that there is no long-range translational order but there is long-range orientational order. However, the difference between this phase and a nematic formed from achiral materials is that the director is twisted into a helix. The helix may twist in a left-handed or a right-handed sense and these structures, shown in Fig. 36.4b, are mirror images of each other. The phase structure is certainly chiral and so is known as a chiral nematic, although originally it was called a cholesteric phase. The symbol for the phase is N*, where the asterisk indicates that the phase has a chiral structure.

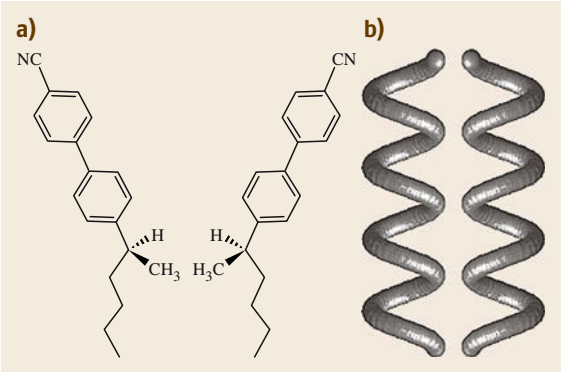

Fig. 36.4 **(a)** A chiral mesogenic molecule, (R) 2-[4′-cyano-4-biphenyl]-hexane, together with its mirror image, (S) 2-[4′-cyano-4-biphenyl]-hexane. **(b)** The left- and right-handed helical organisation of the director for a chiral nematic

The helical structure is characterised by the pitch of the helix p which is the distance along the helix axis needed for the director to rotate by 2π. Since the directions parallel and antiparallel to the director are equivalent the periodicity of the chiral nematic is $p/2$. For many chiral nematics the helical pitch is comparable to the wavelength of visible light. This, together with the periodic structure of the phase, means that Bragg reflection from a chiral nematic will be in the visible region of the spectrum and so this phase will appear coloured with the wavelength of the reflected light being related to the pitch of the helix. This pitch is sensitive to temperature, especially when the chiral nematic phase is followed by a smectic A. This sensitivity has been exploited in the thermochromic application of chiral nematics, where the reflected colour of the phase changes with temperature [36.1].

The chirality of cholesteryl benzoate clearly results from the chiral centres present in the mesogenic molecule. However, the chirality can also be introduced indirectly to a mesogen by simply adding a chiral dopant, which does not need to be mesogenic. The mixture will be chiral and this is sufficient to lead to a chiral nematic. The pitch of this mixture depends on the amount of the dopant and the inverse pitch, p^{-1}, proves to be proportional to its concentration. The handedness of the helix induced by the dopant will depend on its stereochemical conformation and will be opposite for the two enantiomers. Accordingly, if both enantiomers are present in equal amounts, i. e., as a racemic mixture, then doping a nematic with this will not convert it to a chiral nematic.

Chiral smectic phases are also known in which the director adopts a helical structure as a result of introducing molecular chirality into the material either

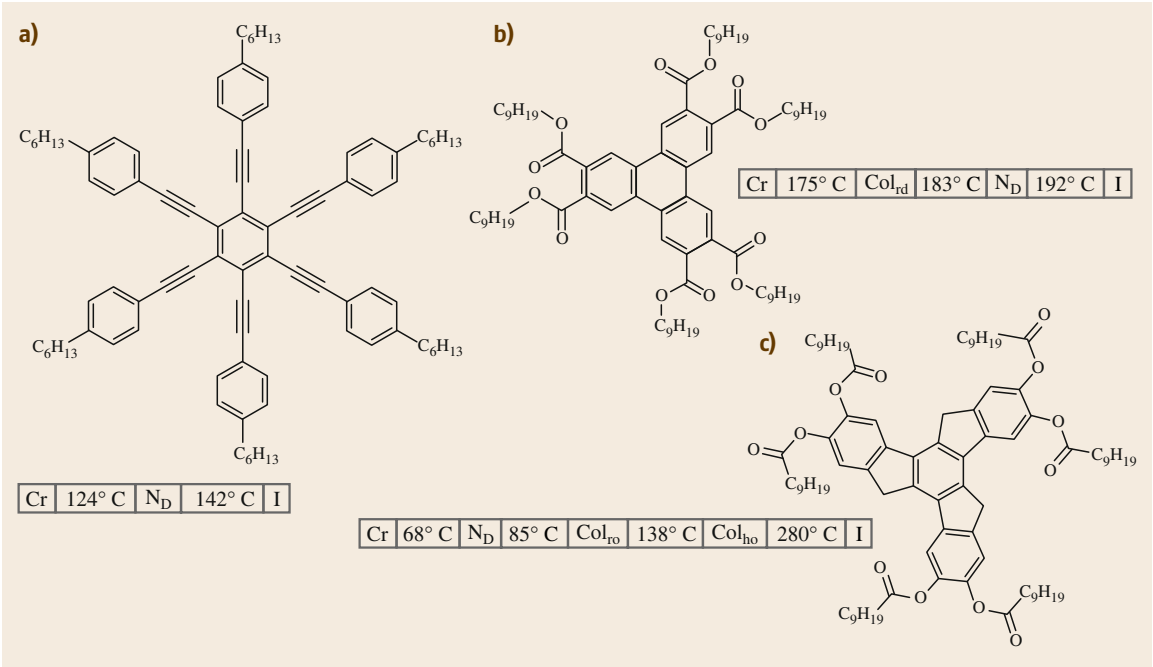

Fig. 36.5 A selection of molecular structures for compounds that form discotic liquid crystals

as a dopant or as an intrinsic part of the mesogenic molecule. The chiral smectic C phase, denoted SmC*, provides an appropriate example with which to illustrate the structure of such phases. In an achiral smectic C phase the tilt direction of the director changes randomly from layer to layer, analogous to the random director orientation in an achiral nematic. For the chiral smectic C phase, as might be anticipated, the tilt direction of the director rotates in a given sense, left-handed or right-handed, and by a small, fixed amount from layer to layer. Other structural features of the smectic C phase remain unchanged. Thus, the director of the chiral smectic C phase has a helical structure with the helix axis parallel to the layer normal. The pitch of the helix is somewhat smaller than that of the associated chiral nematic phase. The magnitude of the pitch is inversely related to the tilt angle of the smectic C, and since this grows with decreasing temperature so the pitch decreases. The reduced symmetry C_2 of the SmC* phase leads to the introduction of a macroscopic electrical polarisation [36.8]. This is of potential importance for the creation of fast-switching displays.

The ability of the SmC* phase to adopt a helical structure results from the fact that the tilt direction for the director acts in an analogous manner to the director in a nematic, and importantly that the layer spacing is preserved in the helical structure. In marked contrast there are strong forces inhibiting the creation of a twisted structure for a smectic A composed of chiral molecules. The director is normal to the layers and so the creation of a twisted structure would require a variation in the layer thickness but this has a high energy penalty associated with it. Accordingly many of the smectic A phases formed from chiral molecules have the same structure as those composed of achiral molecules. There are, however, exceptions and these occur when the chiral interactions are especially strong and, presumably, the translational order of the layers is small. Under such conditions the smectic A structure is partially destroyed, creating small SmA-like blocks about 1000 Å wide, separated by screw dislocations [36.9, 10]. These defects in the organisation allow the directions for the blocks to rotate coherently to give a chiral helical structure; the pitch of the helix is found to be larger than that in an analogous chiral nematic phase. This chiral phase is just one example of a liquid-crystal structure stabilised by defects; it is known as a twist grain-boundary phase and denoted by TGBA*. The letter A indicates that the director is normal to the layers in the small smectic blocks; there is a comparable phase in which the director is tilted, denoted by TGBC*.

36.1.3 Discotic Liquid Crystals

The key requirement for the formation of a liquid crystal is an anisotropic molecule, as exemplified by the rod-like molecules described in the previous sections.

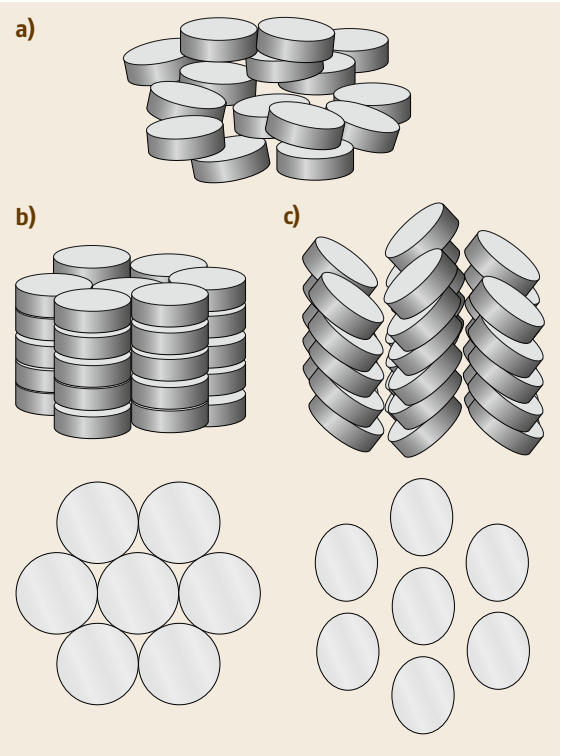

Fig. 36.6a–c The molecular organisation in discotic liquid-crystal phases, **(a)** nematic, **(b)** hexagonal columnar and **(c)** rectangular columnar

However, there is no reason why disc-like molecules should not also exhibit liquid-crystal phases. Nonetheless, it was not until 1977 that the first example of a thermotropic liquid crystal formed from disc-like molecules was reported [36.11]. Since that time several liquid-crystal phases have been identified and these phases are known collectively as discotic liquid crystals. The range of compounds that exhibits these phases is now extensive and continues to grow [36.12], although it does not match the number that form calamitic liquid crystals. The molecular structures of three compounds which form discotic liquid crystals are shown in Fig. 36.5.

As for rod-like molecules, the simplest liquid-crystal phase formed by disc-like molecules is the nematic, usually denoted N_D, where the D indicates the disc-like nature of the molecules. Within the nematic phase, shown in Fig. 36.6a, the molecular centres of mass are randomly distributed and the molecular symmetry axes are orientationally correlated. The nematic structure is the same as for that formed from rod-like molecules, the only difference being that the symmetry axes which are orientationally ordered are the short axes for the discs and the long axes for the rods. The point symmetry of the discotic and calamitic nematic is the same, namely $D_{\infty h}$. The discotic nematic is recognised in the same way as the calamitic nematic; that is it flows like a normal fluid and its anisotropy is revealed by a characteristic optical texture analogous to that shown in Fig. 36.3a. In fact, the refractive index of a discotic nematic along the director is smaller than that perpendicular to it, which is the opposite to that for a calamitic nematic. It has been suggested that this difference may be of value in display devices [36.13] but this concept has not as yet been commercialised.

The other class of discotic liquid crystals possesses some element of long-range translational order and these are known as columnar phases, two examples of which are sketched in Fig. 36.6b,c. The disc-like molecules are stacked face-to-face into columns. A single column has a one-dimensional structure, and as such is not expected to exhibit long-range translational order, although this can result from interactions between neighbouring columns in the liquid-crystal phase. The column–column interactions will result in the columns being aligned parallel to each other; these interactions will also determine how the columns are packed. When the discs are orthogonal to the column axis the cross section is essentially circular and so the columns pack hexagonally, as shown in Fig. 36.6b. The symbol given to this phase is Col_{hd}, where h denotes hexagonal packing of the columns and d indicates that the arrangement along the column is disordered. The point group symmetry of this phase is D_{6h}. The disc-like molecules may also be tilted with respect to the column axis, giving an elliptical cross section to the columns. As a result the columns are packed on a rectangular lattice; there are four possible arrangements and just one of these is indicated in Fig. 36.6c. In general the mnemonic used to indicate a rectangular columnar phase is Col_{rd}. The point group symmetry of the rectangular columnar phase is D_{2h} and the extent to which the structure deviates from that of the Col_{hd} phase will depend on the magnitude of the tilt angle within the column. The columnar phases can be identified from their optical textures and an example of one is shown in Fig. 36.3c.

The columnar phases have potential electronic applications because of the inhomogeneity of the molecules that constitute them, i. e., the central part is aromatic while the outer part is aliphatic. As a result of the overlap between the π-orbitals on the centres of neighbouring discs it should be possible for electrical conduction to take place along the core of the column. This should occur without leakage into adjacent columns because of the insulation provided by the alkyl chains. It should also be possible to anneal these molecular wires because of their liquid-crystal prop-

erties [36.14]. This and the ability to avoid defects in the columns which can prevent electronic conduction in crystals mean that the columnar phase has many potential advantages over non-mesogenic materials. In addition, discotic systems are also used as compensating films to improve the optical characteristics for some liquid-crystal displays.

At a molecular level the factors that are responsible for the formation of the discotic liquid-crystal phases are similar to those for calamitic systems. Thus, the molecular design should aim to increase the liquid crystal–isotropic transition temperature while decreasing the melting point. The latter is certainly achieved by attaching flexible alkyl chains to the perimeter of the rigid disc. The creation of the columnar phases should be relatively straightforward provided the central core is both planar and large. Then, because of the strong attractive forces between the many atoms in the rigid core the molecules will wish to stack face-to-face in a column. The formation of the columns will also be facilitated by the flexible alkyl chains attached to the core. Clearly then it may prove to be difficult to create the nematic phase before the columnar phase is formed unless the disc–disc interactions can be weakened. One way in which this can be achieved is by destroying the planarity of the core, for example, by using phenyl rings attached to the molecular centre so that they can rotate out of the plane (Fig. 36.5a). It is to be expected that the columnar phases should occur below the nematic phase, corresponding to an increase in order with decreasing temperature. This is usually observed, for example, for the hexasubstituted triphenylenes (Fig. 36.5b). However, the truxene derivatives, with long alkyl chains on the perimeter, (Fig. 36.5c) exhibit quite unusual behaviour. For these compounds the crystal melts to form a discotic nematic and then at a higher temperature a columnar phase appears. This deviates from the expected sequence, and because the nematic phase appears at a lower temperature than the columnar phase it is usually referred to as a re-entrant nematic. The occurrence of a re-entrant phase is often attributed to a conformational change which strengthens the molecular interactions with increasing temperature thus making the more ordered phase appear at higher temperatures.

36.2 The Basic Physics of Liquid Crystals

36.2.1 Orientational Order

The defining characteristic of a liquid crystal is the long-range orientational order of its constituent molecules. That is, for rod-like molecules, the molecular long axes tend to align parallel to each other even when separated by large distances. The molecules tend to be aligned parallel to a particular direction known as the director and denoted by $\boldsymbol{n}$. This is an apolar vector, that is $\boldsymbol{n} = -\boldsymbol{n}$, because the nematic does not possess long-range ferroelectric order. The properties of the nematic phase are cylindrically symmetric about the director, which provides a macroscopic definition of this. The anisotropy of the properties results from the orientational order and the extent of this is commonly defined [36.15] by

$$S = \left\langle \frac{1}{2}\left(3\cos^2\beta - 1\right)\right\rangle , \qquad (36.1)$$

although other definitions are possible [36.16]. Here β is the angle made by a molecule with the director and the angular brackets indicate the ensemble average. In the limit of perfect order S is unity while in the isotropic phase S vanishes. The temperature dependence of S is shown in Fig. 36.7 for the nematogen, 4,4′-dimethoxyazoxybenzene; this behaviour is typical of most nematic liquid crystals. At low temperatures S is about 0.6 and then decreases with increasing temperature, reaching about 0.3 before it vanishes discontinuously at the nematic–isotropic transition, in keeping with the first-order nature of this transition. It is also found, both experimentally and theoretically, that the orientational order of different nematic liquid crystals is approximately the same provided they are compared at corresponding temperatures, either the reduced, T/T_{NI}, or shifted, $T_{\mathrm{NI}} - T$, temperatures [36.16]. Since many properties of liquid crystals are related to the long-range orientational order these also vary with temperature especially in the vicinity of the transition to the isotropic phase.

36.2.2 Director Alignment

The director in a bulk liquid crystal is distributed randomly unless some constraint is applied to the system; a variety of constraints can be employed and two of these are of special significance for display applications. One of them is an electric field and because of the inherent anisotropy in the dielectric permittivity of the liquid crystal the director will be aligned. The electric energy density controlling the alignment is given by [36.17]

$$U_{\mathrm{elec}} = -\frac{\varepsilon_0 \Delta\varepsilon}{2}(\boldsymbol{n}\cdot\boldsymbol{E})^2 . \qquad (36.2)$$

Here ε_0 is the permittivity of a vacuum and the scalar product $\boldsymbol{n}\cdot\boldsymbol{E}$ is $E\cos\theta$, where E is the magnitude of the field $\boldsymbol{E}$ and θ is the angle between the director and the field, $\Delta\varepsilon$ is the anisotropy in the dielectric tensor

$$\Delta\varepsilon = \varepsilon_{||} - \varepsilon_{\perp} \,, \tag{36.3}$$

where the subscripts denote the values parallel (||) and perpendicular ($\perp$) to the director. If the dielectric anisotropy is positive then the director will be aligned parallel to the electric field and, conversely, if $\Delta\varepsilon$ is negative, then the director is aligned orthogonal to the field. The molecular factors that control the sign of $\Delta\varepsilon$ will be discussed in Sect. 36.4. Of course, intense electric fields are also able to align the molecules in an isotropic phase but what is remarkable about a nematic liquid crystal is the very low value of the field needed to achieve complete alignment of the director. Thus for a bulk nematic free of other constraints the electric field necessary to align the director is typically about 30 kV/m, although the value does clearly depend on the magnitude of the dielectric anisotropy. This relatively small value results because of the long-range orientational correlations which mean that the field acts, in effect, on the entire ensemble of molecules and not just single molecules.

The other constraint, essential for display devices, is the interaction between the director and the surface of the container [36.18]. At the surface there are two extreme arrangements for the director. One is with the director orthogonal to the surface, the so-called homeotropic alignment. In the other the director is parallel to a particular direction in the surface; this is known as uniform planar alignment. The type of alignment depends on the way in which the surface has been treated. For example, for a glass surface coated with silanol groups a polar liquid crystal will be aligned homeotropically, while to achieve this alignment for a non-polar nematic the surface should be covered with long alkyl chains. In these examples the direct interaction of a mesogenic molecule with the surface produces an orthogonal alignment which is then propagated by the long-range order into the bulk. To achieve uniform planar alignment of the director the surface is coated with a polymer, such as a polyimide, which on its own would result in planar alignment. To force the director to be parallel to a particular direction in the surface the polymer is rubbed which aligns the director parallel to the direction of rubbing. There is still some uncertainty about the mechanism responsible for uniform planar alignment. It might result from alignment of the polymer combined with anisotropic intermolecular attractions with the mesogenic molecules, although it had been thought [36.19] to have its origins in surface groves and the elastic interactions which are described later.

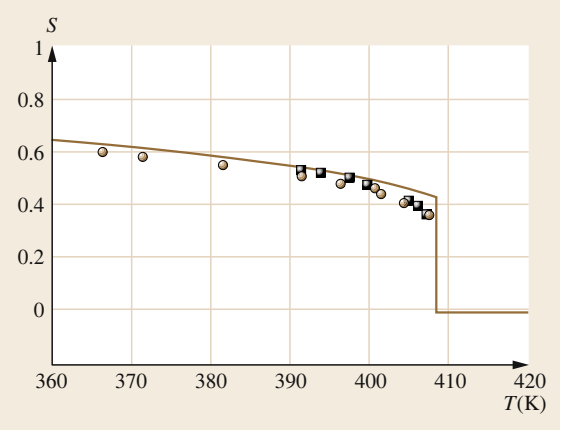

Fig. 36.7 The temperature variation of the orientational order parameter S for 4,4′-dimethoxyazoxybenzene; the different *symbols* indicate results determined with different techniques

The energy of interaction between the surface and the director clearly depends on the nature of the surface treatment and the particular nematic. *Rapini* and *Papoular* [36.20] have suggested the following simple form for the surface energy density

$$U_S = -\frac{A}{2}(\boldsymbol{n}\cdot\boldsymbol{e})^2 \,, \tag{36.4}$$

where A is the anchoring energy and $\boldsymbol{e}$ is the easy axis or direction along which the director is aligned. Clearly it has an analogous form to that for the anisotropic interaction between the nematic and an electric field (36.2) but is essentially phenomenological. The anchoring energy is determined to be in the range 10^{-7}–10^{-5} J/m^2 [36.21]. The upper value corresponds to strong anchoring in that typical values of the electric field would not change the director orientation at the surface. In contrast the lower value is associated with weak anchoring and here the director orientation at the surface can be changed by the field.

36.2.3 Elasticity

As the name suggests, a liquid crystal has some properties typical of crystals and others of liquids. The elastic properties of crystals should, therefore, be reflected in the behaviour of liquid crystals. Here it is the director orientation which is the analogue of the atomic positions in a crystal. In the ground state of a nematic liquid crystal the director is uniformly aligned. However, the elastic torques, responsible for this uniform ground

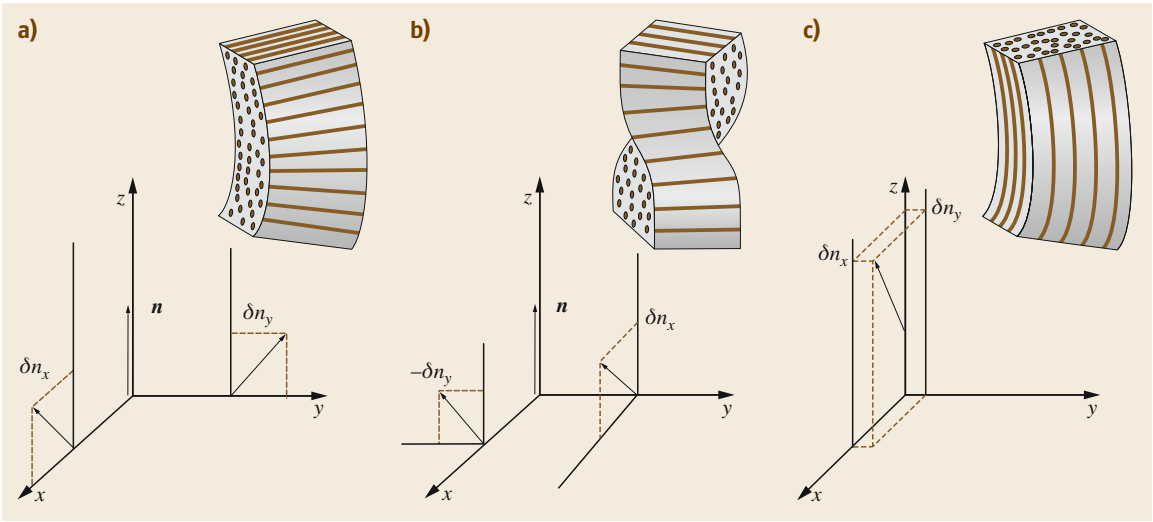

Fig. 36.8a–c The three fundamental deformations for the nematic director (**a**) splay, (**b**) twist and (**c**) bend

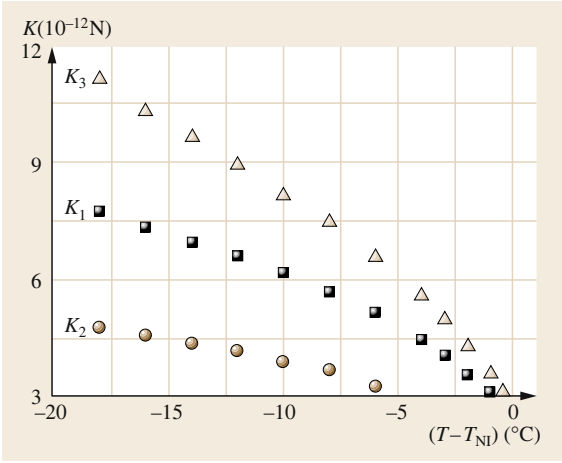

Fig. 36.9 The temperature dependence of the three elastic constants, K_1, K_2 and K_3, for the nematogen 5CB

state, are weak and, at temperatures within the nematic range, the thermal energy is sufficient to perturb the director configuration in the bulk. This perturbed state can take various forms depending on a combination of factors but, whatever the form, it can be represented as a sum of just three fundamental distortion modes. These are illustrated in Fig. 36.8 and are the splay, twist and bend deformations [36.22]. At a more formal level these modes are also shown in terms of the small deviations of the director from its aligned state at the origin as the location from this is varied. For example, for the twist deformation away from the origin along the x-axis there is a change in the y-component of the director, n_y, and the displacement along the y-axis causes a change in n_x. The magnitude of the twist deformation is measured by the gradients $\partial n_y/\partial x$ and $\partial n_x/\partial y$.

The energy needed to stabilise a given distortion of the director field is clearly related to the extent of the deformation via the gradients. This distortion energy density for a bulk nematic liquid crystal is given by continuum theory [36.22] as

$$f = \frac{1}{2}\left[K_1(\nabla\cdot\boldsymbol{n})^2 + K_2(\boldsymbol{n}\cdot\nabla\times\boldsymbol{n})^2 + K_3(\boldsymbol{n}\times\nabla\times\boldsymbol{n})^2\right], \quad (36.5)$$

where the terms $\nabla\cdot\boldsymbol{n}$, $\boldsymbol{n}\cdot\nabla\times\boldsymbol{n}$ and $\boldsymbol{n}\times\nabla\times\boldsymbol{n}$ correspond to the splay, twist and bend deformations, respectively. The contribution each makes to the free energy is determined by the proportionality constants K_1, K_2 and K_3, which are usually known as the Frank elastic constants for splay, twist and bend, respectively. They are small, typically 5×10^{-12} N, and their small magnitude explains why the thermal energy is able to distort the uniform director arrangement so readily. The elastic constants are not in fact constant but vary with temperature and nor are they equal as the results for 4-pentyl-4′-cyanobiphenyl (5CB) shown in Fig. 36.9 demonstrate. The twist elastic constant is seen to be the smallest while the largest is the bend elastic constant. This means that it is easiest to induce a twist deformation in a nematic while a bend deformation is the most difficult to create. All three elastic constants decrease with increasing temperature in keeping with the decreasing order as the transition to the isotropic phase is approached. Like the orientational order the elastic constants vanish discontinuously at the first-order nematic–isotropic transi-

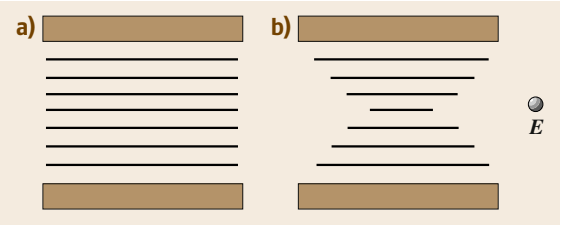

Fig. 36.10a,b The geometry for the Fréedericksz experiment used to determine the twist elastic constant, K_2; **(a)** in zero field and **(b)** above the threshold value

tion.

The continuum theory is especially valuable in predicting the behaviour of display devices and this is illustrated by considering one of the ingenious experiments devised by *Fréedericksz* to determine the elastic constants [36.23]. In these a thin slab of nematic is confined between two glass plates with a particular director configuration, either uniform planar or homeotropic produced by surface forces. These forces control the director orientation just at the two surfaces and the alignment across the slab is propagated by the elastic interactions. A field is then applied which will move the director away from its original orientation and the variation of the director orientation with the field strength provides the elastic constant. To employ the continuum theory in order to describe the experiment it is necessary to add the field energy density (36.2) to the elastic free-energy density in (36.5). The director configuration is then obtained by integrating the free-energy density over the volume of the sample, and minimising this, subject to the surface constraints. The geometry of the experiment is shown in Fig. 36.10 and provided the dielectric anisotropy $\Delta\varepsilon$ is positive the director will move from being orthogonal to the field to being parallel to it. However, the extent of this twist deformation will vary across the cell, being greatest at the centre and zero at the surfaces, in the limit of strong anchoring. The dependence of the director orientation, at the centre of the slab, with respect to the electric field is shown in Fig. 36.11. As the field strength is increased from zero the director orientation remains unchanged until a threshold value E_{th} is reached when the angle between the director and the field starts to decrease continuously. At very high values of the field the director at the centre of the slab tends to be parallel to the field. This behaviour can be understood in the following simple terms. Below the threshold field the elastic energy exceeds the electrical energy and so the director retains its uniform planar alignment. Above the threshold field strength the elastic energy is less than the electrical energy and so

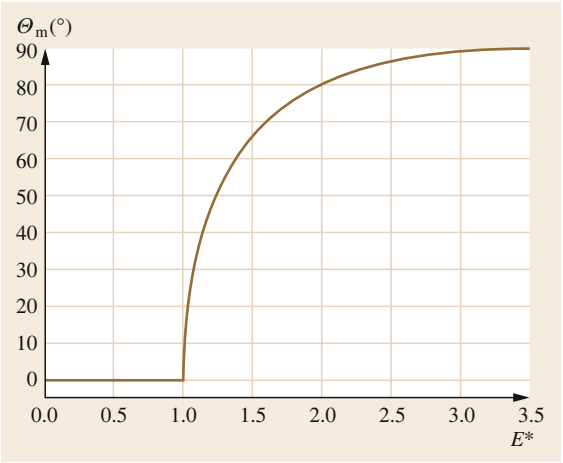

Fig. 36.11 The dependence of the director orientation θ_m at the centre of a nematic slab on the scaled field strength, $E^* = E/E_{th}$

the director begins to move to be parallel to the electric field. The threshold electric field is predicted to be

$$E_{th} = \frac{\pi}{l}\sqrt{\frac{K_2}{\varepsilon_0 \Delta\varepsilon}}\,, \tag{36.6}$$

where l is the slab thickness. Once the threshold field has been measured and provided the dielectric anisotropy is known, the twist elastic constant would be available. Other Fréedericksz experiments with analogous expressions for the threshold field lead to the determination of the splay and bend elastic constants.

For real display applications (Sect. 36.3) the director alignment at the surface deviates from either uniform planar or homeotropic alignment. This deviation is known as a surface pre-tilt and is illustrated in Fig. 36.12a for near-uniform planar alignment with the tilt direction on the two surfaces differing by 180°. The cell with this arrangement has what is known as antiparallel alignment, so named because of the difference in the tilt direction caused by the direction of rubbing on the surfaces being antiparallel. In zero field, therefore, the director is uniformly aligned across the cell but tilted with respect to the x-axis set in the surface. A continuum theory calculation analogous to the case when the pre-tilt angle θ_0 is zero allows the dependence of the director orientation θ_m in the centre of the cell to be determined as a function of the strength of the field applied across the cell. The results of these calculations, for a nematic with positive $\Delta\varepsilon$, are shown in Fig. 36.12b as a function of the scaled

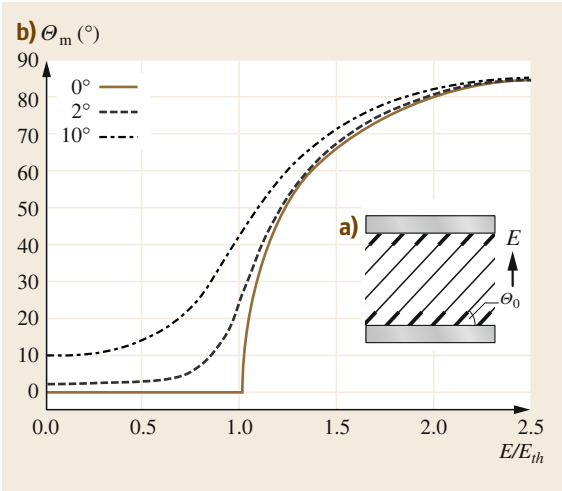

Fig. 36.12 **(a)** The director alignment in a cell with pre-tilt at the two surfaces assembled so that the rubbing directions are antiparallel. **(b)** The electric field dependence of the director orientation θ_m at the centre of the cell for values of the pre-tilt angle of 0° (*solid line*), 2° (*dashed line*) and 10° (*dash-dotted line*)

field strength E/E_{th}, where E_{th} is the threshold field for zero pre-tilt. The theoretical dependence for a tilt angle of zero is analogous to that considered for the twist deformation. In other words, below the threshold field the director is parallel to the easy axis and then above this threshold the director moves to become increasingly parallel to the field. When there is a surface pre-tilt the behaviour is quite different and this is especially apparent for a pre-tilt angle of 10° (Fig. 36.12b). In zero field the angle θ_m made by the director with the x-axis is 10° and, as the field increases, so does θ_m. The rate of increase grows as the threshold field is approached and then is reduced as E/E_{th} increases beyond unity. Comparison of this behaviour with the conventional Fréedericksz experiment (Fig. 36.12b) shows that a pre-tilt of 10° has a significant effect on the way in which the director orientation changes with the field strength. Indeed, even for a pre-tilt of just 2°, there is a pronounced difference in behaviour in the vicinity of the threshold field. This clearly has important implications for the accurate determination of the elastic constants [36.20]. It also shows how unique the behaviour is when the surface pre-tilt angle is zero.

Chiral nematics are often employed in liquid-crystal display devices. Locally, their structure is analogous to a nematic but the director is twisted into a helical structure. The continuum theory for the chiral nematic must, therefore, be consistent with the helical ground state structure of the phase. To achieve this, a constant is

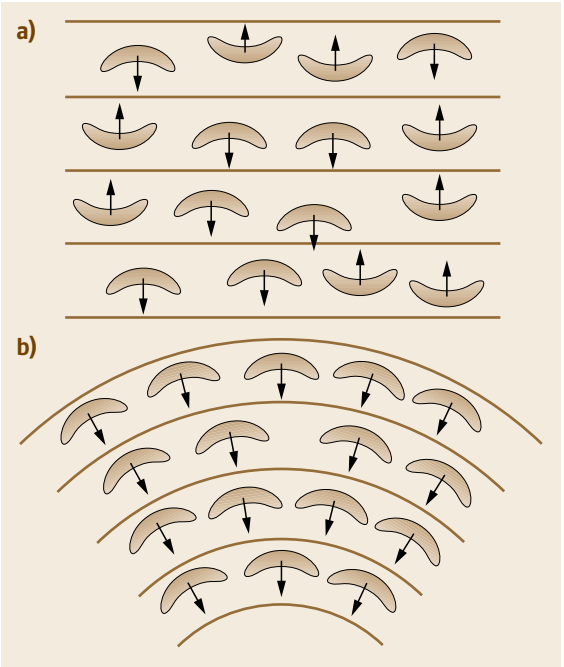

Fig. 36.13a,b The orientational distribution of bent molecules in **(a)** a uniformly aligned nematic and **(b)** one subject to a bend deformation; the x-axes are denoted by *arrows*

added to the twist term in the elastic free-energy density. Thus (36.5) for a nematic becomes

$$f = \frac{1}{2}\left[K_1(\nabla\cdot\boldsymbol{n})^2 + K_2\left(\boldsymbol{n}\cdot\nabla\times\boldsymbol{n} - \frac{2\pi}{p}\right)^2 + K_3(\boldsymbol{n}\times\nabla\times\boldsymbol{n})^2\right] \quad (36.7)$$

for a chiral nematic, where p is the pitch of the helix.

36.2.4 Flexoelectricity

Another property of solids which is mimicked by liquid crystals is piezoelectricity. For solids this is the generation of a macroscopic electrical polarisation as a result of the deformation of certain ionic materials. It is to be expected, therefore, that deformation of the director distribution for a liquid crystal will create a macroscopic polarisation; this proves to be the case [36.24] and the phenomenon is known as flexoelectricity. The origin of flexoelectricity can be understood in the following way. It is generally assumed that mesogenic molecules are cylindrically symmetric but examination of the molecular structure of real mesogens shows that this is not the case. The molecules are asymmetric and at one extreme

can be thought of as bent, as shown in Fig. 36.13; here z is the molecular long axis and x is the axis bisecting the bond angle. When the director is uniformly aligned the z-axis will be parallel to the director and the x-axis will be randomly arranged orthogonal to it (Fig. 36.13). If the director is now subject to a bend deformation the molecular long axis will still tend to be parallel to the local director, however, the x-axis will tend to align parallel to a direction in the plane formed by the bent director. This change in the distribution function for the x-axis will introduce polar order into the system and if there is an electrical dipole moment along the x-axis then the deformed nematic will exhibit a macroscopic polarisation $\boldsymbol{P}$. A similar argument shows that, if the molecule is wedge-shaped, a splay deformation of the director distribution will also induce a polarisation in the nematic [36.24].

The magnitude of $\boldsymbol{P}$, the induced dipole per unit volume, clearly depends on the extent of the deformation in the director distribution. In the linear response regime the induced polarisation for mesogenic molecules of arbitrary asymmetry is given by [36.25]

$$\boldsymbol{P} = e_1 \boldsymbol{n} \nabla \cdot \boldsymbol{n} + e_3 \boldsymbol{n} \times \nabla \times \boldsymbol{n} \,, \tag{36.8}$$

where the vectors $\boldsymbol{n}\nabla\cdot\boldsymbol{n}$ and $\boldsymbol{n}\times\nabla\times\boldsymbol{n}$ represent the splay and bend deformations, respectively. Since the polarisation per unit volume is also a vector then the proportionality constants, e_1 and e_3, are scalars. These are known as the splay and bend flexoelectric coefficients, respectively, and their dimensions are $\mathrm{C\,m^{-1}}$. The determination of individual flexoelectric coefficients is challenging [36.26], however, it seems that $(e_1 + e_3)$ is of the order of 10^{-12}–$10^{-11}\,\mathrm{C\,m^{-1}}$, although from the previous discussion their magnitude should vary amongst the mesogens because of their dependence on the molecular asymmetry and the size and location of the dipole moment. The molecular model proposed to understand the flexoelectricity of nematics suggests that, for rod-like molecules, devoid of asymmetry, the flexoelectric coefficients should vanish, but that does not seem to be the case. Indeed, it has been proposed that polarisation can result even for rod-like molecules if they possess an electrostatic quadrupole moment [36.27]. This is not inconsistent with the polarisation predicted by (36.8) which follows from the reduced symmetry of a nematic with splay and bend deformations of the director [36.24]. Although the existence of flexoelectricity is of considerable fundamental interest the inverse effect in which the director is deformed from a uniform state by the application of an electric field is of relevance for liquid-crystal displays (Sect. 36.3). This deformation occurs because the polarisation induced by the director deformation can couple with the applied electric field and so stabilise the deformation [36.26]. Since the coupling is linear in the electric field then reversal of the field will simply reverse the deformation; a novel bistable device based solely on this reversal is described in Sect. 36.3.

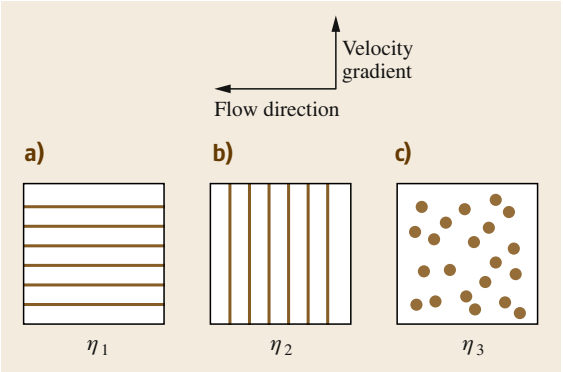

Fig. 36.14a–c The principal flow geometries of the Miesowicz experiments with the director pinned **(a)** parallel to the flow direction, **(b)** parallel to the velocity gradient and **(c)** orthogonal to both the flow direction and velocity gradient

36.2.5 Viscosity

For a nematogen the fluidity of the nematic phase is comparable to that of the isotropic phase appearing at a higher temperature. It is this fluidity, similar to that of a liquid, which is responsible, in part, for the display applications of nematics. An indication of the fluidity of conventional liquids is provided by a single viscosity coefficient η, measured from the flow of the liquid subject to an applied stress in a viscometer. The flow behaviour of a nematic is made more complex by its defining long-range orientational order and the resultant anisotropy of the phase.

This complexity can be appreciated at a practical level in terms of the Miesowicz experiments to determine the viscosity coefficients of a nematic [36.28]. In these experiments it is helpful to consider flow in a viscometer with a square cross section such that there is a velocity gradient orthogonal to the direction of flow. For a nematic, flow through the viscometer will now depend on the orientation of the director with respect to these two axes. A magnetic field is employed to align the director along a particular axis and it must be sufficiently strong that flow does not perturb the director alignment. There are three relatively simple flow geometries and these are shown in Fig. 36.14: with the director parallel to the flow direction (Fig. 36.14a), with the director parallel to the velocity gradient (Fig. 36.14b), and with the direc-

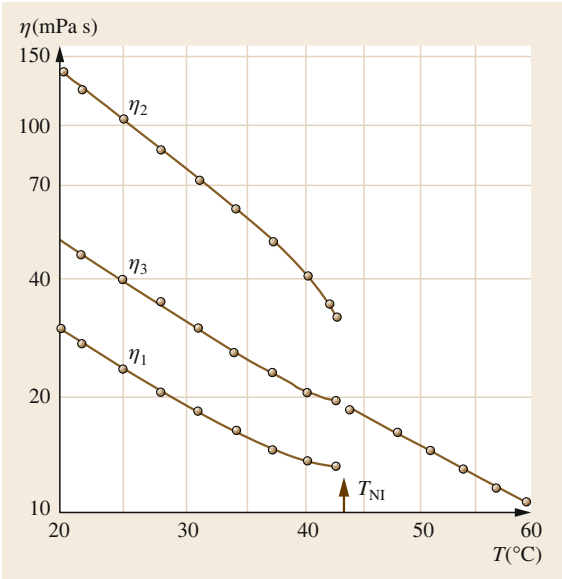

Fig. 36.15 The temperature dependence of the three Miesowicz viscosity coefficients, η_1, η_2, and η_3, for the nematic phase of MBBA; the viscosity coefficient for the isotropic phase is also shown

tor orthogonal to both the flow direction and velocity gradient (Fig. 36.14c). The viscosity coefficients were denoted by Miesowicz as a) η_1, b) η_2, and c) η_3, although other notation has been proposed in which η_1 and η_2 are interchanged [36.29]. The three viscosity coefficients are clearly expected to differ given the anisotropy of the nematic phase and these differences are found to be large. They are illustrated for the room-temperature nematogen 4-methoxybenzylidene-4′-butylaniline (MBBA) [36.30] in Fig. 36.15 where the viscosities are plotted against temperature.

It is immediately apparent that flow is easiest when the director is parallel to the direction of flow, as might have been anticipated. Conversely flow of the nematic is most difficult when the director is orthogonal to the flow direction but parallel to the velocity gradient. The intermediate viscosity η_3 occurs when the director is orthogonal to both the flow direction and the velocity gradient. Here it is seen that this third viscosity coefficient for the nematic is very similar to the viscosity coefficient for the isotropic phase extrapolated to lower temperatures.

The viscosity coefficient $\eta(\theta,\phi)$ for an arbitrary orientation (θ,ϕ) of the director with respect to the flow direction and velocity gradient can be related to the director orientation. It might be expected that this orientation dependence would involve just the three Miesowicz viscosity coefficients, rather like the transformation of a second-rank tensor from its principal axis system. In fact this is not quite the case and a fourth viscosity coefficient η_{12} needs to be introduced. The orientation dependence is then [36.28]

$$\eta(\theta,\phi) = \eta_1 \cos^2\theta + \left(\eta_2 + \eta_{12}\cos^2\theta\right) \times \sin^2\theta\cos^2\phi + \eta_3 \sin^2\theta \sin^2\phi \,. \quad (36.9)$$

We see that for the principal orientations $(0, \pi/2)$, $(\pi/2, 0)$ and $(\pi/2, \pi/2)$ the expression gives η_1, η_2, and η_3, as required. The optimum director orientation with which to determine η_{12} is with the director at 45° to both the flow direction and the velocity gradient; the viscosity coefficient for this is

$$\eta\left(\frac{\pi}{4},0\right) = \frac{\eta_{12}}{4} + \frac{\eta_1+\eta_2}{2} \,. \quad (36.10)$$

The value of η_{12} determined for MBBA proves to be significantly smaller than the other three viscosity coefficients.

The four viscosity coefficients have been defined at a practical level in terms of flow in which the director orientation is held fixed. The converse of these experiments, in which the director orientation is changed in the absence of flow, allows the definition of the fifth and final viscosity coefficient. This is known as the rotational viscosity coefficient; it is denoted by the symbol γ_1 and plays a major role in determining the response times of display devices (Sect. 36.4). To appreciate the significance of γ_1, it is helpful, as for the other four viscosity coefficients, to consider an experiment with which to measure it. In this an electric field is suddenly applied an angle θ to a uniformly aligned director, then providing the dielectric anisotropy is positive the director orientation will be changed and rotates towards the field direction. The electric torque responsible for the alignment is given by

$$\Gamma_{\text{elec}} = -\frac{\varepsilon_0 \Delta\varepsilon}{2} \sin 2\theta \,, \quad (36.11)$$

which is the derivative of the electric energy in (36.2). The rotation of the director is opposed by the viscous torque

$$\Gamma_{\text{visc}} = \gamma_1 \frac{\mathrm{d}\theta}{\mathrm{d}t} \,, \quad (36.12)$$

which is linear in the rate at which the director orientation changes, with the proportionality constant being γ_1. Provided the only constraint on the director is the electric field and provided, $\theta_0 \leq 45°$, the director will move as a monodomain so that the elastic terms vanish. The inertial term for a nematic is small and so the movement of the director is governed by the equation

in which the two torques are balanced. That is, the electric torque causing rotation is balanced by the viscous torque opposing it; this gives

$$\gamma_1 \frac{\mathrm{d}\theta}{\mathrm{d}t} = -\frac{\varepsilon_0 \Delta\varepsilon}{2} E^2 \sin^2\theta \,. \tag{36.13}$$

The solution to this differential equation is

$$\tan\theta = \tan\theta_0 \exp\left(-\frac{t}{\tau}\right), \tag{36.14}$$

where θ_0 is the initial orientation of the director with respect to the electric field and τ is the relaxation time

$$\tau = \frac{\gamma_1}{\varepsilon_0 \Delta\varepsilon E^2} \,. \tag{36.15}$$

Measurement of the time-dependent director orientation allows τ to be determined and from this γ_1, given values of $\Delta\varepsilon$. For MBBA the rotational viscosity coefficient is found to be slightly less than η_2 and to parallel its temperature dependence [36.31].

The five independent viscosity coefficients necessary to describe the viscous behaviour of a nematic have been introduced in a pragmatic manner by appealing to experiments employed to measure these coefficients. However, the viscosity coefficients can be introduced in a more formal way as has been shown by Ericksen and then by *Leslie* in their development of the theory for nematodynamics [36.32]. The Leslie–Ericksen theory in its original form contained six viscosity coefficients, but subsequently Parodi has shown, using the Onsager relations, that there is a further equation linking the viscosity coefficients, thus reducing the number of independent coefficients to five [36.33]. These five coefficients are linearly related to those introduced by reference to specific experiments.

36.3 Liquid-Crystal Devices

The idea to use liquid crystals as electro-optic devices goes back to the early days of liquid-crystal research. In 1918 *Björnståhl*, a Swedish physicist, demonstrated that the intensity of light transmitted by a liquid crystal could be varied by application of an electric field [36.34]. As optical devices of various types became established in the first decades of the 20th century, mainly in the entertainment industry, ways of controlling light intensity became important to the developing technologies. One device that soon found commercial application was the Kerr cell shutter, in which an electric field caused the contained fluid (usually nitrobenzene) to become birefringent. Placing such a cell between crossed polarisers enabled a beam of light to be switched on and off very rapidly. The first report of liquid crystals being of interest for electro-optic devices was in 1936, when the Marconi Company filed a patent [36.35] which exploited the high birefringence of nematic liquid crystals in an electro-optic shutter. However, it was another 35 years before commercial devices became available which used the electro-optic properties of liquid crystals. The long interruption to the development of liquid-crystal devices can be attributed to the lack of suitable materials. We shall see in this Section how the physical properties of liquid crystals determine the performance of devices.

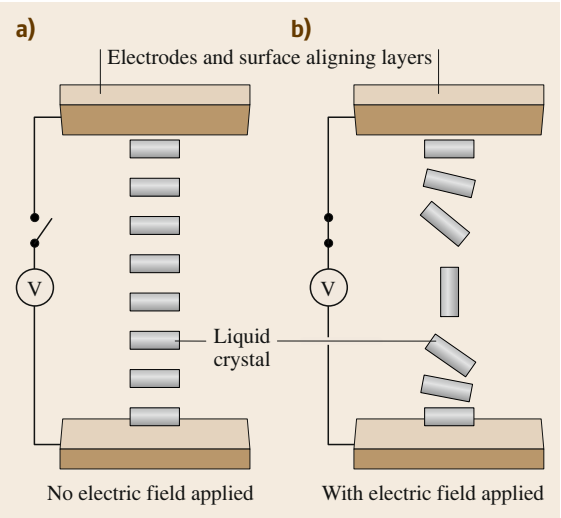

Fig. 36.16 Electrically controlled birefringence (ECB) cell

The optical properties of liquid crystals are exploited in displays, although the operational characteristics of such devices also depend crucially on many other physical properties (Sect. 36.2). Since the devices to be described all depend on the application of an electric field, their operation will be influenced by electrical properties such as dielectric permittivity and electrical conductivity. There is a range of electro-optic effects that can be used in devices, and the precise manner in which the properties of the liquid-crystal materials affect the device behaviour depends on the effect and the configuration of the cell. Thus there is not a single set of ideal properties that can define the best liquid-crystal material, rather the material properties have to

be optimised for a particular application. In this section, different devices will be described, and their dependence on different properties will be outlined. The way in which the material properties can be adjusted for any application will be discussed in the final section of this chapter.

36.3.1 A Model Liquid-Crystal Display: Electrically Controlled Birefringence (ECB) Mode

If an electric field is applied across a film of planar-aligned liquid crystal having a positive dielectric anisotropy, then the director of the liquid crystal will tend to align along the electric field. Thus the director will rotate into the field direction, and the optical retardation or birefringence of the film will change. If the film is placed between crossed polarisers, then the change in optical retardation will be observed as a change in the intensity of transmitted light. The configuration for an ECB-mode display is schematically illustrated in Fig. 36.16. This illustrates the principal components of a liquid-crystal display. The liquid crystal is contained between two glass plates that have been coated with a transparent conducting layer, usually an indium–tin oxide alloy. Such treatment allows the application of an electric field across the liquid-crystal film, which can then be viewed along the field direction. For most applications, the surfaces of the electrodes are treated so that a particular director orientation is defined at the surface. This can be achieved in a variety of ways, depending on the desired surface director orientation. For the ECB-mode display under consideration, the director alignment should be parallel to the glass substrates and along a defined direction, which is the same on both surfaces. The standard technique to produce this alignment is to coat the glass plates with a thin (0.5 nm) layer of polyimide, which is mechanically rubbed in a particular direction. The cell is then placed between crossed polarisers, the extinction directions of which make angles of $\pm 45^\circ$ with the surface-defined director orientation.

The unperturbed state of the liquid-crystal film will be determined by the surfaces which contain it. If these have been treated in such a way that the liquid-crystal director is parallel to the surface along a particular direction, then the film will act as an optical retardation plate. Thus incident polarised light will, in general, emerge elliptically polarised, and there will be a phase retardation between components of the light wave parallel to the fast and slow axes of the retardation plate. For electromagnetic waves polarised at $\pm 45^\circ$ to the director the phase retardation ϕ, in radians, will be determined by the intrinsic birefringence of the liquid crystal ($\Delta n = n_e - n_o$), the film thickness ℓ and the wavelength of the light λ

$$\phi = \frac{2\pi\ell}{\lambda}(n_e - n_o)\,; \tag{36.16}$$

n_e and n_o are respectively the extraordinary (slow) and ordinary (fast) refractive indices of the liquid crystal (assuming that Δn is positive). If the emergent elliptically polarised light passes through a second polariser, crossed with respect to the incident polarisation direction, only a proportion of the incident intensity will be transmitted. The normalised intensity of light transmitted by a pair of crossed polarisers having a birefringent element between them, the axis of which is at $\pm 45^\circ$ to the extinction directions of the polarisers is given by

$$T = \left(\frac{1}{2}\right)\sin^2\frac{\phi}{2} \tag{36.17}$$

(the factor of one half appears for incident unpolarised light – if the light is polarised, as from a laser, then the factor is one).

Thus the initial appearance of the cell will be brightest if the cell thickness, birefringence and wavelength are chosen to give ϕ equal to π, 3π, 5π etc. It is normal to select the cell thickness to give $\phi = \pi$, and under these conditions the display is known as *normally white*. It is possible, though less satisfactory, to configure the display so that it operates in a *normally black* state, corresponding to a phase retardation of a multiple of 2π.

Application of an electric field causes the director orientation to change such that the optical retardation of the cell decreases to zero, and hence the cell becomes non-transmitting, at least in the normally white configuration. Under these circumstances the optical retardation across the cell becomes

$$\phi = \frac{2\pi}{\lambda}\int_0^\ell \left(n_e\left[\theta\,(z)\right] - n_0\right)\mathrm{d}z\,, \tag{36.18}$$

where the effective extraordinary refractive index $n_e[\theta(z)]$ depends on the angle $[90^\circ - \theta(z)]$ between the director and the field and is a function of position z in the cell. This effective index is given by

$$\frac{1}{n_e^2[\theta(z)]} = \frac{\sin^2[\theta(z)]}{n_o^2} + \frac{\cos^2[\theta(z)]}{n_e^2}\,; \tag{36.19}$$

when the director is along the field direction $\theta = 90^\circ$, so $n_e(90^\circ) = n_o$, and $\phi = 0$.

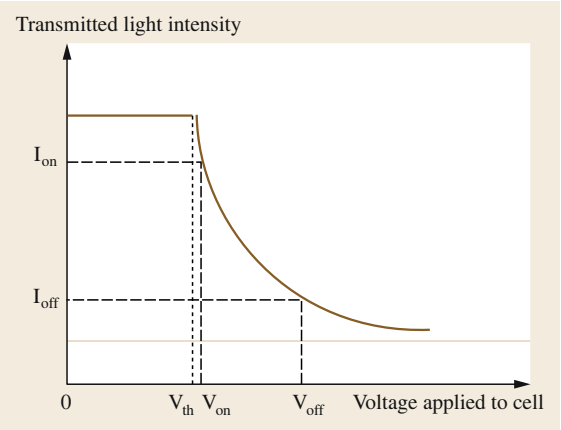

Fig. 36.17 Variation of optical transmission with voltage for an ECB cell between crossed polarisers

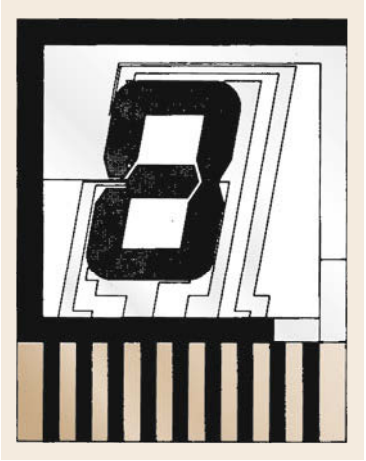

Fig. 36.18 Schematic of a directly addressed seven-segment liquid-crystal display

The orientational distribution of the director in the cell in the presence of an applied electric field is determined by the strength of the field, the electric permittivity and elastic constants of the liquid crystal, and most importantly by the properties at the interface between the liquid crystal and the aligning surfaces. If the director at the surface satisfies the *strong-anchoring* condition, i. e., it is unaffected by the applied electric field, and the surface director is strictly perpendicular to the electric field, then the reorientation of the director exhibits a threshold response, known as a Fréedericksz transition. The change in transmitted intensity as a function of voltage can be calculated using continuum theory and simple optics [36.36], and a typical transmission curve for an ECB cell is illustrated schematically in Fig. 36.17.

The threshold voltage for director reorientation is independent of cell thickness, and is given by

$$V_{\mathrm{th}} = \pi \sqrt{\frac{K_1}{\varepsilon_0 \Delta\varepsilon}} \,, \tag{36.20}$$

where $\Delta\varepsilon$ is the anisotropy in the dielectric permittivity and K_1 is the splay elastic constant. However, it is clear from (36.17) and (36.18) that the intensity of light transmitted by the ECB cell depends on the cell thickness and the wavelength of light. This undermines the usefulness of displays based on the ECB mode, since they require cells of uniform thickness and also they will tend to show colouration in white light. Another important operating characteristic of displays is the *angle of view*, i. e., how the image contrast changes as the angle of incidence moves away from 90° with respect to the plane of the cell. This is clear from Fig. 36.16, where the optical paths in the distorted state for observation to the left or right of the perpendicular to the electrodes are clearly different.

In order to construct a useful display from a simple on/off shutter, it is necessary to consider how image data will be transferred to the display. This is known as *addressing*, and to a large extent it is determined by the circuitry that drives the display. However, we shall see that certain properties of liquid crystals also contribute to the effectiveness of different types of addressing. The simplest method of displaying images on a liquid-crystal display is to form an array of separate cells of the type illustrated by the ECB cell, each having a separate connection for the application of an electric field. Images can then be created by switching on, or off, those cells required to form the image. This technique is known as *direct addressing*, and can be illustrated by the seven-segment displays used in watches and numerical instrument displays (Fig. 36.18).

To create complex displays, a large number of separate cells, known as picture elements or pixels, must be fabricated, usually in the form of a matrix. Providing separate electrical connections for these pixel arrays (e.g., 640×480) for a standard visual graphics array (VGA) computer screen, is impossible, and so other methods of addressing have had to be developed. Historically, the first was the technique known as *passive matrix addressing*, in which the array of cells are identified in rows and columns, and connections are only made to the rows and columns: for an array of $n \times m$ pixels, only $n + m$ connections are made instead of $n \times m$, as required for direct addressing. Each row is activated in turn (sequentially), and appropriate voltage pulses applied to the columns. Only those pixel elements for which the sum of column and row voltages exceeds a *threshold* are switched to an on-state. However, the problem with this method is that many unwanted pixels in the off-state still have a voltage applied, and may

be partially activated in the display: so-called *crosstalk*. The time-sharing of activating signals is known as multiplexing, and it relies on the addressed pixels holding their signal while other pixels which make up the image are activated. Provided that the multiplexing is on a time scale of milliseconds, any fluctuation in the image goes unnoticed. However, if the multiplexing becomes too slow, the image starts to flicker. In fact there is a limit to the number of rows of the matrix which can be addressed ($n_{\max}$), which is related to the ratio of the on-voltage to off-voltage by a result due to *Alt* and *Pleshko* [36.37]:

$$\frac{V_{\text{on}}}{V_{\text{off}}} = \sqrt{\frac{n_{\max}^{1/2}+1}{n_{\max}^{1/2}-1}} \,. \tag{36.21}$$

The cell characteristic which determines the values of V_{on} and V_{off} is the optical transmittance curve, as illustrated in Fig. 36.17. Depending on the desired contrast ratio $I_{\text{on}}/I_{\text{off}}$ for a pixel, then the voltages $V_{\text{on}}/V_{\text{off}}$ are determined. Thus, in the operation of a passively addressed matrix display, there is a tradeoff between the contrast ratio ($I_{\text{on}}/I_{\text{off}}$) and the number of rows, i. e., the complexity of the display. The shape of the transmittance curve is determined by the liquid-crystal material properties, and so these affect the resolution of the image displayed. For a desired contrast ratio of 4, the corresponding on/off ratio for an ECB cell might be 1.82. This gives a maximum number of rows as four, which corresponds to a very-low-resolution display, which would be unusable except for a very basic device. This brief description of a simple electro-optic display operating in the ECB mode illustrates that its performance depends on the dielectric, optical and elastic properties of the liquid-crystal material used. Additionally, the properties at the liquid-crystal-substrate interface and the geometry of the cell will influence the electro-optic response of the cell.

One performance characteristic that is of very great importance is the speed with which the display information can be changed, since this determines the quality and resolution of moving images. The dynamics of fluids are related to their viscosity, and it has already been shown that the viscous properties of liquid crystals are complicated to describe, and are correspondingly difficult to measure. The complication arises because liquid crystals are elastic fluids, and so there is a coupling between the flow of the fluid and the orientation of the director within the fluid. We have seen that the motion of the director can be described in terms of a rotational viscosity, and the optical properties exploited in displays are related to changes in the director orientation. Thus it is the rotational viscosity that is of primary importance in determining the time response of displays. However, the fact that changes of director orientation cause fluid flow in liquid crystals complicates the process.

The time response of a liquid-crystal display pixel can be illustrated by reference to the ECB display, although other cell configurations modify the behaviour to some extent. In what follows, we shall assume that the reorientation of the director within a display pixel does not cause the nematic liquid crystal to flow. For a uniform parallel-aligned nematic-liquid-crystal film, the time for the director to respond depends on the magnitude of the electric field (or voltage) applied to the cell. If the voltage applied is only just greater than the threshold voltage, then the time is very long, while if a large voltage is applied, then the director responds quickly. It is found that the time response can usually be represented as an exponential behaviour, although effects of flow will change this. Neglecting these, a response time τ_{on} can be defined in terms of the change in transmitted-light intensity as

$$\frac{I(t)-I(0)}{I_{\text{on}}-I(0)} = 1-\exp\left[-\left(\frac{t}{\tau_{\text{on}}}\right)\right]. \tag{36.22}$$

and the relaxation time for switching on the display is given approximately by [36.38, 39]

$$\tau_{\text{on}} = \frac{\gamma_1 \ell^2}{\pi^2 K_{\text{eff}}}\left[\left(\frac{V_{\text{on}}}{V_{\text{th}}}\right)^2 - 1\right]^{-1} . \tag{36.23}$$

On removing the applied voltage, the display element returns to its off-state, but with a different relaxation time which is independent of the applied voltage, such that

$$\tau_{\text{off}} = \frac{\gamma_1 \ell^2}{\pi^2 K_{\text{eff}}} ; \tag{36.24}$$

here γ_1 is the rotational viscosity coefficient, and the effective elastic constant K_{eff} that appears in these expressions is the splay elastic constant K_1 for the ECB-mode display. These equations can be modified for other display configurations by changing K_{eff}.

Although the ECB-mode display is the simplest that can be envisaged, based on the Fréedericksz effect, there are many disadvantages, in particular with respect to its viewing characteristics, and it has not been used commercially to any significant extent. However, the apparently simple modification of twisting the upper plate by 90° has resulted in the phenomenally successful twisted nematic display, which represents a large part of today's multi-billion-dollar market.

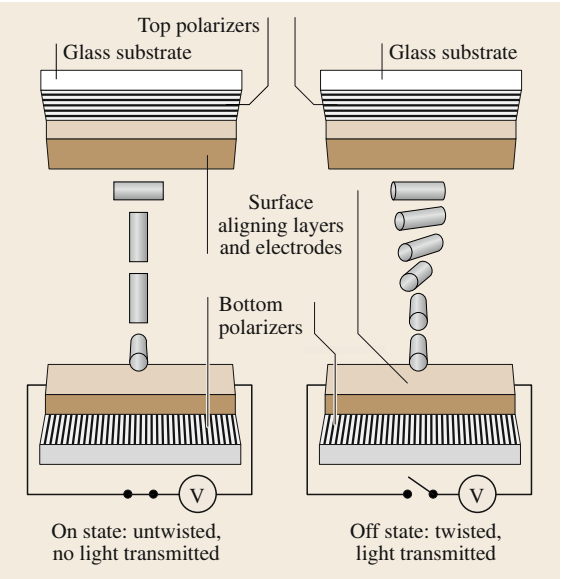

Fig. 36.19 Schematic of a twisted nematic display

36.3.2 High-Volume Commercial Displays: The Twisted Nematic (TN) and Super-Twisted Nematic (STN) Displays

The simple twisted-nematic display is essentially the same as the ECB display depicted in Fig. 36.16, except that the orientations of the surface director at the containing glass plates are rotated by 90°. However, the TN cell, invented by *Schadt* and *Helfrich* in 1970 [36.40], represented a considerable improvement over earlier devices, and rapidly became the preferred configuration for commercial displays. A schematic representation of the TN cell is given in Fig. 36.19.

This twisted configuration for a liquid crystal film was discovered by Mauguin, who found that instead of producing elliptically polarised light, such a twisted film could rotate the plane of polarisation by an angle equal to the twist angle between the surface directors of the glass plates [36.41]. In fact by working through the optics of twisted films, Mauguin showed that perfect rotation of the plane of polarisation only resulted if the film satisfied the following condition

$$2\Delta n\ell \gg \lambda\,. \tag{36.25}$$

Thus for the cell illustrated in Fig. 36.19, the off-state would be perfectly transmitting. This is known as the *normally white* mode. In reality the cells used for TN displays do not meet the Mauguin condition, and the transmission for a 90° twisted cell between crossed polarisers and incident unpolarised light is given by [36.42]

$$T = \frac{1}{2}\left(1 - \frac{\sin^2\left(\frac{\pi}{2}\sqrt{1+u^2}\right)}{1+u^2}\right), \tag{36.26}$$

where $u = \frac{2\Delta n\ell}{\lambda}$. Equation (36.26) shows that, for sufficiently large u, the transmission T is indeed a maximum of 0.5, however it is also a maximum for $u = \sqrt{3}$, $\sqrt{15}$, $\sqrt{35}$, etc. These points on the transmission curve correspond to the *Gooch–Tarry minima*; they are labelled as minima, since they were found for a TN cell operating in the *normally black* state. Most commercial cells operate under conditions of the first or second minima so that thin cells can be used, which give faster responses. It is, therefore, important that the birefringence of the liquid-crystal material can be adjusted to match the desired cell thickness, so that the display can have the best optical characteristics in the off-state.

Application of a sufficiently strong electric field across the twisted film of a nematic liquid crystal having a positive dielectric anisotropy causes the director to align along the field direction. Under these circumstances the film no longer rotates the plane of polarised light, and so appears dark. The transmission as a function of voltage for a twisted cell is similar to that shown in Fig. 36.17, except that the transmission varies more strongly with change in voltage above the threshold, and drops to zero much more rapidly. In contrast to the ECB cell discussed above, the threshold voltage for a TN cell depends on all three elastic constants

$$V_{\mathrm{th}}^{\mathrm{TN}} = \pi\sqrt{\frac{\left(K_1 + \frac{\zeta}{2}(K_3 - 2K_2)\right)}{\varepsilon_0\Delta\varepsilon}}\,, \tag{36.27}$$

where ζ is the twist angle (usually $\pi/2$). The relative change of the transmission intensity with voltage of the TN cell is greater than for the ECB cell, and it can be shown that the steepness of the transmission curve increases as the property ratios K_3/K_1 and $\Delta\varepsilon/\varepsilon_\perp$ decrease. The on/off voltage ratio for a TN cell is closer to unity, than for an ECB cell, and so for similar contrast ratios more lines can be addressed: up to about 20 for typical cells and materials. This is significantly larger than for the ECB cell, and so the TN cell allows more complex images to be displayed. There is still a wavelength dependence for the transmission, although this is less marked than for the ECB mode. However, even with the improved multiplexing capabilities of the TN display over the ECB cell, it is still not good enough to use for computer screens. One very successful approach to solve this problem was to modify the TN cell geometry so that instead of a 90° twist, the directors

on opposite sides of the cell are rotated by about 270°. This is known as a super-twisted nematic cell.

The concept of the 270° super-twisted nematic (STN) display seems at first sight to be irrational [36.43, 44]. The director is an apolar vector and so there should be no difference between a 270° and a 90° twisted cell. However, it is possible to maintain a director twist greater than 90° if the liquid crystal is chiral. The use of chiral additives in 90° TN cells was already established, since a very small quantity of chiral dopant added to a TN mixture would break the left/right twist degeneracy in the cell and so remove patches of reversed twist, giving a much improved appearance to the display. If the amount of chiral dopant was increased, then the chiral liquid-crystal mixture would develop a significant intrinsic pitch. By adjusting the concentration of the chiral dopant, the pitch of the mixture could be matched to the 270° twist across the cell thickness of ℓ, i. e., $p \approx 4\ell/3$. An STN cell operates in the same way as a TN cell, so that an applied electric field causes the director to rotate towards the field direction, thereby changing the optical retardation through the film and the transmission between external crossed polarisers. However, the additional twist in the STN cell has a significant effect on the optical properties of the nematic film.

The optical characteristics of the STN off-state are usually outside the Mauguin condition, which means that polarised light passing through the cell is not guided, and emerges elliptically polarised. The degree of ellipticity is wavelength dependent, and so in white light the off-state appears coloured, as does the on-state. An ingenious solution to this problem is to have two identical STN cells, one behind the other, but where the second compensating cell has a twist of the opposite sense. In operation, only the first of the cells has a voltage applied to it. The compensation cell acts to subtract the residual birefringence of the liquid crystal layer, and the display now switches between white and black. Despite this additional complexity, the huge advantage of the STN display is the rapid change in optical transmission with increasing voltage, and a full optical analysis shows that under optimum conditions the rate of change of transmission with voltage can become infinite. In modern implementations of the STN display, the residual birefringence can be compensated by an optical film, avoiding the need for double cells. It is easy to operate an STN display with a V_{on}/V_{off} ratio of 1.1, which corresponds to an n_{max} of 100. The shapes of the transmission/voltage curve of ECB, TN and STN cells are a direct consequence of the dielectric and elastic properties of the liquid-crystal material, but also depend strongly on the configuration of the cells and the surface alignment

In the description given of displays and their performance, some important aspects have been ignored. The surface orientation of the directors has been assumed to be pinned in the surface plane, which is the requirement for a threshold response. However, it has been found that the performance of displays can be greatly improved if this condition is relaxed, and a pre-tilt is introduced to the cell, such that the surface director may make an angle of up to 60° to the plane of the containing glass plates. This pre-tilt can be introduced by different surface treatments, and it depends on the interfacial properties of the liquid crystal. An important performance characteristic of displays is the angle dependence of the contrast ratio, or more simply how the appearance of the displayed image changes with angle of view. This is largely determined by the display design, and can be accurately calculated from the optical properties of the cell. The refractive indices of the liquid crystal will affect the contrast ratio and angle of view, but precise control of these performance parameters is difficult. Improvements to the appearance in terms of the angle of view or brightness of displays have been achieved by placing precisely manufactured birefringent polymer films behind or in front of liquid-crystal cells.

36.3.3 Complex LC Displays and Other Cell Configurations

The STN configuration described above used passive matrix addressing, and this opened up the possibility of relatively large-area, high-resolution displays, which could be used in laptop computers and other hand-held displays. The next step was to introduce colour by dividing each picture element into three sub-pixels with red, green and blue filters. However, the demand in some market sectors for larger displays with improved appearance having higher resolution (extended graphics array (XGA) displays have 1024×768 pixels) overwhelmed the capability of passive matrix addressing, and the alternative method of active matrix addressing is now used for more complex displays. This technique requires each pixel to have its own switch, as in the simple seven-segment display already described. For high-resolution displays hundreds of thousands of switches are provided by thin-film transistors deposited onto the glass substrate, which forms the screen. These are known as thin-film-transistor twisted-nematic (TFT-TN) displays [36.45]. The sophistication of these displays relies on the capabilities of integrated circuit technology, but the properties of the liquid-crystal materials must still be optimised for the device configuration. A representation of a TFT-TN display is given in Fig. 36.20.

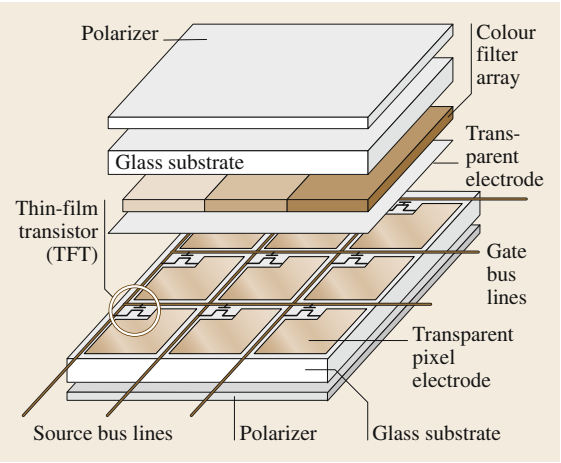

Fig. 36.20 Schematic of a complex colour TFT-TN display

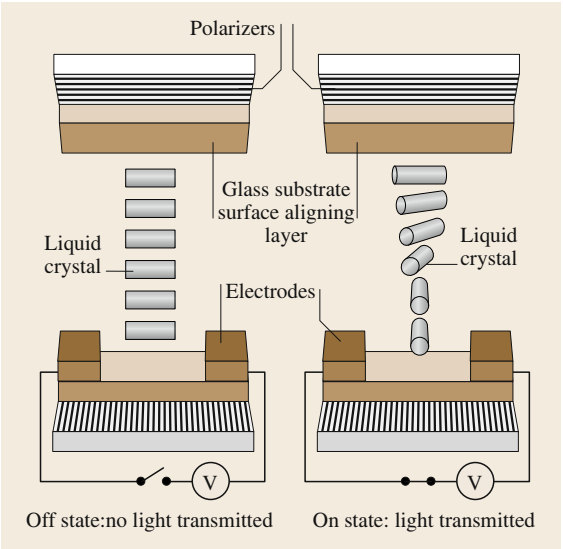

Fig. 36.21 Schematic of an in-plane switching mode display

Although being described as an active matrix, the TFT-TN display still uses sequential addressing of pixel rows, and so activated pixels must remain switched on while the rest of the display image is created. The TFTs provide a source of voltage to each liquid-crystal pixel, which must then hold its charge, as a capacitor, until the image is changed. So another property of liquid crystals becomes important, that of low electrical conductivity, since the charge on a pixel will be lost by conduction through the liquid crystal. This determines the choice of materials for TFT-TN displays. Generally, high dielectric anisotropy is a desirable property for liquid-crystal display mixtures, since it reduces the operating voltage. However, materials with a high dielectric constant tend to have a high electrical conductivity, since charges either from impurities or leached from surfaces will be stabilised in high-dielectric-constant fluids. Thus the selection of suitable materials requires a compromise between its dielectric and conductance properties, and, of course, the all important refractive indices.

Many different cell configurations, which exploit the optical properties of liquid crystals in different ways, have been tried, and some of these have been commercialised to meet particular market requirements. One rather successful approach to the problem of restricted viewing angle has been the development of the in-plane switching (IPS) mode twisted-nematic display [36.46, 47]; this is illustrated in Fig. 36.21. The two optical states of the cells are (i) twisted, and (ii) planar (parallel aligned film), and the director is switched between these states by application of an electric field across electrodes on a single plate of the cell. The state that is stabilised by the electric field depends on the dielectric anisotropy of the liquid-crystal material. The preferred configuration uses materials having a negative dielectric anisotropy, so that the off-state is a planar-aligned liquid-crystal film. Application of an electric field to the in-plane electrodes will cause the director at the bottom surface to align perpendicularly to its initial direction, and so induce a twist through the cell (Fig. 36.21).

From an optical point of view, the director is always in the plane of the cell, and this means there is less distortion of an image when viewed at angles other than 90°. Another advantage of the IPS device is that the electric field is confined to the lower plate, and the lines of force do not extend across the cell to the grounded upper plate. This means that a very low electrical conductivity of the liquid-crystal material is less important than for conventional TFT-TN displays. The threshold voltage for the IPS-mode device is given by

$$V_{\mathrm{th}}^{\mathrm{IPS}} = \frac{\pi d}{\ell}\sqrt{\frac{K_2}{\varepsilon_0 \Delta\varepsilon}}\,, \tag{36.28}$$

where ℓ is the thickness of the liquid-crystal film, and d is the separation of the in-plane electrodes. Not surprisingly the threshold depends only on the twist elastic constant, which is usually smaller by about a factor of two than the splay and bend elastic constants. While this helps to reduce the operating voltage, the smaller elastic energy associated with the pure twist deformation results in longer switching times. A further disadvantage of the IPS display is that the optical transmission of the cell is reduced by the requirement to have both electrodes deposited on one plate, thereby

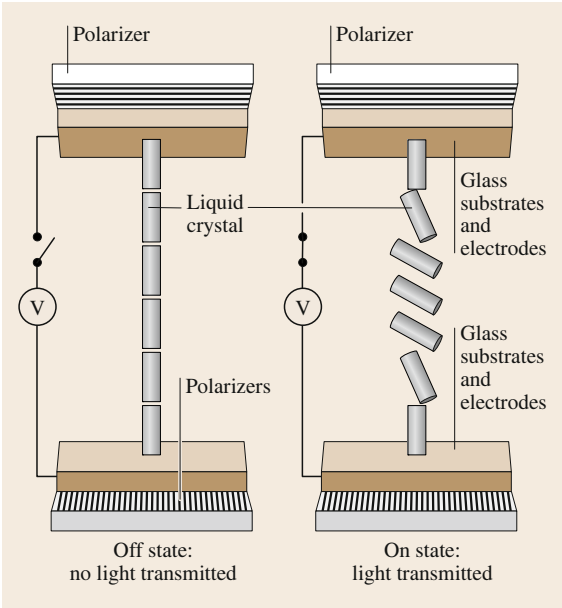

Fig. 36.22 Schematic of a twisted vertically aligned display

making smaller the active area available to display the image.

A configuration which shares some of the characteristics of the IPS cell and has been successfully commercialised is the twisted vertically aligned nematic (TVAN) cell. The two optical states for this configuration are uniform vertical (homeotropic) alignment of the director for the off-state, and a twisted geometry for the on-state (Fig. 36.22). The liquid-crystal material used has a negative dielectric anisotropy, so application of an electric field between the plates causes the director to align perpendicularly with respect to the field direction. A small quantity of optically active material (chiral dopant) is added to the liquid-crystal mixture to ensure that the switched director adopts a twisted configuration through the cell. The advantages of this cell are good viewing-angle characteristics and high optical contrast. Improvements in display technology continue to be made, often simplifying earlier devices. For example, high-quality displays described as vertically aligned nematic (VAN) devices are now available based on the TVAN configuration, but without the twist. The material requirement here is for a liquid crystal of negative dielectric anisotropy, that will align perpendicularly to an applied electric field.

In the devices described above, one state is defined by the surface conditions of the cell, while the other is defined by the action of the applied electric field. A bistable device is one in which two stable field-free states exist, both of which are accessible

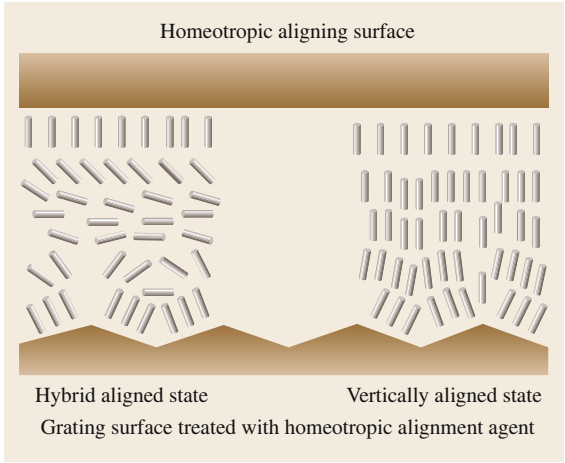

Fig. 36.23 Schematic of a zenithal bistable device

by switching with an external field. The first bistable liquid-crystal display to be developed was based on a ferroelectric effect observed in chiral tilted smectic C liquid crystals [36.48]. This ferroelectric smectic display has achieved some limited commercial success in specialist markets, but relies on a surface stabilisation of smectic layers, which is very sensitive to mechanical shock. Recently [36.49], bistable nematic displays have been developed in which two alignment states within a liquid-crystal cell, having different optical transmission, can be stabilised. If one of the substrates of a normal cell is replaced by a surface which has potentially two states of minimum energy corresponding to two surface alignments of the director, then it becomes possible to switch these states selectively using an electric field. A suitable bistable surface is provided by a grooved surface (grating) which has been treated with a surfactant to favour homeotropic alignment of the director at its surface [36.50]. Thus the two surface states correspond to (i) that determined by the grating, and (ii) that determined by the surfactant where the director is perpendicular to the substrate. Combining this intrinsically bistable substrate with a second substrate having a director alignment direction perpendicular to the grating direction gives a cell configuration capable of supporting two optically distinct stable states, which can be switched between using an applied voltage. Various director configurations are possible with this type of cell, and one example is illustrated in Fig. 36.23.

In the absence of any perturbation, the director orientation within the cell will be determined by the homeotropic alignment at one substrate and the alignment at the grating substrate. This hybrid (uniform planar and homeotropic) alignment causes a spatially varying director tilt through the sample. Application of

an electric field to a positive-dielectric-anisotropy material will cause the director to align parallel to the applied field, and eventually a fully homeotropic configuration for the director is stabilised. The switch back from the homeotropic state to the hybrid state is thought to be due to a flexoelectric interaction. Other alignment configurations are also possible for the so-called zenithal bistable nematic (ZBD) cell. Displays based on these configurations share the good viewing characteristics of both the IPS and TVAN configurations, but they have the great advantage that the image is retained when the voltage is removed.

All the displays described so far rely on the coupling between an applied electric field and the dielectric properties of the liquid-crystal material, but, as we have shown, other material properties are just as important to the operating characteristics of the display. The appearance of a display depends on the optical properties of the liquid crystal and the cell configuration, but the operating voltage and switching times of a display are crucial in determining the types of application. Changing the nature of the interaction between the switching electric field and the liquid crystal gives rise to another range of possibilities for liquid-crystal devices. Under certain circumstances, a liquid crystal can be made to exhibit permanent ferroelectric (or spontaneous) polarisation, and this couples linearly with an external electric field, in contrast to dielectric properties which couple with the square of the electric field strength. Not surprisingly this makes a big difference to the switching behaviour of liquid crystals.

The final display to be considered is based on flexoelectric coupling between the electric field and the liquid crystal. Flexoelectricity occurs, in principle, with all liquid crystals, chiral or not, and shows itself as a bulk electric polarisation induced by an elastic strain. Conversely application of an electric field can cause an elastic strain. In general, flexoelectricity is rather small and difficult to detect, however it is thought to be responsible for an electro-optic effect observed in chiral nematic liquid crystals, which is being investigated for display applications. The effect, sometimes known as the deformed helix mode [36.51], is similar in some respects to the ferroelectric switching observed in chiral smectic C phases, but there is no longer a requirement for a layered structure. Chiral nematic liquid crystals spontaneously form helical structures in which the director rotates with a pitch determined by the molecular structure. If an electric field is applied perpendicularly to a chiral-nematic helix, then there is a tendency for the helix to unwind, depending on the sign of the dielectric anisotropy. Even if the dielectric anisotropy of the material is zero, there is an elastic strain which can generate a polarisation (flexoelectric polarisation), which

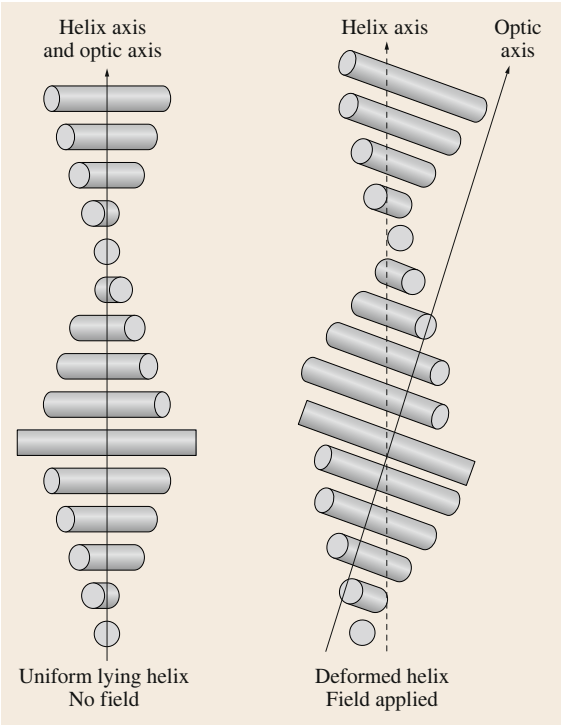

Fig. 36.24 Schematic of a deformed helix mode flexoelectric display

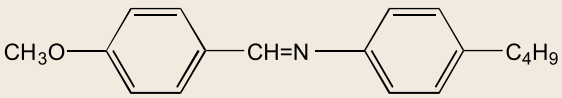
will interact with an applied electric field. This may be exploited in a device configuration, where a thin film of a chiral nematic liquid crystal, having a small or zero dielectric anisotropy, is aligned such that its helix axis is parallel to the containing glass plates (Fig. 36.24).

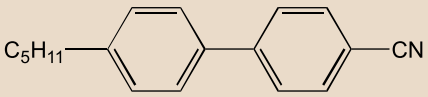
Application of an electric field across the plates will cause a distortion of the helix through the splay and bend flexoelectric coefficients, which appears as a rotation of the optic axis in the plane of the film [36.25]. Reversal of the electric field direction will reverse the rotation of the optic axis, with an intrinsic switching time about one hundred times faster than conventional nematic displays. Optically, the effect observed is very similar to that exhibited by smectic ferroelectric displays.

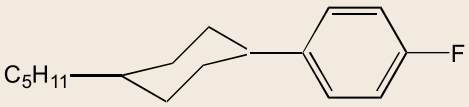
There are many cell configurations that can be used with liquid crystals to produce optical switches, displays or light modulators, and some of the more important have been described. The precise operation and performance of these liquid-crystal devices depends on both the cell design and the material properties of the liquid crystal. To a large extent the configuration of the liquid crystal within the cell is determined by such factors as the surface treatment of the plates enclosing the liquid crystal and the interactions between the surfaces and the liquid crystal. Our under-

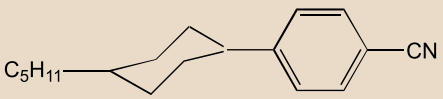
standing of these interactions is very limited at the present time, and much more research is necessary before a quantitative theory can be formulated. However, given the cell configuration, the performance of the liquid-crystal device depends critically on the physical properties of the liquid-crystal material. Thus the electrical switching characteristics will depend on the dielectric properties, while the optical appearance of the device will be determined by the refractive indices. Elastic properties contribute to both the electric field response and the optical appearance, since any deformation of the director will be determined by the elastic properties of the liquid crystal. Finally, the all-important dynamical behaviour will be controlled by the viscous properties of the liquid crystal. All these material properties will be discussed in the next section.

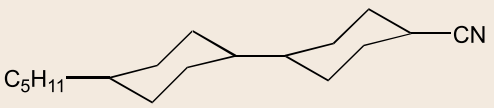
36.4 Materials for Displays

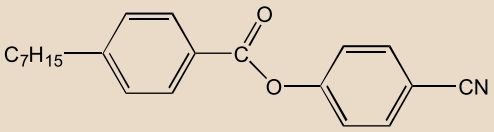


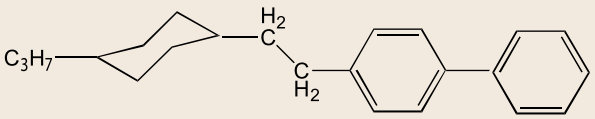












The most important requirement for a liquid-crystal display material is that it should be liquid crystalline over the temperature range of operation of the device. Despite this, some of the first experimental display devices incorporated heaters in order to maintain the material in the liquid-crystal phase: for example, the first liquid-crystal shutter patented by Marconi and early prototype displays developed by the Radio Corporation of America (RCA). It was not until the late 1960s that room-temperature nematic liquid crystals suitable for display applications were discovered. The first of these were based on Schiff's bases, which although easy to prepare, were difficult to purify and were susceptible to chemical decomposition in a device. One material which attracted particular attention from experimental physicists was MBBA, which has a nematic range of 22–47 °C (Table 36.1). The basic two-ring core linked by an imine group was the structural unit of many compounds having different terminal groups which were prepared for display mixtures in the early 1970s. It was found that mixtures of Schiff's bases often had lower crystal-to-nematic transition temperatures than any of the components, and furthermore would often remain liquid crystalline even below the thermodynamic crystallisation temperature. These two phenomena of eutectic behaviour and super-cooling have been exploited in the development of materials for devices. The early experiments on liquid-crystal displays were primarily focused on nematic or chiral compounds, but we have seen that other displays have been developed which use different liquid-crystal phases, most importantly the chiral smectic C phase.

Early studies established guiding principles for the development of display materials. First, the phase behaviour must be acceptable, i. e., the right phase stable over a suitable temperature range. Secondly, the material must have the correct electrical and optical properties for the particular display application envisaged, and above all must be of sufficient chemical purity to prevent any deterioration in performance over time. Again, guided by the early experiments, suitable display materials require the synthesis of compounds of appropriate chemical structure, and then the formulation of mixtures to optimise the properties. There have been a number of reviews of liquid-crystal materials for displays [36.53, 54, 56–59] and these contain many tables of data on a wide range of compounds. In this Section, we will give a brief account of the basic chemical structures used for materials in modern liquid-crystal displays, and then show how mixtures are devised to give the best possible performance characteristics for different displays. It has to be recognised that many of the details of display materials are matters of commercial confidentiality, and so it is not possible to give precise accounts of materials currently used or under investigation. However, the generic chemical structures and principles used in developing suitable mixtures are generally applicable.

36.4.1 Chemical Structure and Liquid-Crystal Phase Behaviour

There is a huge literature on the relationship between the structure of mesogens and the nature and stability of the liquid-crystal phases they form [36.60]. The studies have embraced empirical correlations of chemical structure and phase behaviour, theoretical calculations for simple particles (hard rods, spherocylinders etc.) representing mesogens, and computer simulations of collections of particles of varying complexities. For the display applications considered in this Chapter, the desired phases are nematic, and occasionally chiral nematic or chiral smectic C. Such phases are formed by molecules having extended structures, which usually require the presence of terminal alkyl chains to reduce the crystallisation temperatures. Components in nematic display mixtures typically have two, three or four carbocyclic rings joined directly or through a variety of linking groups.

Table 36.1 Some typical liquid-crystal materials, including selected physical properties ((ex) – extrapolated from measurements on a nematic solution)

Compound Transition temperatures (°C) [reference]	$\Delta\varepsilon$ (T °C)	Δn (T °C)	Rotational viscosity (γ_1/m Pa s)
 T_{CrN} 22 °C T_{NI} 47 °C [36.53]	≈ 1	0.2	$\gamma_1 = 109$ [36.52] (37 °C)
 T_{CrN} 22 °C T_{NI} 35 °C [36.53]	8.5 (29 °C)	0.18 (25 °C)	$\gamma_1 = 102$ [36.52] (25 °C)
 T_{CrI} 34 °C [36.54]	3.2 (ex)	0.05 (ex)	
 T_{CrN} 31 °C T_{NI} 55 °C [36.53]	9.9 (48 °C)	0.12 (40 °C)	$\gamma_1 = 128$ [36.52]
 T_{CrN} 62 °C T_{NI} 85 °C [36.53]	3.5 (78 °C)	0.05	
 T_{CrN} 44 °C T_{NI} 57 °C [36.53]	19.9 (40 °C)	0.15	
 T_{CrN} 67 °C T_{NI} 82 °C [36.55]	≈ 0	0.15	

36.4.2 The Formulation of Liquid-Crystal Display Mixtures

The two requirements for a liquid crystal to be used in a display are a suitable temperature range of phase stability and appropriate physical properties. These requirements cannot be satisfied for complex displays by a single compound, and commercial display materials may contain up to twenty different components. The formulation of these mixtures is essentially an empirical process, but guided by the results of thermodynamics and experience. The principles behind the preparation of multicomponent mixtures can be illustrated initially by consideration of a binary mixture.

It is well-known that the melting point of a binary mixture of miscible compounds is depressed, sometimes below the melting points of both components. Furthermore, the melting point of the binary mixture may exhibit a minimum at a particular composition, known as the eutectic. This occurs with liquid-crystalline compounds, and provides a method of reducing the lower temperature limit for liquid-crystal phase stability in mixtures. The upper temperature limit of the liquid-crystal range is fixed by the transition to an isotropic liquid. The phase rule of Willard Gibbs

predicts that in binary mixtures there will always be a region of two-phase coexistence in the vicinity of a phase transition; that is, the transition from liquid crystal to isotropic occurs over a range of temperatures for which both the isotropic liquid and liquid crystal are stable in the mixture. Because of the weak first-order nature of most liquid crystal to isotropic phase transitions, the two-phase region is small. The character of phase transitions is determined by the corresponding entropy change, and a weak first-order transition has a small $\left(\approx 2\,\mathrm{J\,K^{-1}\,mol^{-1}}\right)$ associated entropy. If the latter were zero, then the transition would be second order, and there would no longer be a region of two-phase coexistence. The phase diagrams of multicomponent nematic mixtures can be calculated by thermodynamic methods [36.61, 62] and the transition temperatures of the mixtures can vary with composition in a variety of ways. For mixtures of two liquid-crystalline compounds of similar chemical constitution, the variation of the nematic to isotropic transition temperature is approximately linear with composition [36.63].

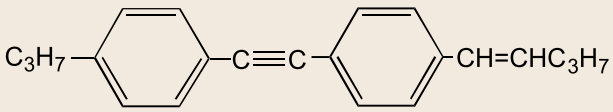
It is possible to calculate the variation of the melting point with composition using an equation attributed to Schroeder and van Laar. For each component i, the mixture composition (mole fraction x_i) and the melting point of the mixture T are related by

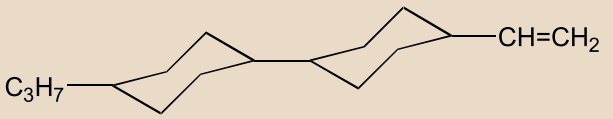
$$\ln x_i = -\frac{\Delta H_i}{R}\left(\frac{1}{T} - \frac{1}{T_i}\right), \tag{36.29}$$

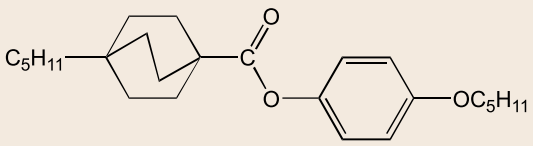
where ΔH_i and T_i are, respectively, the latent heat of fusion and melting point of the pure component i. For a binary mixture there are two such equations which can be solved to give the eutectic temperature and composition. In a multicomponent mixture, the set of equations (36.29) can be solved subject to the condition,

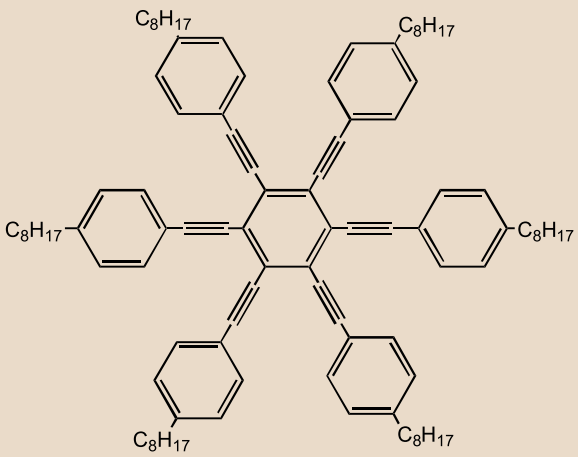
$$\sum_i x_i = 1 \tag{36.30}$$

to predict the eutectic of the mixture.









While there is a reasonable thermodynamic basis to the prediction of the phase diagrams of mixtures, the determination of the physical properties of mixtures from the properties of individual components is much more difficult. Given the absence of any better theories, it is common to assume that in mixtures, physical properties such as dielectric anisotropy, birefringence and even viscosity vary linearly with the amount of any component, at least for small concentrations. While this may give an indication of the effect of different components on the properties of a display mixture, it can also be very misleading. One theoretical problem is that, for a mixture at a particular temperature, the orientational order parameters of the different components are not equal. The more anisometric components (e.g., three-ring mesogens) are likely to have a larger orientational order parameter than smaller (two-ring) mesogens. Since the various physical properties of interest in displays depend on the order parameter in different ways, it is difficult to predict the contribution of different components to the overall mixture properties. Despite this, many tables of data for liquid-crystal compounds of interest for display mixtures are prepared [36.60] on the basis of extrapolated measurements on mixtures at low composition, normally $< 20\,\mathrm{wt\%}$. There is always a problem concerning the temperatures at which to compare the physical properties of liquid crystals and their components. Many measurements are made at room temperature, so that this becomes the temperature for comparison. However, a more useful approach is to compare properties at equal reduced temperatures (or at the same shifted temperatures, $T_{\mathrm{NI}} - T$), since under these conditions the orientational order parameters are likely to be similar.

36.4.3 Relationships Between Physical Properties and Chemical Structures of Mesogens

Electrical and Optical Properties

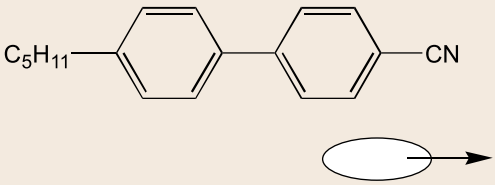
These properties include the dielectric permittivity, electrical conductivity and refractive indices. The magnitude of the dielectric anisotropy determines the threshold voltage necessary to switch a display, and influences the transmission/voltage characteristics of the cell. Depending on the particular display configuration, a positive or negative dielectric anisotropy may be required. Refractive indices strongly affect the appearance of a display. Usually the refractive indices or birefringence must be adjusted for a particular cell configuration to give the optimum on/off contrast ratio. Coloration in displays can sometimes occur in materials of high refractive index, and so it is desirable to keep the birefringence as low as possible, compatible with an acceptable contrast ratio. For twisted structures, the magnitude of the birefringence also determines the efficiency of light guiding, and so close control of the values of the principal refractive indices of a display mixture is important. For non-conducting materials, the refractive indices are measures of the dielectric response of a material at very high, i. e., optical frequencies, and it is possible to formulate a single theory which relates the dielectric and optical properties of a liquid crystal to its molecular properties. Unfortunately this is

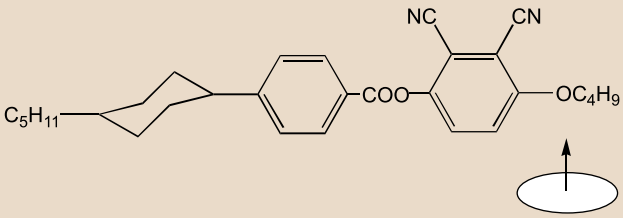
Table 36.2 Materials of high, low and negative birefringence

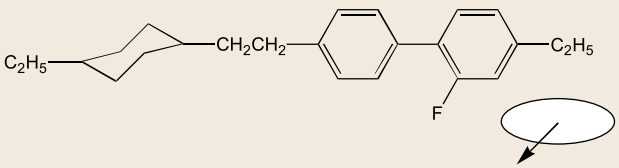
Compound	Transition temperatures	Δn [reference] (T °C)
	T_{NI} 112 °C	0.31 [36.64] (92 °C)
	T_{CrSmB} 23 °C T_{SmBN} 35 °C T_{NI} 49 °C	0.052 [36.59]
	T_{NI} 93.5 °C	0.074 [36.64] (58.5 °C)
	T_{CrN} 80 °C T_{NI} 96 °C	−0.193 [36.64] (61 °C)

not possible for the electrical conductivity. The latter is largely determined by the purity of the liquid crystal, but it is found that the higher the value of the permittivity, the larger the electrical conductivity. Materials of high electrical conductivity tend to leak charge, and so an image may deteriorate during a multiplexing cycle. In general it is desirable to minimise the conductivity of a display mixture, although this was not the case for the first liquid-crystal displays reported [36.65]. These utilised the strong light scattering which results when an electric field is applied to certain nematic materials. The scattering is due to electrohydrodynamic instabilities in liquid-crystal materials which have a significant electrical conductivity. Such materials are not suitable for use in modern, fast-multiplexed displays.

The dielectric anisotropy $\Delta\varepsilon$ and birefringence Δn of a nematic can be related to molecular properties of polarisability and dipole moment using a theory originally developed by Maier and Meier [36.66]. The birefringence is given by







$$\Delta n \approx \frac{NS}{\varepsilon_0}(\alpha_l - \alpha_t)\,, \tag{36.31}$$

where N is the density in molecules per m^3 and $\Delta\alpha = (\alpha_l - \alpha_t)$ is the anisotropy of the molecular polarisability. S is the order parameter, defined in Sect. 36.2.1, and small corrections due to the local field anisotropy have been neglected. Such corrections cannot be ignored in the corresponding expression

$$\Delta\varepsilon = \frac{NhFS}{\varepsilon_0}\left[\Delta\alpha + \frac{\mu^2}{2k_B T}(3\cos^2\beta - 1)\right] \tag{36.32}$$

for the dielectric anisotropy, especially for materials of high permittivity. In (36.32) h and F are local-field correction factors, while μ is the molecular dipole moment, and β is the angle between the dipole direction and the long axis of the molecule. For molecules containing a number of dipolar groups, μ is the root mean

Table 36.3 Materials of high, low and negative dielectric anisotropy; the *inset* figure indicates the direction of the total dipole moment with respect to the core of the molecule ($1\,\mathrm{D} = 3.33564 \times 10^{-30}\,\mathrm{C\,m}$)

Compound	Transition temperatures	$\Delta\varepsilon$ [reference] (T °C)	Total dipole moment μ (D)
	T_{CrN} 22.5 °C T_{NI} 35 °C	11.5 [36.67] (25 °C)	4.8
	T_{CrN} 143 °C T_{NI} 150 °C	−10.0 [36.68] (145 °C)	6.4
	T_{CrN} 13 °C T_{NI} 64 °C	0.0 [36.69] (58 °C)	1.4

square of the vector sum of all contributing groups. Both the birefringence and the dielectric anisotropy increase with decreasing temperature, and the detailed variation with temperature is largely determined by the temperature dependence of the order parameter S.

The manipulation of birefringence is achieved by changing the chemical constitution of the mesogen. Thus extending the electronic conjugation along the axis of a mesogen will result in an increase in longitudinal polarisability, and hence an increase in birefringence. Saturated carbocyclic rings, such as cyclohexane, and aliphatic chains generally have small polarisabilities and mesogens containing a predominance of such moieties form low-birefringence liquid crystals. Mixtures for displays require a positive birefringence, which is associated with calamitic or rod-like mesogens. In order to improve the viewing characteristics of displays, optically retarding films are placed in front of the display, and depending on their function, these may be of negative or positive birefringence. The latter can be fabricated by encapsulation or polymerisation of suitable molecules of an extended structure. On the other hand, films of negative birefringence have been made using discotic materials, i. e., mesogenic molecules formed from disc-like structures which have a negative polarisability anisotropy (Sect. 36.1.3). Some examples of liquid crystals having different birefringence are shown in Table 36.2.

The introduction of chirality into liquid crystals has important consequences for their optical properties. The selective reflection of coloured light from the helical structure of a chiral nematic has already been mentioned in Sect. 36.1.2. All chiral materials will rotate the plane of incident polarised light, and the particular optical properties associated with chiral thin films are exploited in many liquid-crystal device applications.

The dipole moment of a molecule is increased if strongly electronegative or electropositive groups are substituted into the structure, with the result that the dielectric permittivity increases. For mesogenic molecules, the locations of the electropositive or electronegative groups are important, since not only the magnitude but also the orientation of the molecular dipole strongly influences the dielectric anisotropy. From (36.32) it can be seen that the dipolar contribution to the dielectric anisotropy may be positive or negative depending on the value of the angle β, since for values of β greater than 54.7° the dipolar contribution to the permittivity anisotropy becomes negative. This is illustrated by the mesogens shown in Table 36.3, where different structures can be designed to give large positive, negative or zero dielectric anisotropy.

The most effective substituent for producing materials of high dielectric anisotropy is the cyano group, and mixtures containing cyano-mesogens were the basis for the rapid development of complex displays in the 1980s

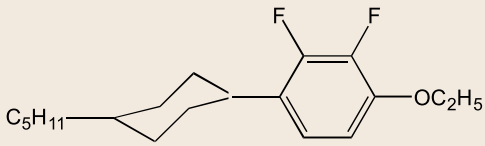
and early 1990s. However, these mixtures tended to have relatively high viscosities, which gave rise to slow switching times. Another disadvantage was the high electrical conductivity associated with the high dielectric anisotropies which caused charge leakage during multiplexing, and hence degradation of the image.

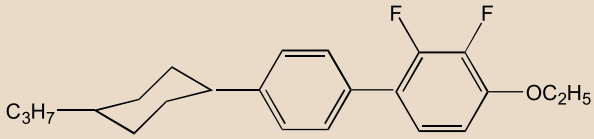
As the demands placed on liquid-crystal materials by more sophisticated display technologies have increased, new families of molecules have been synthesised and screened for their physical properties. However, it is no longer the properties of the pure mesogens that are of interest, rather how they behave in mixtures. For this reason, the physical properties of most components of display mixtures are measured in mixtures, and values for the pure mesogens are obtained by extrapolation. Data derived in this way are useful in designing display mixtures and for comparison purposes, but cannot be relied upon to give quantitative information about the relationship between molecular structure and physical properties.

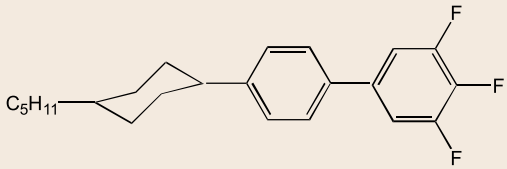
The major display technologies using TN, STN or TFT-TN configurations require display mixtures having a positive dielectric anisotropy. Many materials have been developed to improve the electro-optical behaviour of these displays, particularly using fluorine-substituted mesogens to provide the required dielectric and optical properties (for examples see [36.54, 58, 70]). Some of these fluorinated mesogens are shown in Table 36.4. However, within the past seven years, new display configurations have emerged, such as the in-plane switching (IPS) and vertically aligned (VAN and TVAN) nematic modes, which require mixtures with negative dielectric anisotropy. Using the design strategy illustrated above for simple mesogens, it has been possible to prepare a large number of materials with the desired negative dielectric anisotropy. These are again mostly based on fluorine-substituted compounds, and as before their properties have mostly been determined by extrapolation of measurements on mixtures.

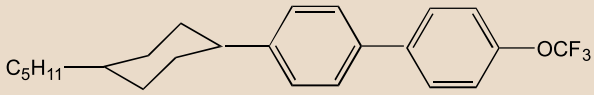
Elastic Properties

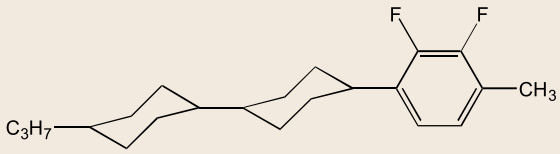
The property known as elasticity is characteristic of liquid crystals, and distinguishes them from isotropic liquids. It has been shown in Sect. 36.2.3 that the macroscopic orientational disorder of the director in liquid crystals can be represented in terms of three normal modes, designated as splay, twist and bend, and associated with each of these deformations is an elastic constant. Since the elastic properties of display materials contribute to the electro-optic response, their optimisation for particular display configurations is important to maximise the performance of commercial devices. However, despite their importance, the relationships between the magnitudes of elastic constants and the chemical structure of mesogens are poorly understood. There is a good reason for this; the optical and dielectric properties are to a first approximation single particle properties. That is they are roughly proportional to the molecular number density and are also linearly dependent on the order parameter. Because elastic properties are a measure of the change in energy due to displacements of the director, they are related to the orientation-dependent intermolecular forces. Thus, at a molecular level, elastic properties are two-particle properties, and are no longer linearly proportional to the number density. A further consequence is that the elastic properties depend to lowest order on the square of the order parameters. Molecular theories of elasticity in nematic liquid crystals have been developed [36.71] and the simplest results suggest that the different elastic constants can be related to molecular shape

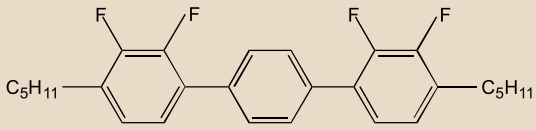


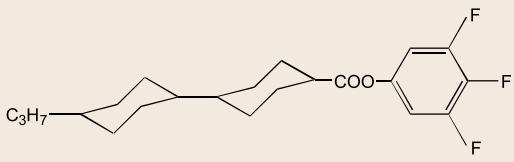












$$K_1 = K_2 \propto \langle x^2 \rangle \quad \text{and} \quad K_3 \propto \langle z^2 \rangle \,, \tag{36.33}$$

where $\langle z^2 \rangle$ and $\langle x^2 \rangle$ are the average intermolecular distances parallel and perpendicular to the molecular alignment direction, respectively. Thus theory predicts that for rod-like molecules the splay elastic constant should be smaller than the bend elastic constant, and increasing the molecular length should increase K_3, while increasing the molecular width should increase K_1. This is roughly in accord with experimental results, except that the prediction of equal splay and twist elastic constants is not confirmed (Fig. 36.9). In general, the twist elastic constant is about one half of the splay elastic constant. Hard particle theories [36.72] evaluated for spherocylinders provide further guidance on the relationship of elastic constants to molecular shape. These theoretical results can be presented in a simplified way as follows

$$\begin{aligned} \frac{K_1 - K}{K} &= \Delta(1 - 3\sigma) \,; \\ \frac{K_2 - K}{K} &= -\Delta(2 + \sigma) \,; \\ \frac{K_3 - K}{K} &= \Delta(1 + 4\sigma) \,, \end{aligned} \tag{36.34}$$

where $K = \frac{1}{3}(K_1 + K_2 + K_3)$. The quantities Δ and σ are parameters of the theory, where Δ is approximately equal to the square of the length:width ratio of the spherocylinder, and σ depends on the degree of orientational order. Despite the fact that details of internal chemical structure are ignored, these theoretical results for nematics are in approximate agreement with experimental measurements on simple nematics. If the nematic material has an underlying smectic phase, or if there is a tendency for local smectic-like ordering,

Table 36.4 Fluorinated mesogens of positive and negative dielectric anisotropy used in liquid-crystal mixtures for modern displays. All measurements listed have been obtained by extrapolation from measurements on nematic solutions

Compound Transition temperatures (°C) [reference]	$\Delta\varepsilon$	Δn	Rotational viscosity (γ_1/m Pa s)
 T_{CrN} 49 °C T_{NI} 13 °C [36.59]	−6.2	0.1	$\gamma_1 = 110$
 T_{CrN} 80 °C T_{NI} 173 °C [36.59]	−5.9	0.156	$\gamma_1 = 233$
 T_{CrN} 30 °C T_{NI} 58 °C [36.54]	11.3	0.134	$\gamma_1 = 191$ [36.73]
 T_{CrSmB} 43 °C T_{SmBN} 128 °C T_{NI} 147 °C [36.54]	9	0.14	$\gamma_1 = 180$ [36.73]
 T_{CrN} 67 °C T_{NI} 145 °C [36.59]	−2.7	0.095	$\gamma_1 = 218$
 T_{CrN} 88 °C T_{NI} 89 °C [36.59]	−4.3	0.2	$\gamma_1 = 210$
 T_{CrN} 56 °C T_{NI} 117 °C [36.59]	11.1	0.067	$\gamma_1 = 175$

this can strongly affect the elastic constants. Both the twist and bend elastic constants are infinite in a smectic phase, and in a nematic phase they diverge as the transition to a smectic phase is approached.

The elastic constants contribute directly to the threshold voltage and the response times of displays. Threshold voltages increase with increasing elastic constants, and the elastic constants responsible depend on the configuration of the display. Thus for the planar-aligned electrically controlled birefringence display (ECB), the threshold voltage depends on K_1, while the switching voltage for TN displays depends on a combination of all three elastic constants (36.27). The IPS display voltage depends only on K_2, and for VAN and

TVAN devices, the threshold voltage is determined by K_3. Different combinations of elastic constants determine the transmission/voltage curves, which are important in the multiplexing of complex displays. For example, decreasing the ratio K_3/K_1 increases the steepness of the curve for TN displays, and so increases the number of lines that may be addressed. On the other hand, for the STN display, if the ratio K_3/K_1 is decreased, the number of lines that may be addressed also decreases. Identification of the important elastic constants necessary to optimise the operation of these displays is relatively straightforward; however, manipulation of the components of displays mixtures to give the best results is much more difficult.

Ferroelectric and Flexoelectric Properties

The electro-optic properties considered so far result from interaction of an electric field with the anisotropic permittivity of a material. This might be termed a quadratic response since the dielectric term in the free energy (36.2) is quadratic in the electric field, and as a consequence the electro-optic response does not depend on the sign of the electric field. For materials having a centre of symmetry, such as achiral nematic and smectic liquid crystals, this response is the only one possible. However, if the centro-symmetry of the liquid crystal is broken in some way, then a linear electric polarisation becomes possible, which results in a linear response to an applied electric field. One example of this, in the context of displays, is the chiral smectic C phase, which in the surface-stabilised state exhibits ferroelectricity, i. e., a spontaneous electric polarisation. The origin of the symmetry breaking in this case is the chirality of the material, and the polarisation is directed along an axis perpendicular to the tilt plane of the smectic C. Another way in which the symmetry can be broken is through elastic strain. This effect was first described by *Meyer* [36.24], and it can be represented as a polarisation resulting from a splay or bend deformation (Sect. 36.2.4). Since at a molecular level, strain is related to molecular interactions, the flexoelectric response depends on a coupling of intermolecular forces and the molecular charge distribution. Two molecular mechanisms have been identified which contribute to the strain-induced polarisation. If the molecules have a net dipole moment, then the longitudinal component can couple with the molecular shape to give a splay polarisation along the director axis, while the transverse component couples with the shape to give a bend polarisation perpendicular to the director axis. Even in the absence of a net dipole, a quadrupolar charge distribution in a molecule can result in strain-induced polarisation [36.26]. Both contribute to the splay and bend flexoelectric coefficients, but only the dipolar part

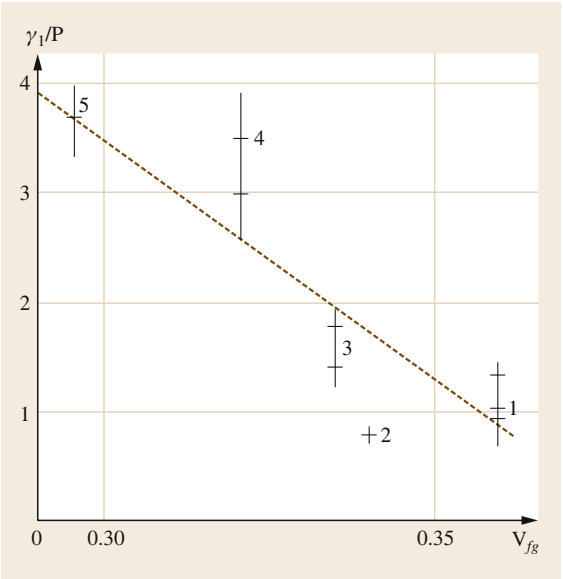


Fig. 36.25 Relationship between the rotational viscosity coefficient γ_1 ($P = 10^{-1}$ Pa s) and the geometric free volume (V_{fg}) at 25 °C for bicyclic polar mesogens. Compound numbers represent alkyl series as follows: 1-cyanophenylalkylcyclohexanes; 2-alkylcyanobiphenyls; 3-cyanophenylalkylpyridines; 4-cyanophenylalkylbicyclooctanes; 5-alkoxycyanobiphenyls. (After [36.52])

persists in the sum $e_1 + e_3$. Thus it is common to quote flexoelectric coefficients as a sum and difference rather than as separate coefficients.

The measurement of flexoelectric coefficients has been a challenge to experimentalists, and there is a wide range of values in the literature for standard materials (Sect. 36.2.4). It is, therefore, premature to draw any conclusions about structure/property relationships for flexoelectricity from the limited experimental data available. There have been attempts [36.74, 75] to model flexoelectricity for collections of Gay–Berne particles simulating wedge-shaped molecules. Application of the surface interaction model to flexoelectric behaviour [36.76] has allowed the calculation of flexoelectric coefficients for a number of molecules; these calculations include the quadrupolar contribution. The importance of molecular shape is clearly demonstrated, and in particular changes of shape, either through conformational changes or *cis–trans* isomerisation, have large effects on the magnitude and sign of the flexoelectric coefficients.

Flexoelectric effects contribute to the electro-optic response of nematic displays, especially those with hybrid alignment, i. e., planar on one electrode and homeotropic on the other electrode, but they are not usually considered in the optimisation of mixture prop-

erties. However, flexoelectric properties are of direct importance to the operation of displays based on the switching of the direction of the optic axis in chiral nematics: the so-called deformed helix mode [36.25].

Viscous Properties

As explained in Sect. 36.2.5, the flow properties of liquid crystals are complicated. Since the materials are anisotropic, the viscosities in different directions are different, furthermore because of the torsional elasticity, viscous stress can couple with the director orientation to produce complex flow patterns. Thus there are five viscosity coefficients necessary for nematics, in addition to the elastic constants, and as many as 20 viscosities for smectic C liquid crystals [36.77]. To relate all or indeed any of these to molecular structure is a formidable challenge. However, for most liquid-crystal displays, the only viscosity of interest is that which relates to the reorientation of the director: the so-called rotational viscosity. This depends on the temperature and order parameter, and on the forces experienced by the rotating director. The rotational viscosities for all liquid-crystalline materials can be represented by one or other of the following parameterised relations

$$\gamma_1 = aS^x \exp\left(\frac{A(T)}{k_B T}\right)$$

or

$$\gamma_1 = bS^y \exp\left(\frac{B}{T - T_0}\right), \qquad (36.35)$$

where a, b, A and B are material parameters, and S is the order parameter raised to a power of x or y between 0 and 2. The first of these expressions emphasises the diffusional nature of rotational relaxation in a liquid crystal, that is molecules rotating in an external potential. The second expression taken from polymer physics describes rotation in terms of free volume, where T_0 is the temperature at which the free volume becomes zero, and the rotational viscosity infinite, i. e., a glass transition.

At the simplest level, the rotational viscosity depends on the molecular shape and size. As the length of the molecule increases, from two rings to three rings etc. γ_1 increases, similarly it increases with the length of the alkyl chain. Varying the nature of the rings in the mesogenic core can have a dramatic effect on the rotational viscosity, which correlates well with free volume, as shown in Fig. 36.25, and the glass temperature of the material.

There is a correlation between the increasing dielectric anisotropy and increasing rotational viscosity which can be attributed to local dipolar intermolecular forces which impede end-over-end rotation of molecules. Thus mesogens having cyano-groups in a terminal position tend to have relatively high viscosities. Other dipolar groups such as fluorine do not have such a deleterious effect on viscosity as the cyano-group, and so fluorine-containing mesogens are increasingly preferred in the formulation of display mixtures.

As with the determination of other properties, the rotational viscosities of mesogenic components are often determined by extrapolation from measurements on mixtures doped with the component under investigation. Such a method only provides approximate values to compare different components, but in the formulation of mixtures for display applications it is only the rotational viscosity of the final mixture that is important. Rotational viscosities of some mesogens of interest for display mixtures are given in the Tables 36.1 and 36.4 accompanying this section. In many instances, the viscosities, as with other properties, have been determined by extrapolation from measurements on mixtures. The measurement of rotational viscosities is experimentally difficult, and some authors prefer to quote the results of bulk-viscosity measurements in terms of a kinematic viscosity. In fact there is a good correlation between kinematic viscosity and rotational viscosity, and where possible both values have been included in the tables. From the various tables, the effect of increasing the molecular length on the viscosity is clearly seen, as is the effect of replacing an F atom with a CN group. Lateral substitution, which produces materials of negative dielectric anisotropy, tends to increase the rotational viscosity. Despite this the fastest nematic displays now use vertical alignment and materials of negative dielectric anisotropy. The operating characteristics of display mixtures depend on the physical properties of individual components in a very complex manner, and optimisation of mixture properties has to be carried out in a concerted way.

37. Organic Photoconductors

David S. Weiss, Martin Abkowitz†

This Chapter surveys organic photoreceptor devices used in electrophotography. Included in the discussion are the materials (polymers, pigments, charge-transport molecules, etc.), device architecture, fabrication methods, and device electrical characteristics that are critical to the successful functioning of an electrophotographic device (printer).

The Chapter is organized as follows. A brief discussion of the history of xerography and the contributions of Chester Carlson is followed by operational considerations and critical materials properties. The latter includes dark conductivity, photodischarge–charge transport, and photogeneration. Organic photoreceptor characterizations of dark decay, photosensitivity, and electrical-only cycling are discussed in detail. This is followed by discussions of photoreceptor architecture, coating technologies, substrate, conductive layer, and coated layers which carry out specific functions such as smoothing, charge blocking, charge transport, backing, and surface protection.

References 992

Organic photoconductors, devices fabricated from organic photoconductors, and the applications of these devices, are the topics which will be covered in this chapter. The term *organic* is used in the chemical sense to encompass materials with carbon as a major constituent. This includes molecular as well as polymeric materials that are not naturally occurring but are purposefully designed and synthesized in the laboratory for specific physical, chemical, dark-electrical, and photoelectrical characteristics. Organic photoconductors are single, or more commonly, a formulated blend of materials which have photoconductive characteristics. Put simply, these are materials in which the electrical conductivity increases on exposure to light [37.1, 2]. Organic photoreceptors are thin-film devices made from organic photoconductive materials with physical, chemical, dark-electrical, and photoelectrical characteristics designed for optimum performance in specific applications. The most important application is in electrophotography, where organic photoreceptors are utilized in machines for digital printing and copying. In this chapter we will discuss details of organic photoreceptor architecture and their composition and characteristics that have enabled their utilization in electrophotographic printing. In this space it will only be possible to touch briefly on many important aspects of organic photoreceptors but references will be provided for those wishing to delve deeper [37.3–7].

Organic photoconductors are materials and organic photoreceptors are devices made from organic photoconductors. The common acronym for an organic photoreceptor is OPC, which of course stands for organic photoconductor, and simply indicates that acronyms are often inscrutable. The application for which or-

ganic photoreceptors have received the most attention and development effort is as the photosensitive image-creating element in electrophotographic-based printers and copiers. In these machines the photoreceptor is a highly uniform, defect-free, multilayer thin film ($\approx 20-50\,\mu m$ photoconductor thickness) coated on a metal drum or a flexible belt, with an active area from 160 to over $12\,000\,cm^2$. Organic photoreceptors for electrophotography were first introduced in the 1960s and, after years of development for improved physical and electrical characteristics, they form the basis of a multi-billion-dollar industry today.

37.1 Chester Carlson and Xerography

Electrophotography has an interesting history [37.8–11] and we will briefly tell this story with emphasis on the enabling aspects of organic photoreceptors in this technology. The story begins with Chester F. Carlson, a patent lawyer who saw the need for a method of reproducing documents. In his kitchen laboratory in Queens, New York, he demonstrated that a charged photoconductor could be used to produce an electrostatic latent image which could subsequently be visualized by contact with oppositely charged particles. The first electrophotographic image was *10.-22.-38 Astoria*. The patent application was filed on 4th April 1939 and on 6th October 1942, US patent 2 297 691 was issued [37.12]. Figure 37.1 shows the title page of that patent. In concept, electrophotography is a relatively simple process with six (or seven) steps but it took over 20 years to bring it to fruition and another decade to make it truly practical. The essential steps are all illustrated in the US patent cover page: charging, exposure, developing, transfer and fixing. Not pictured are the final steps, blanket exposure and cleaning, to prepare the photoreceptor for the next electrophotographic cycle.

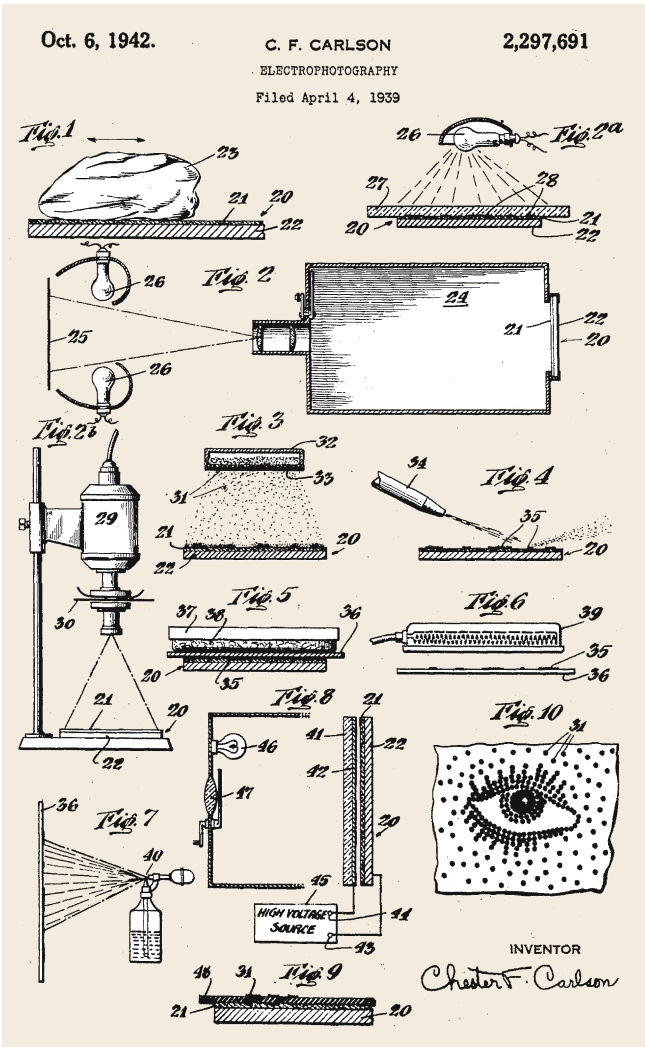

Fig. 37.1 Title page of the first U.S. Patent on electrophotography by C.F. Carlson

Carlson had great difficulty finding commercial backing for his invention. He was unable to convince the management at a long list of influential and affluent companies that making copies of documents was an attractive business proposition. In the end the Battelle Development Corporation took on the project and made significant advances towards making it more practical. In Carlson's invention a coating of photoconductive material such as sulfur or anthracene is prepared on a conductive, grounded, metal substrate. The photoconductor is tribocharged by contact with an appropriate material (silk rabbit's fur, etc.). The photoconductor is then image-wise exposed with light of a wavelength that causes the photoconductive response. The areas struck by light become conductive and the surface charge is neutralized. Thus, there is now a difference in surface charge density, and hence surface potential, between the exposed and unexposed areas. This difference in surface potential, the so-called electrostatic latent image, was visualized by contacting the surface with small marking particles, such as spores from the lycopodium club moss, with surface charge opposite to the original surface charge. The final copy is produced by transferring the *toned* image on the photoreceptor to the receiver (Carlson accomplished this with a heated sheet

of waxed paper). Carlson later dubbed his process *xerography*, meaning dry writing, based on the use of dry powder as the marking particles. Electrophotography is a more general term encompassing, for example, the use of liquid toners in which the charged marking particles are suspended in an insulating fluid.

Two significant early advances were the use of amorphous selenium as the photoconductive material and the development of a practical method (the corotron) for the generation of an air corona for surface charging the photoconductive material. The corotron is simply a fine wire held at high potential (above the air ionization threshold of $\approx 7\,\mathrm{kV}$) and shielded on the back with a grounded metal plate. Xerography was eventually purchased by the Haloid Corporation of Rochester, New York, (later to become the Xerox Corporation) with Carlson as a consultant. The first xerographic product was the XeroX Copier model A introduced in 1949. This initial product had totally manual operation which required several minutes to produce a copy. The photoreceptor was a selenium plate that measured 9×14 inches. From these modest beginnings, advances in engineering the various processes and materials progressed in an evolutionary manner leading to the introduction of the automated copy machine, the Xerox 914 in 1959. This utilized a selenium-coated drum photoreceptor. The evolution continues today and new product introductions have rapidly shifted from copiers (reflection of light from a document to expose the photoreceptor) to digital printers (pixel-wise exposure of the photoreceptor based on data from a previously compiled image file) using drum- or flexible-belt-based organic photoreceptors. Early examples of copiers utilizing organic photoreceptors are the IBM copier 1 (1970) and the Kodak Ektaprint 100 (1975). Initially the photoreceptors were *single-layer* in that the photoconductive materials were all contained in a single layer. For high-speed high-quality applications more complex photoreceptors were introduced. These had multilayer structures with each layer being optimized for a specific function. The single-layer OPC architecture is, on the other hand, what one finds today in desktop laser printers. The choice of single versus multilayer OPC hinges on the quality and printing speed requirements of the end use printer, and on the OPC manufacturing cost. The details of photoreceptor architecture and composition will be discussed later.

There are some subtle differences in the electrophotographic process between copiers and digital printers. Since the electrostatic image in a copier is produced by reflection of the exposing light from a document (black text for example), areas of the document which are dark (text) reflect no light and the corresponding area of the photoreceptor retains its surface charge. To produce a final print in which the dark areas correspond to dark areas in the original document one must *develop* the image with a marking particle (toner) with charge that is opposite to that on the photoreceptor surface. This process is called *charged area development*. In a digital printer the exposure is controlled by an image file and the image is composed of a microscopic halftone pattern of *pixels*. Pixel size is determined by the desired *resolution* such that 600 dpi corresponds to a pixel size of about $40\,\mu\mathrm{m}$. In a digital process it is possible to expose either those areas which will be developed or undeveloped in the final print. The approach sometimes chosen is to expose only those areas which will be toned since most documents are text-based and text occupies only a small fraction of the total document area. This approach decreases the on-time of the exposing system and lengthens its lifetime. Thus, in this case those areas to be developed have been exposed and have decreased surface potential. This process, *discharged area development*, is carried out by using toner with a charge polarity that is the same as that of the photoreceptor surface. Factors in OPC design relating to their optimization for digital imaging have been investigated but in practice the OPCs used in today's copiers and printers differ little [37.13–16]. Discussion of the chemistry, physics, and engineering involved in toners, developers, and development systems is beyond the scope of this chapter [37.17, 18].

In addition to the photoreceptor some of the major subsystems of a modern digital printer are:

- Exposure: Scanning laser or light-emitting diode (LED) arrays.
- Development: Magnetic brush or other technology with black and/or colored marking particles plus magnetic carrier.
- Transfer: Heat, pressure, etc. to remove toner from the photoreceptor and place it on the receiver. In some systems the toner is transferred first to an intermediate drum or web and then to the final receiver.
- Erase: Blanket exposure to return the photoreceptor to a uniform surface-charge state.
- Clean: Blade or brush to remove untransferred toner from the photoreceptor surface.
- Fixing: Melting the toner particles onto the receiver.
- Computers and software: Image capture, rendering, and storage, process control, receiver handling, etc.
- Process control: Software and hardware (sensors, voltmeters, etc.) to maintain image quality.
- Sensors and controls: For receiver handling.

A full listing would be much longer and the modern electrophotographic printer is a highly complex sys-

tem where the hardware, software, and materials have been successfully co-optimized to meet the product aims [37.19–21].

Since the photoreceptor surface is either in physical contact with (development, transfer, cleaning), or exposed to, effluents (fusing, corona charging) from the various subsystems its physical and electrical characteristics must be stable to these interactions throughout its life. Much of the development in OPCs has been to extend the photoreceptor process lifetime. Today the most durable OPCs might be replaced after 100 000 or more imaging cycles.

37.2 Operational Considerations and Critical Materials Properties

The steps involved in the electrophotographic process were detailed previously [37.17, 19]. In this section we discuss some of the underlying physics in the formation of the electrostatic latent image. From the point of view of device physics the OPC is a large-area transducer configured as a belt or drum which converts optical information into a latent charge (primary) image. The photoreceptor material is a high-dielectric-strength insulator that is converted to the electrically conducting state with the application of a field and illumination. Phenomenologically, a high field is applied across the thin-film photoconductor (corona charging) and the film is exposed to radiation absorbed by the material. The photon energy is converted into charge carriers at or near the site of absorption and these drift under the influence of the field. Since the charged photoreceptor is an open-circuit device the surface potential decreases as the charges drift through the material and the photoreceptor is discharged.

In this section we focus on some of the key physics and materials issues governing the field-biased motion of electronic charge through the photoreceptor during light-induced xerographic discharge – the process which leads to latent image formation. Work done in optimizing the design and characterization of photoreceptors in order to service an evolving technology operated in a push–pull relationship with the growth in scientific understanding of photoinduced charge generation, injection, transport and trapping first in amorphous semiconductors and then, in what will concern us here, disordered molecular media.

Because the photoreceptor assembly is a sensitized large-area device, the materials which simultaneously optimize all the required properties have always been glassy coatings. (Polycrystalline media are largely unsuitable for a variety of reasons.) The inorganic materials used especially in light-lens copiers were initially amorphous chalcogenides [37.22, 23] and to a much lesser extent hydrogenated amorphous Si [37.24, 25]. Much of the early work was therefore focused on the physics and chemistry of amorphous semiconductors. In this case photogeneration and the subsequent transport of charge occur in precisely the same medium, and design latitude is clearly restricted by the particular combination of optical and transport characteristics of that single layer. In addition these inorganic films are relatively brittle and therefore unsuitable for applications which require a belt architecture, i. e., one in which the photoreceptor is required to bend around small rollers. On the other hand, polymer-based OPCs are inherently flexible and multilayer architectures are readily fabricated such that each layer can be optimized for a particular function such as photogeneration and charge transport [37.26]. In fact, all OPCs for high-end applications have been developed according to this principle with the photoconductor divided into a thin light-absorbing charge-generation layer (CGL) adjacent to the electrode and a thicker charge-transport layer (CTL) which transports holes. With this photoreceptor configuration the surface is negatively charged prior to exposure. The details of OPC architecture and the materials chosen for specific layer functions will be discussed later.

37.2.1 Dark Conductivity

The electrophotographic imaging process begins by applying a surface charge to the photoreceptor. A parallel-plate-capacitor model is appropriate and the surface potential and surface charge density are related through the capacitance per unit area as, $Q/A = (C/A)V = (\varepsilon\varepsilon_0/L)V$, where Q/A is the surface charge density ($\mathrm{C/cm^2}$), C/A is the capacitance per unit area ($\mathrm{F/cm^2}$), V is the surface potential (V), ε is the dielectric constant, ε_0 is the permittivity of free space, and L is the photoreceptor thickness. For a typical organic photoreceptor ($L = 25\,\mu\mathrm{m}$, $\varepsilon = 3$, and $V = -500\,\mathrm{V}$) C/A is $3.2\times10^{-10}\,\mathrm{F/cm^2}$, corresponding to $10^{12}\,\mathrm{charges/cm^2}$. Assuming the surface is composed of molecules with an area of $100\,\mathrm{Å}^2$ ($10^{-14}\,\mathrm{cm^2/molecule}$) only $\approx 1\%$ of the surface molecules are associated with the surface charge. The applied field (V/L) is $2\times10^5\,\mathrm{V/cm}$.

Electrophotographic imaging is enabled by a difference in surface potential between exposed and unexposed areas when the imaged area enters the development subsystem. Generally a potential difference of

at least 300 V is desired. The materials comprising the bulk of the OPC must be highly insulating. A resistivity of $10^{13}\ \Omega$ cm at a field of 2×10^5 V/cm will give rise to a dark decay rate of nearly 200 V/s. Since development typically occurs at a fraction of a second to one second after charging, the photoconductor resistivity needs to be $> 10^{13}\ \Omega$ cm. Organic polymers such as bisphenol-A polycarbonate meet this requirement and are the major component in OPCs.

There are other sources of dark conductivity such as electrode and/or surface charge injection, bulk charge generation, and/or charge detrapping [37.27–30]. Electrode injection is prevented with the interposition of a charge-injection blocking layer between the electrode and the photoconductive material. Surface injection is prevented by the chemical composition of the surface layer (which is typically a hole-transporting CTL). Detrapping can be a significant source of dark decay in OPCs and must be controlled by a balance between the process and the materials (the charge-generation material in particular).

37.2.2 Photodischarge–Charge Transport

The photoreceptor must retain charge in the dark and also be photosensitive enough to discharge exposed areas to half their initial charge potential when irradiated with (nominally for a mid-volume laser printer engine) 4–10 erg/cm^2. The xerographic gain or quantum efficiency of supply describes the fractional number of surface charges neutralized per absorbed photon. For a dual-layer OPC it is a complicated convolution of the quantum efficiency of generation in the charge-generation layer, CGL, the efficiency of carrier injection from the CGL to the CTL and the transport parameters of the CTL. For this discussion we will for the moment ignore issues of charge generation and focus on transport. In dual-layer OPCs the majority of photodischarge occurs via charge transport through the CTL with the CGL playing a minor role. In the transport lexicon [37.26, 31] there are essentially two parameters that constitute the figures of merit to characterize charge motion through the polymeric CTL. These are (1) the drift mobility μ, the measure of *how fast* the carrier moves per unit applied field, and (2) the normalized carrier range $\mu\tau$ (τ is the free-carrier lifetime against deep trapping), which is *how far* the injected carrier moves per unit field before becoming immobilized in a deep trap. The time for a photoinjected carrier to traverse the CTL is called the transit time. The transit time t_{tr}, and mobility μ are related to the specimen thickness L according to $t_{tr} = L/(\mu E)$. The importance of mobility as a critical parameter in the electrophotographic process can be understood as follows: for an increase in the exposure intensity d(F), the final decrease in surface potential d(V) is proportional to the number of injected carriers and the distance they travel within the CTL. During xerographic discharge, a charge of CV_0 (C is the CTL capacitance and V_0 the initial voltage) traverses the bulk and induces time-dependent variation in the electric field behind the leading edge of the injected carrier front. Thus, as the fastest carriers transit the CTL, the electric field behind them is reduced, and the carriers behind the leading edge transit at a lower field, which in turn makes their velocities lower. Thus during xerographic discharge the transit times of individual photoinjected carriers become dispersed over a wide range, typically about an order of magnitude. For discharge to proceed to completion, even in the complete absence of deep trapping, enough time is required for the slowest carriers in the packet to exit the layer before the photoreceptor reaches the development zone – nominally 0.3–1.0 s after exposure in mid-volume printers. The latter must be allowed for in practice. Thus, carrier mobility in this particular illustration should exceed 10^{-6} cm^2/(V s). For example, consider that a dual-layer photoreceptor with a 25 μm CTL, in which there are no deep traps, is subjected to a light flash intense enough to ultimately induce complete discharge (CV_0 of absorbed photons). Consider further that in this CTL the mobility $\mu = 10^{-6}$ cm^2/(V s) at $E = 10^4$ V/cm and that the device is initially charged to 1000 V. It can be calculated that under these conditions the device will have a residual voltage of 20 V after 0.3 s or 7 V after 1 s. Incomplete discharge, unless compensated for, might result in an inadequate toning potential and a toned density less than desired. Note further that, if the mobility is even lower, the results can become totally unacceptable. For example when the mobility is $\mu = 10^{-7}$ cm^2/(V s) under the conditions just described, the residual voltage a full second after exposure is 60 V, even in a completely trap-free CTL. In light of the foregoing illustration for the trap-free case, which sets the mobility benchmark, the effect of traps in the polymeric CTL must be of paramount concern. More precisely, we are concerned with traps whose release time at ambient temperature discernibly exceeds the period of a complete electrophotographic cycle. In the present context we take the latter as the operational definition of a deep trap. With such traps present it is clearly the case that, after repeated charge–expose cycling, some quantity of image degrading charge would remain immobilized in the bulk for times now exceeding the period of a complete xerographic cycle. If ρ is the density of uniformly trapped space charge in a CTL of thickness L and relative dielectric constant ε then there is an associated residual potential V_R, where $V_R = e\rho L^2/(2\varepsilon\varepsilon_0)$. Here

e is the electronic charge and ε_0 is the free-space permittivity. In a nonpolar dielectric medium ($\varepsilon = 3$) with a layer thickness of 25 μm, as few as 10^{13} electronic charges trapped per cm^3 already give rise to a residual of 19 V. Unless process control utilizing electronic feedback correction can be employed, bulk-trapping-induced space-charge buildup during cycling can result in severe image degradation. Residual potential arising from bulk-trapped space charge is a critical electrophotographic process parameter. A residual potential can be related to the normalized carrier range $\mu\tau$ in the weak-trapping limit from the physically plausible ansatz that the residual potential corresponds to that applied voltage for which the carrier range is about half the specimen thickness L. Thus, $\mu\tau$ is approximately $L^2/(2V_R)$. On this basis the tolerable trap density is defined by the requirement that the $\mu\tau$ product in practical devices should typically exceed $10^{-6}\,cm^2/V$. Even highly purified polymer will typically contain many chemical impurities in the 1–10 ppm range, which the foregoing calculations show is vastly higher than permissible trap levels. However, chemical impurities, even when present at relatively high concentration, can be rendered trap-inactive by employing molecular design principles to guide the overall choice of active materials. Concepts derived from scientific understanding of photogeneration, injection across interfaces, and electronic transport in disordered organic materials, in combination with the unique compositional flexibility characteristic of the organic solid state, were together responsible for making multilayer OPCs the dominant practical receptor technology for electrophotography.

As discussed above, successful electrophotographic imaging requires that charge transport through the CTL occur with little trapping in the time scale of the electrophotographic cycle. Here we discuss how this is accomplished in an *impure* organic-chemical-based CTL. The CTL is a glassy solid solution of a charge-transport-active moiety dispersed in a polymer binder. The charge-transport moiety can be molecular or a polymer component. The molecular solutions are called molecularly doped polymers (MDP). The transport-active component is typically 40–50% weight fraction of the CTL. Thus, *doping* in the present context is decidedly different from what doping refers to in conventional semiconductor physics [37.32]. In the latter case the dopant is typically introduced at very low concentration to control the relative proportion of electrons and holes in the bands of a semiconductor crystal leaving optical properties largely unaffected. In a semiconductor crystal at ambient temperature the dominant field driven transport mechanism is scattering perturbed motion of charge carriers in the bands. Under these circumstances, mobility decreases algebraically with

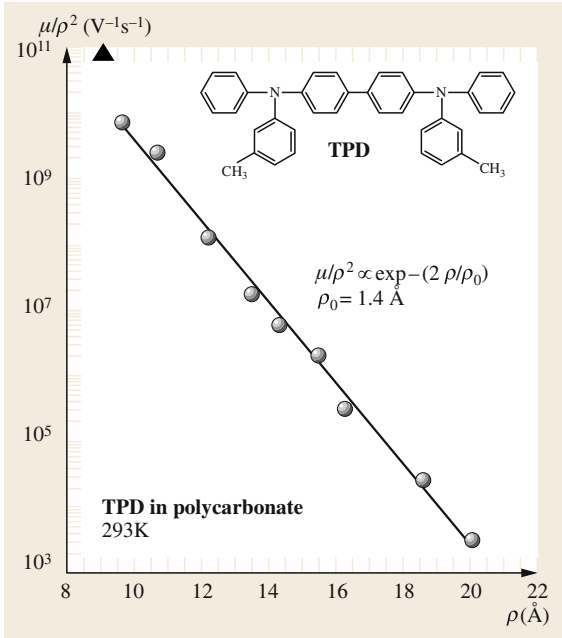

Fig. 37.2 Log (μ/ρ^2) versus average intersite separation ρ of TPD molecules in bisphenol-A polycarbonate ($E = 5 \times 10^4$ V/cm). The *triangle symbol* is the hole drift mobility in pure TPD film

increasing temperature, while carrier population in the bands is thermally activated. The convolution of these processes manifests in a thermally activated conductivity. On the other hand, in MDPs under equilibrium conditions the transport-active molecule is in the neutral state, and the glassy films are perfect insulators, that is, there are no free carriers present in thermal equilibrium [37.33]. These systems can nevertheless support relatively efficient charge transport under the action of an applied field when in contact with a charge reservoir. At fixed temperature the drift mobility of extrinsic carriers decreases exponentially with increasing average intersite separation of the active molecule (ρ) so the drift mobility of MDPs can be tuned over a broad range by simply adjusting concentration [37.34, 35]. This feature of tunability can readily accommodate a wide range of xerographic process speeds as described above and is therefore advantageous from a technological point of view [37.36]. This is illustrated in Fig. 37.2 for a common hole-transport material, N,N′-diphenyl-N,N′-bis(3-methylphenyl)-(1,1′-biphenyl)-4,4′-diamine (TPD, Fig. 37.3). The data is in conformity with a simple tunneling model where ρ_0 is the wavefunction localization radius and the transport states are sited on the TPD molecules. At 40–50 wt% doping approximately 10^4 *hops* are required for the hole to transit a 20 μm photoreceptor.

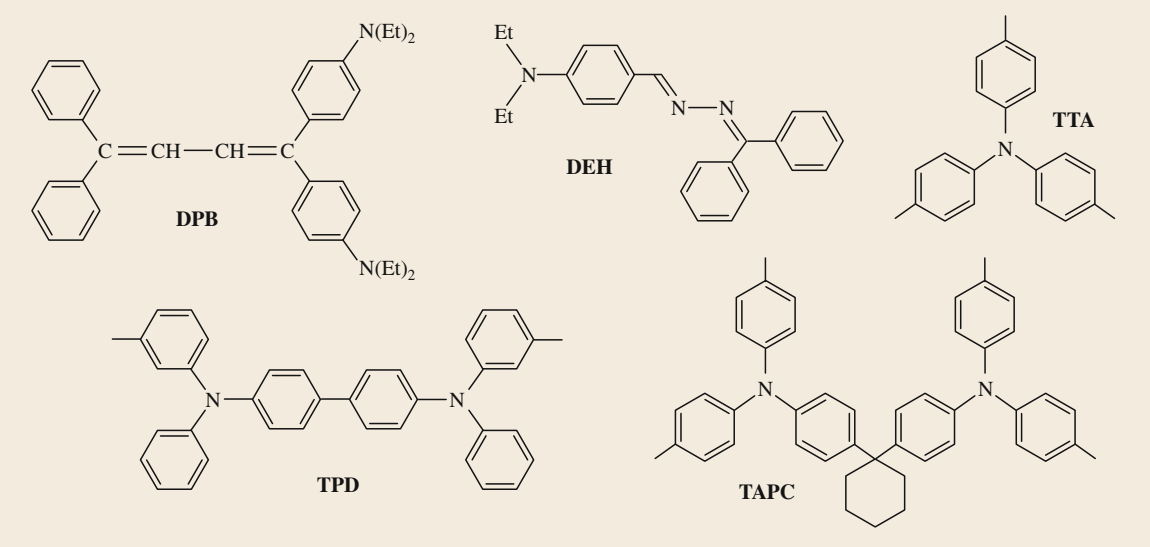

Fig. 37.3 Chemical structures of representative hole transport materials

Drift mobility of holes in CTL films is most conveniently measured by the canonical small-signal time-of-flight (TOF) technique [37.37, 38]. However, for a given composition of the CTL, and all other conditions analogous, the same drift motilities can be inferred by analyzing transport-limited xerographic discharge in bilayer photoreceptors [37.39, 40]. In TOF, the MDP film is prepared with semitransparent blocking contacts and maintained at a bias which is high enough to insure that the transit time of any excess injected carrier is shorter than the bulk dielectric relaxation time. The sample is exposed to a very short and weak pulse of strongly absorbed light (typically 337 nm from a nitrogen laser) incident on the positive electrode. Under these circumstances photoexcited transport molecules are oxidized at the positive electrode to the radical cation (the *hole* in transport terminology). This process sets up a chain of redox steps where electrons are progressively transferred from neutral molecules to their neighboring radical cation. The concentration of the advancing pulse of holes is low, such that the applied field remains uniform during their transit. In the ideal case the current from the advancing pulse of holes is constant until the leading edge reaches the counter-electrode, after which it rapidly decreases. The transit time can be extracted from the transient current and from this the mobility. For a given MDP composition drift mobilities are determined for films of known thickness as a function of applied field and temperature. The drift mobility in MDPs always has a thermally activated temperature dependence; thus the log of the drift mobility scales with inverse temperature, as illustrated in Fig. 37.4, where earlier measurements [37.34] have here [37.41] been extended to encompass the characteristic slope change displayed in the glass-transition region [37.42]. However, in a significant number of cases cited in the literature [37.5] the analogous scaling is with the square of the inverse temperature, (i. e., non-simple activation), as predicted by the disorder

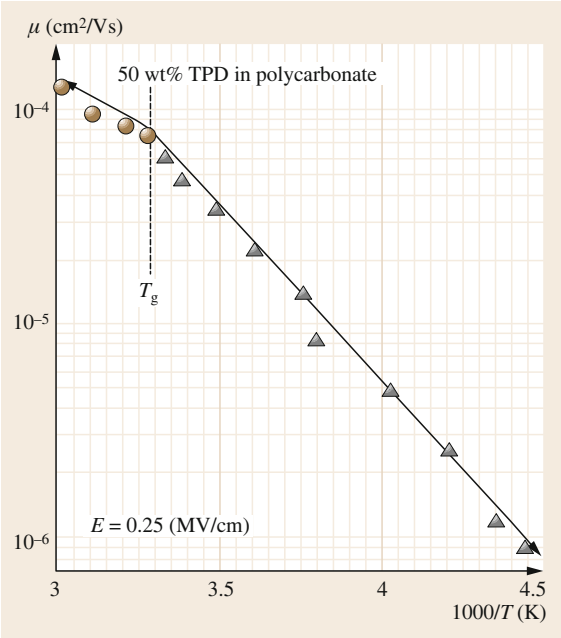

Fig. 37.4 Temperature dependence of the drift mobility in a film of 50 wt% TPD in bisphenol-A polycarbonate ($E = 2.5 \times 10^5$ V/cm). T_g is the glass transition temperature of the film

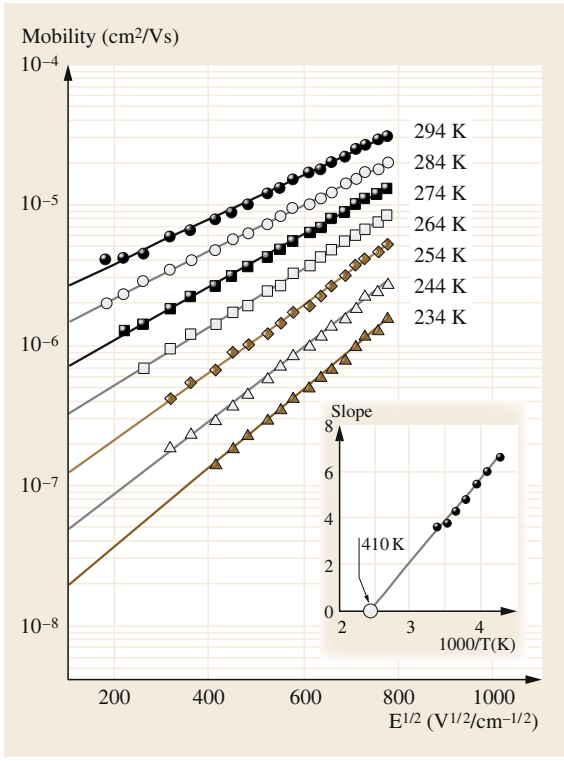

Fig. 37.6 Data set at each temperature in Fig. 37.5 replotted against $E^{1/2}$. The temperature dependence of the slope of each data set is plotted against reciprocal temperature in the *insert*

model [37.43]. The experimentally observed scaling with intersite separation, the temperature dependence, and the high degree of disorder in these systems clearly indicate that electronic transport must involve the field-biased hopping of carriers in an energetically inequivalent manifold of states sited on the transport-active molecules. Apart from their technological importance in electrophotography [37.44] and light-emitting displays [37.45], what has made MDPs a laboratory for the study of hopping transport is that a number of key secondary features in their transport behavior are in fact pervasive in other disordered molecular media [37.46]. There is then the suggestion of a common underlying mechanism susceptible to theoretical treatment. Thus, the field- and temperature-dependent behavior of molecular dispersions is also observed in polymers with transport-active pendant groups such as poly(N-vinylcarbazole) [37.47], in polymers in which small molecule moieties are incorporated in a main chain [37.48] in sigma-conjugated polymers [37.49, 50] and in certain poly π-conjugated systems [37.51, 52]. Figure 37.5 is a plot of the field dependence of the hole drift mobility in the polymer polytetraphenylbenzidine (PTPB) (see insert for the molecular structure) versus field and parametric in temperature over a 60 K range [37.53]. PTPB is a glassy polymer in which tetraphenylbenzidine (TPD) moieties are covalently bonded into a main chain [37.48]. The data is replotted in Fig. 37.6 to show the explicit dependence of the log mobility on the square root of the applied field. The field dependence is itself temperature dependent and clearly becomes stronger with decreasing temperature. The two TPD-based hole-transport media are closely related but qualitatively identical results are reproduced in polysilylenes and polygermylenes which have a sigma-conjugated backbone capable of supporting electron delocalization as inferred from analysis of absorption and emission spectra [37.54, 55]. For example, hole transport in PTPB can be represented in an Arrhenius plot over the temperature range illustrated in Fig. 37.7. In this purely phenomenological description the activation decreases with the square root of the applied field, as displayed in the insert. Precisely the same behavior is exhibited when the same phenomenological description is applied to hole drift mobility data in poly(methylphenylsilylene) (PMPS), as shown in Fig. 37.8. Combining drift mobility [37.56] and spectroscopic data [37.57] has in fact suggested that transport in these sigma-conjugated polymers involves the

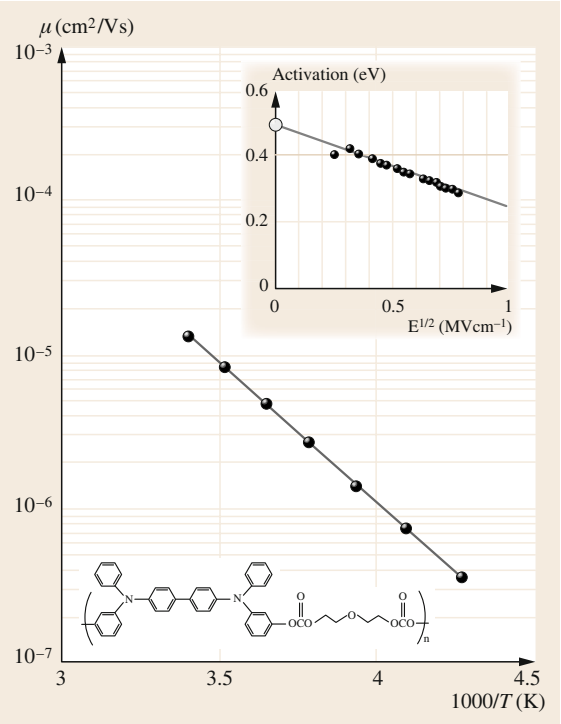

Fig. 37.7 Arrhenius representation of the temperature dependence of hole drift mobility in PTPB. The field dependence of activation is shown in the *insert*

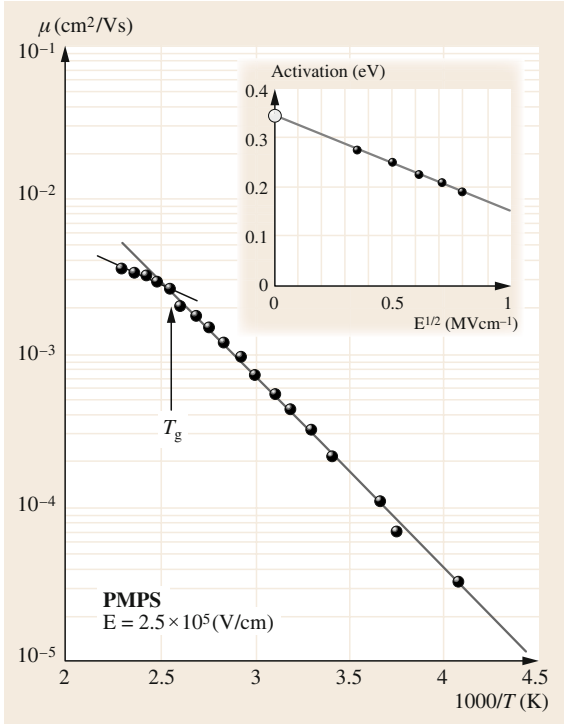

Fig. 37.8 Arrhenius representation of the temperature dependence of hole drift mobility in poly(methylphenylsilylene), PMPS. The field dependence of activation is shown in the insert. T_g is the glass transition temperature of the PMPS film

hopping of holes among chromophore-like main-chain segments of varying length whose function for transport is therefore analogous to the TPD sites in PTPB. This convoluted pattern of behavior first identified in MDPs and therefore clearly characteristic of hopping among discrete energetically in equivalent molecular sites has been reported in TOF experiments on π-conjugated systems notably the phenylene vinylenes. The sites, like those in polysilylenes, are interpreted to be domain-like backbone segments of varying conjugation length [37.51, 52]. These combined results and the recurrent pattern of behavior they reveal in systems of widely varying composition and morphology suggest that a transport theory must be founded on universally shared characteristics [37.58]. The theoretical literature stimulated by these observations is in fact extensive and far too detailed to be adequately described here. In the present context it suffices to comment briefly on certain general trends. The activated temperature dependence universal to all these materials systems arises because states in the hopping manifold are energetically inequivalent. Energetic inequivalence can be understood on the basis of site relaxation accompanying polaron formation [37.59–61]. Energetic inequivalence of sites is also a common feature of disordered solids resulting from site-to-site fluctuation of the static and dynamic electrostatic potential [37.43, 62, 63]. The combination of both effects cannot be excluded. In fact, there is a general need to develop the framework to distinguish the relative contributions of these key processes in the analysis of experimental data [37.64, 65]. A particularly challenging issue has been the attempt to account for the special features of the Poole–Frenkel-like field dependence illustrated in Fig. 37.6. Polaron models typically predict that the log mobility should scale linearly with the applied field [37.59, 66]. The disorder model based on analysis of Monte Carlo computer simulation of hopping on a finite lattice as originally proposed by *Bässler* [37.43] was in fact able to self-consistently account for a number of key experimental features in terms of a limited set of disorder parameters. On the other hand, it could only model the observed field dependence over a very narrow range. It was later recognized in the formulation of dipole disorder models [37.67, 68], that slow site-to-site variation, as distinct from fully random fluctuation, in the effective electrostatic potential could more properly account for the field-dependent behav-

ior of mobility commonly observed over several orders of magnitude [37.69–71]. The more general formulation of the disorder model developed by Dunlap and coworkers, treats the disorder potential as fully correlated and therefore slowly varying, and argues that such a supposition is physically plausible on general grounds in glassy solids. Further advances in the theories of hopping charge transport in organic materials can be found in review articles [37.72–74].

If every chemical impurity remaining in even the most scrupulously processed polymer film could act as a trap, organics as a materials class would be completely excluded as a basis for the design of xerographic photoreceptors. Trap-free transport in CTLs was achieved not by entirely eliminating impurities but by properly designing the transport-active moiety [37.75, 76]. The associated studies first carried out in this technologically critical context on molecularly doped systems [37.77] were instrumental in generally elucidating trap interactions in hopping systems and in first unambiguously illustrating and analyzing the mechanism of trap-controlled hopping transport [37.78]. It was already pointed out that hole transport is supported in MDPs when the neutral transport molecule is donor-like. For electrons the corresponding neutral transport molecule is acceptor-like in character. In each case, the CTLs are typically unipolar when analyzed by TOF or xerographic techniques. As it turns out the principle (simple in hindsight) which applies for example to hole-transport CTLs is to make the transport molecule significantly more donor-like than any of the resident impurity species. The limit is that the material must be stable to air oxidation. From an energetic point of view the impurity levels which then lie above the hole transport states are anti-traps. An important class of small molecules which have these desired characteristics are the aromatic amines and TPD is a prime example of a particularly strong donor in this class of molecules. The trap-free nature of these transport layers is xerographically apparent because there is no buildup of bulk space charge as measured by Kelvin-probe techniques [37.79] even after tens of thousands of (CV_0)s of holes are discharged through a photoreceptor with this CTL as a component. The trap-free nature of hole transport can also be independently demonstrated by combining TOF drift mobility and analysis of current–voltage measurements carried out on any transport layer fitted with a semitransparent blocking contact on one surface and an ohmic contact on the opposite face [37.80–82]. Figure 37.9 illustrates the result for the polymer PTPB in which TPD is covalently incorporated as the transport active unit [37.81]. Semitransparent Al on the films exposed surface is used for the TOF measurements of drift mobility. Dark injection occurs under positive bias from the gold-coated mica substrate onto which the PTPB film had initially been deposited. PTPB is highly insulating so that the bulk dielectric relaxation time is always much longer than the transit time of any excess injected carrier at all applied voltages. With the Al contact under positive bias, hole drift mobility is measured as a function of applied voltage V. From the measured drift mobility the trap-free space-charge-limited current density (TFSCLC), J, [37.83] that would be sustained by an ohmic contact under positive bias can be calculated to a goodapproximation, even when the drift mobility is itself field dependent [37.84, 85] using the expression $J = 9\varepsilon\varepsilon_0\mu V^2/(8L^3)$. These values are represented by open circles in Fig. 37.9. The electric field in the film is, of course, nonuniform and E in plots of this sort is simply a shorthand for V/L, where V is the externally applied voltage. It should be noted that, under the present conditions, the TFSCLC is in principle the maximum current that the bulk of a transport medium such as PTPB can demand from a contact in the steady state. It should also be noted that the

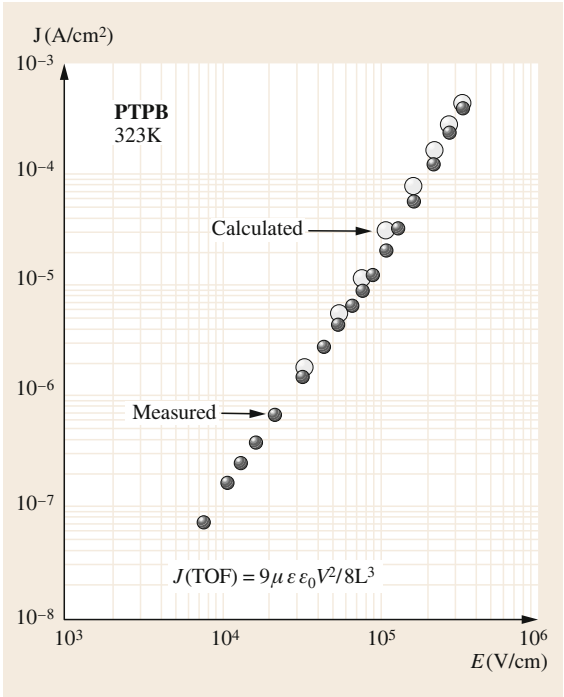

Fig. 37.9 The field dependence of the dark current for a PTPB film at 323 K measured with positive bias applied to an Au coated Mica substrate (*filled circles*). The trap free space charge limited current (*open circles*) is calculated from the hole drift mobilities obtained by the time of flight method

observation that an injecting contact under test is capable of sustaining a space-charge-limited dark current is a prima facie demonstration of ohmicity [37.26]. Filled circles represent the steady-state current measured when positive bias is applied to the substrate. That these calculated and measured currents coincide demonstrates that the injecting Au contact is ohmic and that the PTPB film is trap-free. Similar results have been obtained for other commonly used CTL MDPs such as TPD in bisphenol-A polycarbonate and in films of poly(methylphenylsilylene).

37.2.3 Photogeneration

The CGL material is designed to strongly absorb light from the exposure system (red to near-infrared LEDs and lasers are typical). In a typical dual-layer OPC the CGL material is a thin (submicron) coating of a dispersed pigment. Simply, the pigment material absorbs a photon and mobile charge is created which is *injected* into the CTL and then drifts under the influence of the applied field to discharge the device. Charge generation is a very complex topic [37.86]. In general terms, absorption of a photon produces an excited state (exciton) of a correlated hole–electron pair (valence band and conduction band, respectively) which has some mobility. Measured exciton ranges can be on the order of 0.1 μm. The exciton may then undergo recombination, with the release of energy to the environment, or it may be converted into charges. Conversion into charges can occur *spontaneously* or through chemical (impurities or dopants) or physical (crystal defects or the crystal surface) interactions. With the trapping of one of the charge carriers the other is free to drift under the influence of the applied field and geminate recombination is suppressed. The mobile carrier (assume holes) must drift to where it is in contact with the hole transport moieties of the CTL. In fact, in most cases the CTL penetrates and mixes with the CGL so that, even if the CGL is formulated without transport material, we can assume that these molecules are in molecular contact with the pigment particle surface. Now the *hole* is available to oxidize or *inject* into the transport moiety to produce the radical cation. Useful hole-transport materials have relatively low oxidation potentials (≈ 1 V versus the saturated calomel electrode (SCE)). The oxidation potential must be lower than that of the hole at the pigment surface but not so low that the material is unstable to air oxidation. The CTL hole is now transported through the CTL, discharging the photoreceptor, by sequential one-electron redox reactions between adjacent transport molecules as described in the previous section.

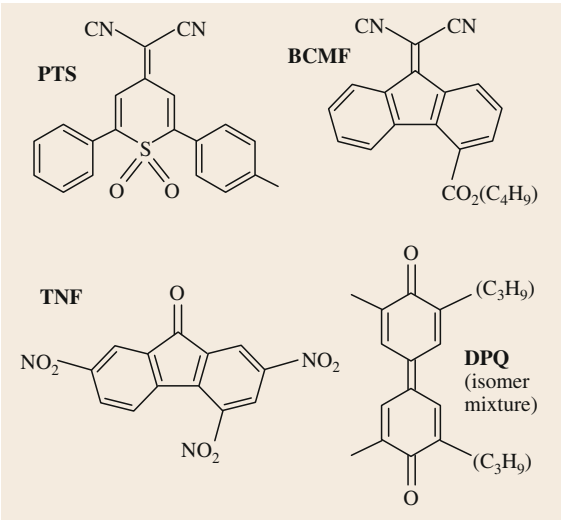

Fig. 37.10 Chemical structures of representative electron transport materials

The charge-generation mechanism is characterized as *intrinsic* when the hole is generated within the pigment particle without the influence of any externally added materials. In this case the hole is injected into the CTL with concomitant oxidation of a transport moiety at the pigment surface. *Sensitized* generation is said to take place when the photoconductivity is enhanced by an added material (dopant). In this case the dopant is available to react with the pigment exciton at the particle surface. In most cases the dopant is in fact the hole-transport moiety. Dopants may also influence charge generation by forming a (charge-transfer or other) complex which facilitates charge separation. Such complexes may be accessed by direct photoexcitation or via exciton diffusion. Sensitization of the photoconductivity of poly(N-vinyl carbazole) (PVK) by electron acceptors such as 2,4,7-trinitro-9-fluorenone (TNF) (Fig. 37.10) has been extensively studied [37.87–95]. Charge-generation mechanisms in pigment-based CGLs depend on the pigment molecular structure, crystal structure, morphology, and on the transport molecule used in the formulation.

The fundamental quantity of interest in charge generation is the quantum efficiency as a function of field. A strong field dependence is always observed, as shown in the example of Fig. 37.11. Several models have been proposed to explain charge-generation characteristics. These will be summarized here but more complete discussions can be found in *Pope* and *Swenberg* [37.86], *Popovic* [37.97], *Law* [37.3]; *Borsenberger* and *Weiss* [37.5], and *Weiss* et al. [37.7]. One of the early models to be applied to organic

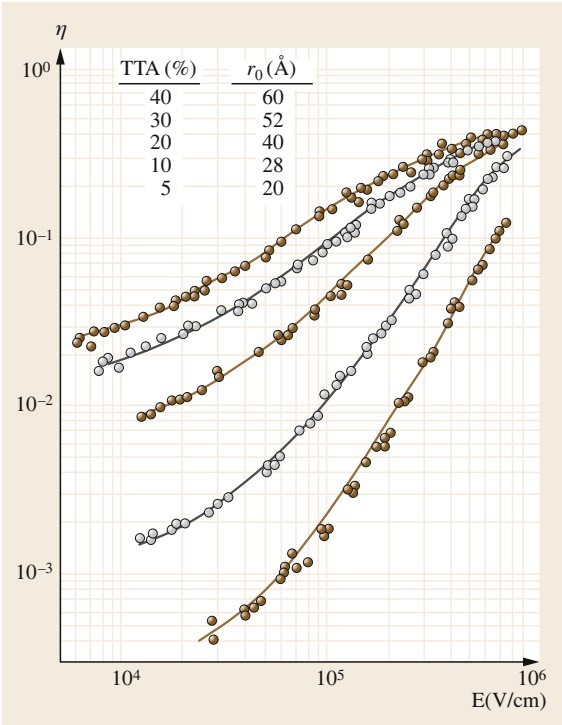

Fig. 37.11 Quantum efficiency of the field dependence of generation for a dual layer dye-polymer aggregate based OPC. The solid lines were calculated from the Onsager model with $\eta_0 = 0.60$ and r_0 as shown. (After [37.96])

photoconductors was the *Onsager* model of geminate recombination [37.98]. The 1938 theory gives the probability that a charge pair in thermal equilibrium will separate under the influence of an applied field in competition with geminate recombination. In this model charge separation occurs from an upper vibrational state to produce a *geminate* pair of charges which either recombine due to their Coulombic attraction or are separated under the influence of the applied field. The parameters in this model are the field-dependent quantum efficiency for geminate-pair formation, η_0, and the initial separation distance of the geminate pair (r_0) [37.99]. The data in Fig. 37.11 is for a dual-layer dye–polymer-aggregate-based OPC with varying concentrations of charge-transport material (tri-*p*-tolylamine, TTA) in the CTL [37.96]. The data has been fit to the 1938 model with $\eta_0 = 0.60$ and r_0 as shown. The model has been refined using a modified basis, also due to *Onsager* [37.100]. Further refinements have involved modifications of the distribution function assumed for the separation distances [37.101, 102]. This model has been successfully used to describe charge generation in amorphous materials [37.103]. However, these models predict a wavelength-dependent quantum efficiency and a photoconduction threshold which is at higher energy than the absorption, neither of which is observed in pigment-based generation materials. A model for charge generation in these materials invokes decay (radiative or radiationless) of the initially formed excited state followed by a competition between field-dependent charge separation and internal conversion [37.104]. Sensitized generation occurs with the reaction of the thermalized excited state with a dopant. Studies of the field dependence of pigment fluorescence quenching and lifetime have been used to sort out the details with specific generation materials [37.97, 105–107].

The quantum efficiency for carrier generation can be defined in several ways, as described above. The efficiency of geminate-pair formation refers to the initially produced charge pair and this is also the efficiency which has been obtained with fluorescence quenching studies. On the other hand, the generation efficiency determined with xerographic discharge always includes some contribution from charge transport because a measured decrease in photoreceptor surface potential is due to charge motion. In addition, very-high-intensity exposures may give rise to (bimolecular) recombination of positive and negative carriers during transport [37.108–112]. Quantum-efficiency determinations from xerographic discharge are carried out with very short, low-light-intensity continuous exposures to minimize the influence of charge transport and recombination (see the following section).

37.3 OPC Characterization

Photoreceptors may be characterized by many techniques. On the one hand one wishes to determine the fundamental characteristics of the materials, while on the other hand one wishes to determine electrophotographic performance-based characteristics of the photoreceptor. The quantum efficiency of charge generation and, depending on the model chosen, the initial separation distance of the charge pair, are common characterizations. Electrophotographic performance characterizations include dark decay, photoinduced discharge sensitivity, and residual potential as well as their stability to electrical-only cycling.

37.3.1 Dark Decay

The quantity of interest is the rate of dark discharge (V/s) as a function of field and environment. However, the dark decay characteristics of a dark-adapted photoreceptor when incrementally corona charged to higher and higher fields will be significantly different from what is observed in the electrophotographic process. This is because OPCs seldom behave as perfect capacitors and there is typically a depletion charging component where previously trapped charges are mobilized and drift in the photoreceptor on the application of the corona charge [37.28–30, 113]. Thus, in addition to field and environment, the observed dark decay characteristics depend on prior exposure history (trapped charges), corona charger characteristics, and timing. Thus, a given photoreceptor will have a higher dark decay rate if the photoreceptor is charged exactly to the desired initial potential (V_0) and the dark decay rate determined immediately, as opposed to charging well above the desired potential and measuring when the surface potential decreases to the desired potential. Dark decay measurements which are meaningful to the electrophotographic process must be carried out in an apparatus in which the exposures, charging, and timing elements are fixed. Dark decay is an important characteristic of an OPC because, although process control will attempt to maintain V_0, the imaging system in a printer will in general not tolerate a significant V_0 drop.

37.3.2 Photosensitivity

Measurements to determine fundamental characteristics (quantum efficiency of generation materials, mobility, etc.) are often carried on photoreceptors that differ from what might be eventually used in a printer. The layer of interest (CGL or CTL) may be isolated or the device may be modified with the application of a vacuum-deposited electrode (Au is common) on the free surface. Common fundamental characterizations include quantum efficiency as a function of field and wavelength, and mobility. Mobility was discussed in Sect. 37.2.2. The quantum efficiency of carrier generation has several definitions as applied to OPCs. On the one hand it can refer to the number of ion pairs generated per incident or absorbed photon. This fundamental characteristic might be determined experimentally by fluorescence quenching, or calculated based on a model such as the Onsager model discussed above. On the other hand a photodischarge efficiency can be determined based on the decrease in surface potential per photon absorbed or incident. The photoinduced discharge (PIDC) method is commonly used to characterize OPCs as a function of field, wavelength, temperature, humidity, exposure intensity, etc. The photoreceptor is corona charged to apply the desired field and is photodischarged. Using the parallel-plate-capacitor model, $Q = CV$ (terms as defined previously), the change in surface charge density can be calculated from the decrease in the surface potential. The change in surface charge density per unit area per photon incident or absorbed is a measure of photosensitivity. This measure includes the efficiency of charge generation, injection into the CTL, and transport through the CTL. Because of carrier bimolecular recombination and range limitations the quantum efficiency determined using this method may depend on the light intensity and the extent of photodischarge. The photodischarge method is carried out with either continuous or flash exposures. With continuous exposures ($J/(cm^2\,s)$) the surface potential is monitored as a function of time. One measure of OPC photosensitivity which relates to the electrophotographic process is the exposure required to discharge the photoreceptor a fixed amount, often 50%, from an initial potential. This is typically carried out using exposures (wavelength and duration) relevant to a particular electrophotographic process. The photoreceptor sensitivity is usually reported in terms of J/cm^2 (the inverse is often used to report spectral sensitivity). A related method is to determine the initial photodischarge rate (dV/dt). This can be related to the decrease in surface charge density through the capacitance, $dQ/dt = C dV/dt$. The light intensity is kept low and the discharge time short to avoid space-charge perturbations during charge transport and to keep the field essentially constant. The ratio of the decrease in surface charge density to the exposure ($photons/cm^2$) is a measure of photodischarge efficiency. In fact the photodischarge per exposure ($V/(J\,cm^2)$) is another commonly used metric for OPC photosensitivity. When determined as a function of field, data obtained in this manner can be analyzed in terms of the Onsager models. Because photosensitivity depends on field (surface potential per unit OPC thickness) and the exposure produced decrease in surface charge density (related to the change in surface potential through $\Delta Q = C\Delta V$), meaningful comparisons can only be made between OPCs of similar thickness, charged to similar initial potentials, and exposed to similar discharged potentials.

For a process using a flash exposure the photoreceptor discharge is determined at several exposure levels (with the surface potential determined at a fixed time after the exposure) and the data is plotted as surface potential (V) versus log(exposure, J/cm^2). An arbitrary

photodischarge point (typically 50%) can be determined from this plot for comparison purposes. The utility of this characterization is that the exposure characteristics and the timing for reading the discharged surface potential directly relate to the printing process. As discussed above, short high-intensity exposures may give rise to Langevan recombination [37.110, 112, 114], resulting in decreased sensitivity (reciprocity failure) relative to low-intensity exposures.

An often overlooked sensitivity factor is that there are more photons per energy unit (J) as the wavelength increases. For example, there are about 30% more photons/J at 820 nm relative to 630 nm. Thus, for a photoreceptor with a given quantum efficiency for carrier generation the sensitivity will increase with increasing wavelength of the exposure source.

37.3.3 Electrical-Only Cycling

Electrophotographic performance characterizations are necessarily carried out on the photoreceptor in an apparatus which has the key elements of the electrophotographic process. The most *relevant* apparatus would of course be the fully configured printer. However, the use of such a complex device is often undesirable, or unnecessarily, for screening purposes. In the laboratory it is common to use *electrical-only* test fixtures in which the process always includes charge and expose, and may include erase (or unique process elements), with the surface potential being determined after the application of each. With an apparatus such as this it is possible to determine process-relevant characteristics such as: chargeability, dark decay, photosensitivity, and residual potential, all as a function of cycling. Of course large changes in any of these characteristics is generally undesirable and long cycling (10–100 kcycles) is often necessary to adequately determine the electrical stability of the photoreceptor to the electrophotographic process. Such stability is a necessary, but not sufficient, condition for eventual commercialization, and extensive testing in the machine for which the photoreceptor was designed is always the final step in the development process. Other factors, often connected to the device physical characteristics (wear rate, corona chemical sensitivity, layer adhesion, seam strength, etc.) may in fact determine the eventual success or failure of a particular OPC in a printer.

37.4 OPC Architecture and Composition

As we have described, OPCs are large-area thin-film devices that are insulating in the dark and become conductive when exposed to light. A high field is applied by exposure to an air corona (or similar charging method) and the photoreceptor is image-wise exposed to produce an electrostatic latent image. The surface potential in the exposed areas is determined by the exposure intensity and the OPC photosensitivity while the surface potential in the unexposed areas is determined by the dark conductivity. The development system deposits charged marking particles (toner) on the photoreceptor surface according to the difference in surface potential between the exposed and unexposed areas. The key photoelectrical processes which enable latent image formation are photoinduced charge generation and the transport of the generated charge through the device. Organic photoreceptors accomplish this in a multilayer architecture with specific materials (monomers and polymers) designed and optimized for specialized functions: binder, charge generation, charge transport, dark conductivity, etc. In this section we will discuss the architecture and composition of organic photoreceptors with details on the function and composition of each layer.

37.4.1 OPC Architecture

The choice of photoreceptor thickness is a balance between capacitance, surface potential, and internal field. Capacitance relates to surface charge density, which determines the achievable developed toner density for toners with a given surface charge per area. Surface potential, in combination with the development system, provides the potential difference to attract toner to the photoreceptor surface. The internal field enables efficient charge generation and transport. In most electrophotographic printing machines the balance is achieved with an OPC thickness of $\approx 20-30\,\mu m$ and a surface potential of 500–1000 V.

A schematic cross section of a fully configured modern electrophotographic photoreceptor is shown in Fig. 37.12. In its most simple form the photoreceptor consists of a conductive substrate and a single layer of photoconductive material to accomplish charge generation and transport. The advantage of this structure is in its simplicity, but the disadvantage is that not all characteristics will be optimum. In the modern embodiment the photoreceptor is constructed with separate layers for charge generation (CGL) and charge

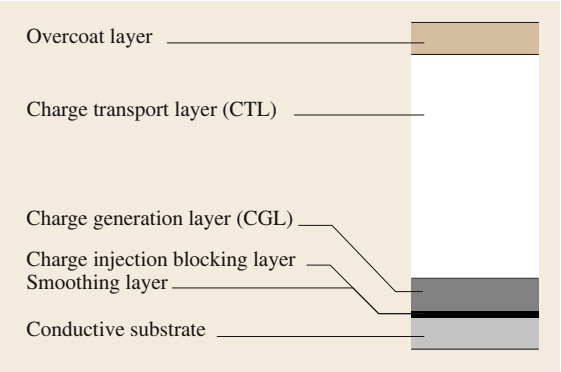

Fig. 37.12 A schematic cross section of a fully configured *modern* electrophotographic photoreceptor

transport (CTL). Other layers shown in Fig. 37.12 include: substrate, smoothing layer, charge-injection blocking layer, charge-generation layer (CGL), charge-transport layer (CTL), and protective overcoat layer. Additional layers, such as adhesive interlayers, and a back-side anti-curl layer may also be present. OPCs with separate CGL and CTL are termed dual-layer. Each of these layers may be a complex formulation of materials. The advantage in separating layers is that each layer can be optimized for its specialized function. This adds materials expense and manufacturing complexity but has the advantage of superior performance.

In a single-layer photoreceptor when exposed with strongly absorbed radiation directed at the free surface, charge generation will occur near the free surface and the photodischarge will be dominated by the transport of positive or negative charge through the bulk of the layer. The polarity of the mobile charge will be the same as the applied surface potential. In most commercial dual-layer photoreceptors the architecture is substrate–CGL–CTL. Because the CTL is formulated for hole transport, dual-layer OPCs are charged with a negative surface potential. Positive corona charging has some advantages over negative (better uniformity and less ozone production). A single-layer OPC can function with either a positive or negative surface charge depending on the exposure direction and the transport characteristics of the materials used in the formulation. Positive-charging dual-layer photoreceptors with the architecture substrate–CTL–CGL have been commercialized but these require a protective overcoat to prevent the CGL from being damaged by contact with the electrophotographic process elements. The typical substrate–CGL–CTL architecture will function with positive charging if the CTL is formulated for electron transport. Electron-transporting CTLs have been widely studied by not yet commercialized.

In a multilayer photoreceptor the principle is that the functions of each layer are optimized. Thus, with separate CGL and CTL the former is designed for strong absorption of the wavelength of light used in the process and efficient charge generation, and the latter is optimized for the injection of photogenerated charge from the CGL and transport of that charge to the free surface. In general, most charge-generation materials efficiently transport only one polarity of charge (electrons or holes depending on the material) so that it is generally desirable to have the CGL as thin as possible while retaining the required optical density at the exposure wavelength. It is also necessary that the CGL be uniform over the entire area of the photoreceptor to maintain consistent sensitivity for the entire photoreceptor surface. Submicron CGLs are typical of the photoreceptors used in most modern digital printers. The CTL determines the device capacitance and a thickness of $\approx 25\,\mu m$ is typical. However, the CTL thickness also influences the ultimate latent-image resolution in a digital printer because holes transiting the CTL experience mutual Coulombic repulsion [37.13, 115]. It has been shown that for optimum resolution the photoreceptor thickness should be about one quarter of the pixel size [37.13, 14]. Thus, for 600 dpi imaging ($\approx 40\,\mu m$ pixel size) the ideal photoreceptor is on the order of $10\,\mu m$. Thin OPCs have not yet been introduced into digital printers but one might anticipate that this will occur as toners get smaller and the processes of toner transfer and fusing are refined to minimize image disruption [37.116].

37.4.2 Coating Technologies

Hopper coating of continuous webs and dip coating of drums are the two technologies commonly used to fabricate photoreceptors. As with any large-area photoelectrical device absolute cleanliness is required to prevent artifacts in the coated layers. In a multilayer device one must carefully control the interfaces between the layers. For example, a key interface is that between the CGL and CTL. Here it is important that the two layers adhere but do not mix to such a degree that the desired characteristics of either layer are compromised. Attaining the desired degree of mixing is a process of optimization depending on the materials, solvents, and coating method.

In hopper coating the coating solution is continuously pumped through a slot onto the moving web. Film thickness is controlled by the pumping rate and solids content of the coating solution. Precise control of drying temperature, humidity, and air flow enable optimization of the coated layers. Curing of the coated film involves removal of solvent and annealing of the

polymer binder(s). In a hopper coating process several layers can be coated in a single pass with sequential hoppers as long as the previous layer is adequately cured. Hopper coatings can be carried out at a very high speed (m/s) to produce a roll of many thousands of feet. To coat subsequent layers the previously coated substrate is re-run through the coating machine. Because the hopper coating process involves contact of the coated surfaces, and winding of the coated web, there is the possibility of film damage. Final inspection for film defects must be carried out and damaged, or imperfectly coated, regions must be removed before construction of the final photoreceptor loops.

In a dip coating process the substrate and coated layers are dipped into a solution or dispersion of the next layer to be coated and slowly withdrawn and cured. The coated layer thickness is determined by the rheological characteristics of the coating solution and the rate of withdrawal. Under these conditions there is the opportunity for extensive interaction between the previously coated layer and the solution into which it is dipped. Thus, formulations which are suitable for hopper coating may be inadequate for dip coating even though the chemical compositions of the final coated layers might be identical after curing. Another consideration with dip coating is that components of the previously coated layers which are soluble in the solvent used in the subsequent dip will contaminate the dip reservoir. Low levels of contamination may be insignificant, but since the amount of fluid removed in each coating operation is a small fraction of the total volume one must make sure that such contamination does not degrade performance.

Other processes such as ring coating (a dipped drum is withdrawn through an annulus which acts as a doctor blade to control the wet coating thickness), spray coating, vacuum coating, etc. may be used for specific applications and materials. In all layers coated from solution it is often necessary to add a small quantity of surface-active agent as a coating aid to enable smooth, defect-free coatings.

In recent studies on charge transport in free-standing doped polymer films it has been reported that the surface exposed to the air during drying may have degraded transport characteristics, and a depleted concentration of charge transport material was suggested as the cause [37.117, 118]. This finding demonstrates that solvent coated layers are not necessarily of uniform composition. Inhomogeneous composition of a charge-transport layer could lead to degraded electrophotographic performance. Thus, in analyzing the electrophotographic performance of an OPC one must consider not only the composition of each layer, but also its uniformity both spatially and compositionally particularly at the interface with another layer.

In the following sections we will discuss details around the compositions of each of the layers which might be found in an organic photoreceptor for electrophotographic printing. The order of discussion is in the order in which the typical photoreceptor would be constructed: substrate and ground layer, smoothing layer and charge-blocking layer, charge-generation layer (CGL), charge-transport layer (CTL), and protective overcoat layer.

37.4.3 Substrate and Conductive Layer

A common element to all electrophotographic photoreceptors is a substrate on which all the layers are deposited. In a research environment a small square of glass or quartz is convenient, but in commercial applications the substrate is invariably either a polymer film or a metal drum. Some of the material characteristics which might be considered in the choice of a polymer film are: stiffness, toughness, transparency, core set, and surface friction. Polymeric photoreceptor substrates are often 3–7 mil. A common polymer film material is the polyester poly(ethylene terephthalate) (PET). PET film is very durable, optically transparent, and readily available in a wide range of thickness. Since it is highly insulating it must be coated with a conductive material to act as the ground plane. PET or other polymer films are available in large rolls and the coating operations are usually done on the roll rather than cut-to-size sheets. Although a solution-coated conductive layer is possible, the most common ground layers are metals such as Ni, Al, Cr, and Ti, which are applied in a continuous sputtering or similar vacuum technique. The metallized rolls are subsequently coated with the photoconductive layers. If a metal drum is the chosen substrate it is almost invariably aluminum (1–10 mm wall thickness). The conductive metal serves as the ground layer but typically it receives further treatment before coating the photoconductive layers. The treatment may be chemical such as anodization to form a thin hole-blocking layer, or physical such as turning or sanding. Because these secondary surface treatments add cost, a smoothing layer is often used instead.

The electrical conductivity requirements of the conductive layer are modest. The higher the process speed the greater the conductivity required for adequate surface charge accumulation. Analysis by *Chen* [37.119] demonstrated that the result of inadequate conductivity in corona charging of a photoreceptor is a nonuniform surface potential. The surface potential is decreased depending on the distance from the actual grounding

contact. For a typical situation the upper limit of the sheet resistance is $\approx 10^4\ \Omega$ per square.

Alternative approaches such as *seamless* webs and conductive plastic drums have been developed but have not yet been commercialized.

37.4.4 Smoothing Layer and Charge-Blocking Layer

For xerographic applications it is important that the conductive layer does not inject charge into the photoreceptor in the dark. However, the metals used as grounding layers all have the potential to inject holes into the photoreceptor CGL via direct contact with the charge-generation material or the hole-transport material. The injection and transport of charge in the dark would cause a loss of surface potential (dark decay). Since the formation of a latent image relies on a difference between the rate of dark- and light-induced surface potential decrease, a high dark decay rate means that the process must be amenable to a small imaging potential. Another aspect of dark injection from the conductive layer is that such phenomena often occur in small localized *charge-deficient spots*. In a process where the discharged areas are developed small deposits of toner are found in what should be non-toned background. To counter such processes it is common to interpose a charge- (typically hole-)blocking layer between the ground layer and the CGL. With drum photoreceptors it may be the roughness of the metal surface which initiates the charge injection. In this case it may be necessary to interpose a relatively thick *smoothing layer* between the metal surface and the CGL.

In principle, any good film-forming insulating material will suffice as a charge-blocking layer as long as adhesion to the ground layer and CGL are adequate. Several types of materials have been used for this purpose including polysiloxanes and nylons. Since these materials are insulating, in an electrophotographic charge/expose cycle there will be a residual potential due to the field remaining across the layer. This will build up with cycling depending on the layer conductivity and the process cycle time. Although residual potentials typically decrease when the photoreceptor is rested in the dark, in practice such relaxation is usually incomplete and in subsequent cycling the residual builds up at a faster rate. The physics and chemistry of such hysteresis is not well understood. At some point the residual potential may cause image degradation and necessitate photoreceptor replacement. Thus, the blocking layer must be thick enough to cover the ground layer uniformly but not so thick as to cause an undesirable residual potential. Generally such a layer is coated at around 1 μm or less. On the other hand, if a thicker layer is required (perhaps combining the functions of both charge blocking and surface smoothing) this can be accomplished with a charge transporting insulating layer. With the conventional multilayer OPC architecture (holes transported through the CTL), this layer must transport electrons injected from the CGL to the electrode and block hole injections from the electrode into the OPC. Such polymer films have been described with naphthalene bisimides as the electron transporting moiety [37.120, 121].

With an aluminum drum, a thin anodized layer is often used to prevent charge injection. However, anodization is relatively expensive, and it has been reported that a simple chemical process (dilute alkali treatment followed by immersion in boiling water) produces an effective blocking layer [37.122]. Making the drum surface smooth on a submicron scale is expensive and an alternative is to use a relatively thick smoothing/blocking layer to cover the surface irregularities. Smoothing layers are typically metal oxides (titanium for example) in a polymer binder. The oxide loading is high to impart sufficient conductivity to prevent a residual potential. If the metal oxide does not inject holes it also serves as the charge-blocking layer. Such layers are up to around 10 μm thick.

Imaging with monochromatic radiation in digital printers has led to a new imaging artifact caused by interference between the incoming and reflected light. In dual-layer OPCs with the CTL uppermost, if the CGL incompletely absorbs the exposing light it can be reflected from the ground layer. The interference pattern that is produced can be visible in the developed image as a *wood grain* pattern. One way to counter this is to scatter the incoming light before it's reflected. There are many patents describing techniques for carrying this out including roughening of the surface of the conductive layer.

37.4.5 Charge-Generation Layer (CGL)

The CGL is where the imaging light is absorbed and charges are generated. The first major consideration in choice of material is that it strongly absorb the wavelengths of light emitted by the exposure system. In copiers light is reflected from a document onto the charged photoreceptor. Since an original may have colored components the light source must cover the visible range (400–700 nm) and the photoreceptor must have broad sensitivity to visible light. Common light sources in copiers are fluorescent or xenon lamps. Both sources are generally filtered to remove ultraviolet and infrared light. In digital printers the exposing source may be an LED array (680–780 nm) or a scanned laser

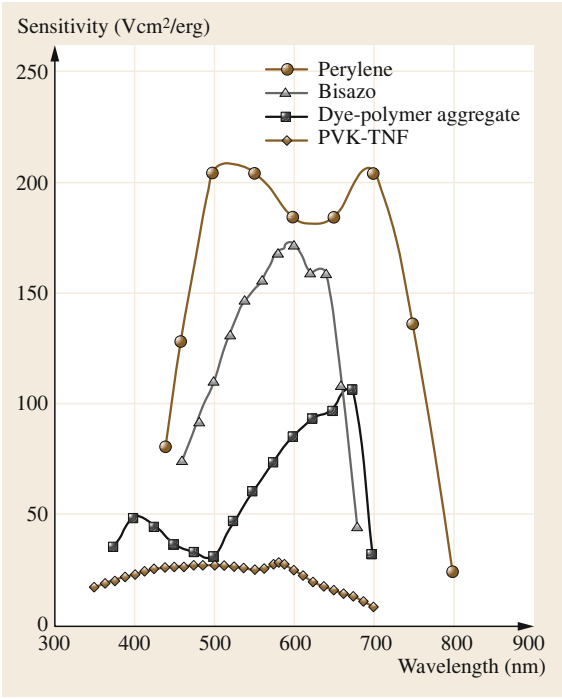

Fig. 37.13 Sensitivity action spectra of visible sensitive OPCs. The chemical structures of the CGL materials are given in Fig. 37.15

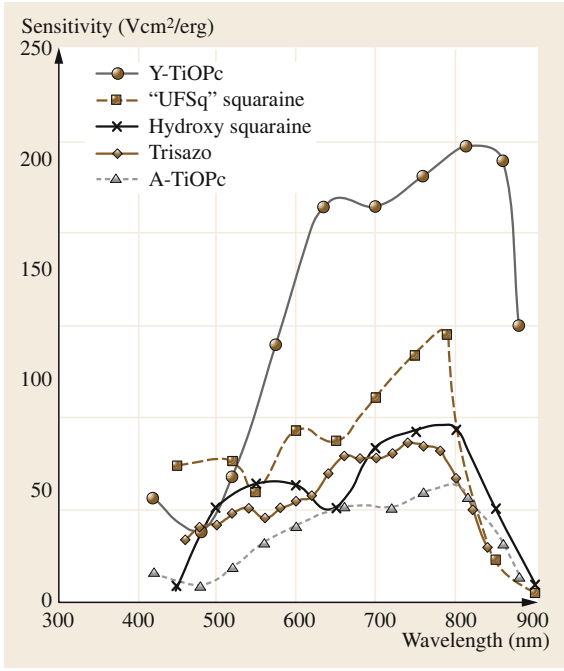

Fig. 37.14 Sensitivity action spectra of near-infrared sensitive OPCs. The chemical structures of the CGL materials are given in Fig. 37.16

(633 nm from He−Ne or 740, 780, and 820 nm from laser diodes).

Most modern commercial photoreceptors utilize pigments as charge-generation materials. Pigment-based CGLs comprise submicron crystals of the charge-generation material suspended in a polymer binder. Pigments are milled to the desired size and stabilized with appropriate additives and binders to produce a coating dispersion. Charge-generation materials are generally classified according to their chemical identity. Materials which absorb primarily in the visible region are dye–polymer aggregate, PVK–TNF charge-transfer complex, perylenes, and bisazos. Phthalocyanines, trisazo, and squarylium pigments are utilized for near-infrared absorption. Figures 37.13 and 37.14 show the sensitivity action spectra and Figs. 37.15 and 37.16 the chemical structures of these charge-generation materials. The sensitivity action spectra in these figures are taken from literature data and the sensitivities converted into consistent units ($V/(cm^2\,erg)$) based on information given in the cited publication. Because the data are from OPCs with different thickness, exposure intensity, exposure time, initial potential, and exposed potential, the sensitivities are not directly comparable. However, the wavelength ranges are accurate. When the exposure is through the CTL (in a negative-charging dual-layer OPC) the photosensitivity will be decreased at wavelengths below ≈ 400 nm because of light absorption by the transport material.

Perylenes, azos, and phthalocyanines are best known for their use as colorants and it is because these materials were readily available that they were investigated as charge-generation materials. A complication with pigments is that some exhibit polymorphism. Over many decades the colorant industry has developed technologies for controlling polymorphism to obtain pigments with specific colorant characteristics and similar technologies have been developed to obtain polymorphs with the appropriate absorption as well as charge-generation characteristics for electrophotographic applications. Thus, in many cases to prepare a CGL it is first necessary to convert the pigment-generation material into a dispersion of submicron particles of the desired polymorph. Examples of charge-generation materials are discussed below.

The donor–acceptor charge-transfer (CT) complex between poly(N-vinyl carbazole) (PVK) and 2,4,7-trinitrofluroren-9-one (TNF) was the first commercialized organic photoreceptor [37.123, 124]. The photoconductivity characteristics have been extensively studied [37.87–89, 92–94] and reviewed [37.125–128]. With the addition of TNF the carrier-generation efficiency of PVK is increased and extended into the region

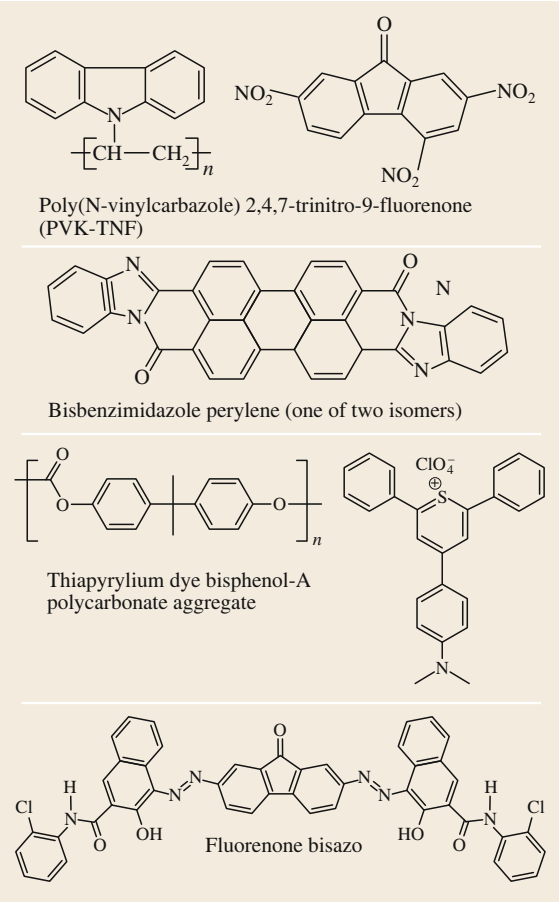

Fig. 37.15 Chemical structures of visible sensitive charge generation materials

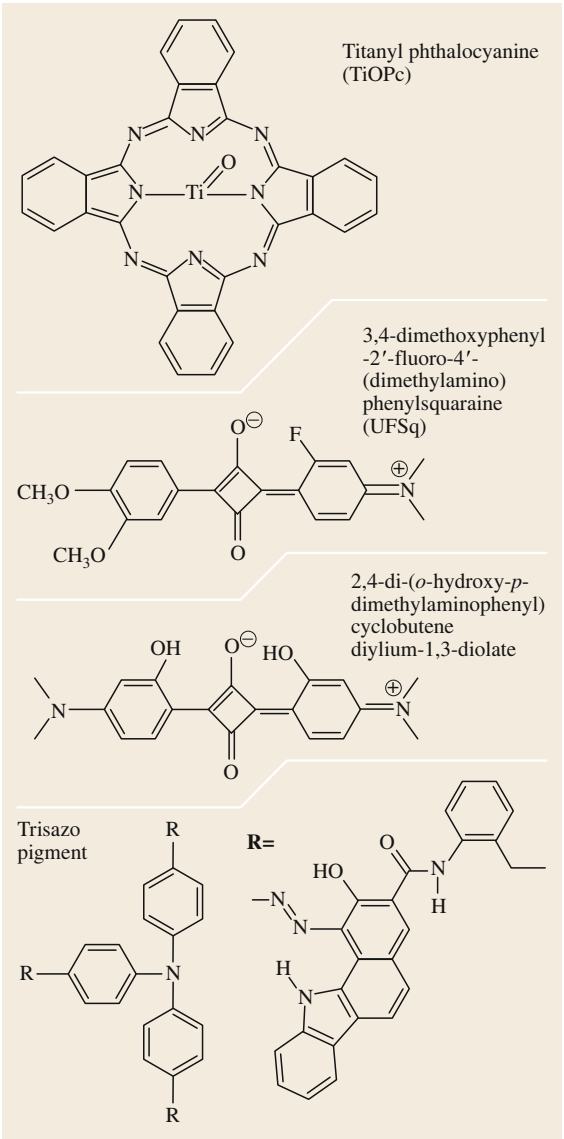

Fig. 37.16 Chemical structures of near-infrared sensitive charge generation materials

of CT complex absorption. Based on field quenching of exciplex fluorescence a mechanism for PVK–acceptor systems was proposed involving carrier generation from a nonrelaxed exciplex which is accessed by either direct absorption into the CT state or via an encounter complex between excited PVK and TNF [37.92–95]. As used in the IBM copiers I and II a 1 : 1 molar ratio of PVK to TNF was coated as a single 20 μm layer and electron-dominated transport was used to create the latent image (negative surface charge) with a He−Ne laser exposure (632.8 nm) [37.124]. An exposure of 5.5 $\mu J/cm^2$ was used to decrease the surface potential from −750 to −200 V. The quantum efficiency based on incident photons was ≈ 0.2 while the maximum efficiency was ≈ 0.3 at ≈ 400 nm. The photosensitivity action spectrum for this OPC is shown in Fig. 37.11 [37.123]. Using the photoinduced discharge technique [37.90] the maximum quantum efficiency (charges transported through the device per photon absorbed) was found to be 0.14 at 375 nm and a field of 10^6 V/cm. The PVK–TNF-based OPC had several drawbacks: low photosensitivity, short lifetime in the electrophotographic process, and concerns about the safety of TNF. It was eventually replaced with dual-layer OPCs with CGL materials based on pigments. Acceptor-doped PVK continues to receive attention particularly with C_{60} and related molecules as the acceptor [37.129].

The dye–polymer-aggregate based CGL is unique in that the active material is formed in situ during the coating process. A solution of thiapyrylium dye (2,6-diphenyl-4(4-dimethylaminophenyl)thiapyrylium per-

chlorate) and bisphenol-A polycarbonate is coated to form a CGL in which the dye and polymer spontaneously aggregate [37.130–132]. The aggregate is a dense filamentary structure which has an absorption spectrum red-shifted from that of the dye. The aggregate filaments transport electrons with high field trapping due to carrier immobilization at filament dead ends. The photosensitivity of the aggregate is several orders of magnitude larger than that of the nonaggregated dye [37.133]. To prepare a CGL the formulation also includes hole-transporting materials. Because the CGL transports both holes and electrons it is possible to use the aggregate as a single layer or as the CGL in a dual-layer photoreceptor. Because the aggregate absorption drops rapidly at wavelengths longer than 700 nm this material is only useful for visible-light exposure systems, Fig. 37.13. In this example the CGL (2 μm) comprised dye and tri-*p*-tolylamine (TTA) hole-transport material in polycarbonate, and the CTL (13 μm) was a solid solution of 40 wt% tri-*p*-tolylamine in a polyester binder [37.96]. This was charged to −600 V and exposed with very low-intensity continuous irradiation to obtain the initial rate of photodischarge. At 680 nm the photogeneration efficiency is 0.34 per absorbed photon. The quantum efficiency (Onsager model) was 0.6 and the thermalization distance was dependent on the concentration of hole-transport material ranging from 200 nm (5 wt%) to 600 nm (40 wt%) [37.96], Fig. 37.11.

Azo compounds contain the −N=N− functionality. Bisazo compounds have the general structure R′−N=N−R−N=N−R″. Trisazo compounds have the general structure R(−N=N−R′)(−N=N−R″)(−N=N−R‴). The R substituents generally have extended conjugation to provide the colors which have made bisazo compounds important dyes and pigments for many years. Bisazo CGLs generally absorb in the visible and trisazo into the near-infrared. An early example of a bisazo pigment-based OPC (chlorodiane blue, 4,4′-bis(1″-azo-2″-hydroxy-3″-naphthanilide)-3,3′-dichlorobiphenyl) was used in the IBM 3800 printer. This photoreceptor had over four times the photosensitivity of the PVK–TNF-based OPC [37.134]. Azo charge-generation materials are often synthesized from the reaction of an aromatic amine with an o-hydroxyaromatic carboxylic acid such as naphthol-AS. As CGL materials these materials are used as dispersed pigments. Although bisazo pigments do not generally exhibit polymorphism they can exist as hydroxy-azo or keto-hydrazone tautomers. In some cases, it has been found that the active form is the keto-hydrazone tautomer [37.135]. Because the synthesis of azo compounds is relatively easy there is a considerable literature on the effects of chemical structure on electrophotographic characteristics and carrier-generation efficiency [37.136–140]. In azo pigments charge is generated extrinsically with the pigment exciton oxidizing a hole-transport molecule at the pigment surface [37.140, 141] and it was demonstrated that penetration of the CTL into the CGL occurs during the coating process [37.142]. The photosensitivity action spectrum for a fluorenone bisazo pigment is shown in Fig. 37.13 [37.141]. In this OPC the CGL (0.17 μm) consisted of the pigment in a binder of poly(vinyl butyral) (10 : 4 weight ratio) and the CTL (17.4 μm) a solid solution of hydrazone transport material, p-diethylaminobenzaldehyde diphenylhydrazone (DEH), in polycarbonate (9 : 10 weight ratio). The initial potential was −800 V and the exposure required for a discharge to −400 V determined. The quantum yield of carrier generation from the Onsager model was 0.52 with a thermalization length of 1400 nm. Time-resolved transient absorption spectroscopy has been used to study the formation and decay of the oxidized transport material [37.143]. With a bisazo-based CGL (chlorodiane blue) [37.144] and trisazo-based CGL it was found that the charge-generation efficiency depended on the oxidation potential of the CTL transport materials [37.138]. In the most favorable case the bisazo had a quantum efficiency of 0.25 and the trisazo about 0.5. This was interpreted in terms of the energy gap between the hole at the pigment surface and the transport material. In a study using a series of bisazo pigment CGLs and a common CTL it was found that neither electron donating nor withdrawing substituents favor high photosensitivity [37.139]. Photosensitivity was found to depend inversely on the crystallinity of the pigment, which was interpreted in terms of pigment surface area. The development of high-sensitivity azo-based CGLs has been reviewed by *Murayama* [37.145]. The trisazo pigment-based OPC has an absorption which extends into the near-infrared, making it suitable for laser exposures. Figure 37.14 shows the photosensitivity action spectrum of an OPC with a trisazo pigment CGL [37.146]. The CGL (0.33 μm) consisted of the pigment in poly(vinyl butyral) binder (10 : 4 weight ratio) and the CTL (18.5 μm) was a solid solution of DEH transport material in polycarbonate (9 : 10 weight ratio). The initial surface potential was −700 V and the exposure to discharge to −300 V used to determine the photosensitivity at each wavelength. A photoreceptor with CGL (0.12 μm) and CTL (19.5 μm) had a quantum efficiency for charge generation of 0.46 from 500−800 nm [37.146].

Perylenes used as CGL materials are diimides of perylene-3,4,9,10-tetracarboxylic acid. One example is the N,N′-bis(2-phenethyl)-perylene-3,4:9,10-bis(dicarboximide). In this case the CGL was pre-

pared by vacuum deposition of an amorphous film (0.1 μm). Exposure to dichloromethane (as when overcoating with the charge transport layer) converts the film into a crystalline form with enhanced absorption at 620 nm [37.147]. The mechanism of carrier generation of this pigment in the presence of tri-*p*-tolylamine has been studied by studying the field dependence of quenching of perylene fluorescence [37.148]. The results were interpreted in terms of both intrinsic (directly from the perylene singlet state) and sensitized (interaction of holes on the pigment surface with the amine) charge generation. A bisbenzimidazole perylene has been developed as a CGL [37.149–151]. Dual-layer OPCs with a CGL of 0.1 μm vacuum-deposited bisbenzimidazole perylene, and a 15 μm CTL of 35 wt% TPD in polycarbonate, exhibit high sensitivity ($E_{1/2}$ 2 erg/cm^2 for −800 V_0) out to 700 nm, Fig. 37.13. Further research has involved the synthesis and study of novel materials such as dimeric perylene pigments [37.152].

Phthalocyanines have received considerable attention as CGL materials for near-infrared exposure systems. Metal-free (H_2Pc) [37.153–156], titanyl (TiOPc) [37.157], and hydroxygallium (HOGaPc) [37.158] phthalocyanines have been extensively studied as CGL pigments. Although these materials are relatively easy to synthesize their intractability makes them difficult to purify. Except for halogen substituents on the aromatic rings there has been little research into the effect of chemical structure on performance. Instead, much of the development has been to understand and control polymorphism. Compared with solution absorption spectra, the spectra of many CGL pigments are broadened with enhanced absorption in the red and near-infrared. With specific combinations of milling technique, solvent exposure, and thermal treatment many phthalocyanine polymorphs can be produced [37.159–162]. Polymorphs have been characterized by visible and near-infrared absorption spectroscopy, x-ray diffraction, nuclear magnetic resonance (NMR) spectroscopy, infrared spectroscopy, and infra-red (IR) absorption spectroscopy. Examples of TiOPc polymorph absorption spectra are shown in Fig. 37.17 [37.157]. Polymorphs may have very different photogeneration characteristics as CGLs in OPCs. The materials shown in Fig. 37.17 were fabricated into OPCs: CGL, 0.4 μm, pigment and poly(vinyl butyral) 1 : 1 weight ratio; CTL, 20 μm, 43 wt% triarylamine hole-transport material, 4-(4-methylstyryl)-4′,4″-dimethoxytriphenylamine, in polycarbonate. The photosensitivity action spectra for OPCs from the Y- and A-forms of TiOPc are shown in Fig. 37.14. The OPC with the Y-form had a photosensitivity for half photodischarge (600−850 nm) of 0.75 erg/cm^2 (initial potential −600 V) while the

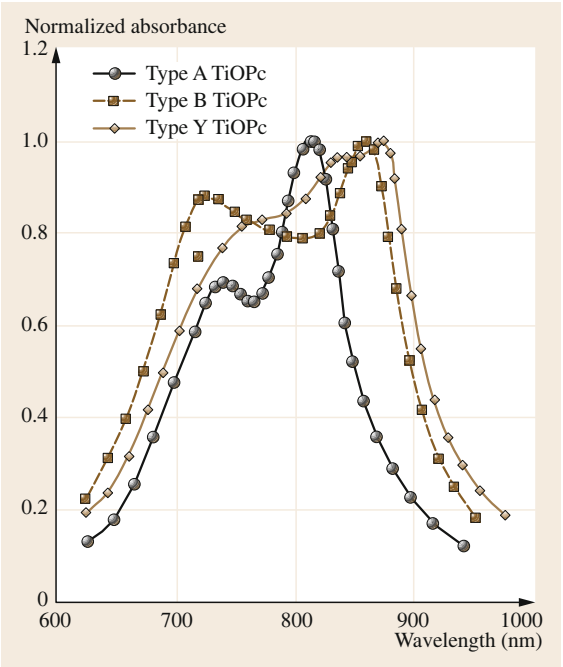

Fig. 37.17 Absorption spectra of polymorphs of TiOPc. (After [37.157])

A-form was much less sensitive. In another study, photoreceptors formulated with α-, β-, τ-, and X-forms of H_2Pc had generation efficiencies as follows (5×10^5 V/cm): $\tau_2 \approx 0.1$, $X_2 \approx 0.09$, $X_1 \approx 0.03$, $\beta_1 \approx 0.01$, $\alpha_2 \approx 0.005$, and $\alpha_1 \approx 0.001$ [37.163]. In the preparation of a generation material a common procedure is to prepare the pigment in the amorphous form by acid pasting or with a specific milling technique, and then to convert the pigment to the desired polymorph with a specific solvent treatment. The desired polymorph must of course be stable to all the subsequent operations. In addition to the dominant influence of crystal form on electrophotographic performance, studies have implicated water in carrier generation of Y-form TiOPc [37.157, 164]. A recent paper has reviewed the carrier generation mechanisms in several phthalocyanines [37.165]. In all the pigments studied (x−H_2Pc, TiOPc (I) (low sensitivity), TiOPc (IV) (also known as Y, high sensitivity), HOGaPc (V)), fluorescence quenching implicates a neutral excited state (not a charge-transfer state) as the precursor to carrier generation. Studies of the effect of field on fluorescence amplitude and lifetime reveal that with HOGaPc and TiOPc (I and IV) carrier generation comes from a non-relaxed excited state and TiOPc (IV) has an additional generation channel from a trapped state. With x−H_2Pc trapped excitons appear to be the major source of charge carriers.

Squarylium (squaraine) pigments are a class of materials which were first synthesized in the 1960s. Squaryliums (2,4-di-(*o*-hydroxy-*p*-dimethylaminophenyl)cyclobutene and 1,4-bis-(4-dimethylamino-2-methylphenyl diylium-1,3-diolate)) were the first pigments to be utilized as a near-infrared-sensitive CGL in an IBM printer [37.144, 166, 167]. The photoreceptor based on the hydroxy squarylium with a CTL (21 μm, DEH in bisphenol-A polycarbonate) had high photosensitivity from 500–800 nm (≈ 3 erg/cm^2 for a −700 to −200 V photodischarge), Fig. 37.14 [37.167]. This class of pigment has been extensively investigated for use as pigment-dispersion CGLs for near-infrared exposure systems [37.149, 168–174]. A nonsymmetrical squaraine (UFSq)-based OPC with CGL, 0.4 μm UFSq in poly(vinyl formal) (80 : 20 weight ratio), and CTL 26 μm 40 wt% TPD in bisphenol-A polycarbonate, exhibited an $E_{1/2}$ photosensitivity of 1.9 erg/cm^2 at 790 nm (−980 V_0) when optimally purified [37.174], Fig. 37.14.

37.4.6 Charge-Transport Layer (CTL)

In all current commercial organic photoreceptors holes are the carriers that dominate photodischarge of the device. Hole transport is carried out by aromatic amines which are either doped into, or are incorporated as part of, the binder polymer. The key molecular characteristic is that aromatic amines have relatively low oxidation potentials. The oxidation potential of the transport moiety must be lower than that of the charge-generation material such that photogenerated holes are injected from the generation material into the charge-transport layer. In a chemical sense the key reaction is oxidation of the charge-transport material by the photogenerated hole on the surface of the generation material. If the oxidation potential of the transport material is too low it will undergo air oxidation, if it is too high its oxidation will require an activation energy and will be inefficient. Molecular orbital studies suggest that molecules with little change in geometry with oxidation will be favorable for hole transport [37.175]. Aromatic amines with oxidation potentials between about 0.8–1.2 eV (relative to SCE) are generally useful as hole-transport materials. The synthesis and study of hole-transport molecules is a very active area. Figure 37.3 shows the chemical structures of some common hole-transport materials:

- 1,1-Bis(*p*-diethylaminophenyl)-4,4-diphenyl-1,3-butadiene (DPB)
- *p*-Diethylaminobenzaldehyde diphenylhydrazone (DEH)
- tri-*p*-Tolylamine (TTA)
- N,N′-Diphenyl-N,N′-bis(3-methylphenyl)-(1,1′-biphenyl)-4,4′-diamine (TPD)
- 1,1-Bis(di-4-tolylaminophenyl)cyclohexane (TAPC).

These are often referred to by acronym and classified according to one of their structural functionalities: arylmethane, diarylamine, enamine, triarylamine, heterocyclic, butadiene, and hydrazone. A more complete listing is available in *Borsenberger* and *Weiss* [37.5]. A wide variety of new hole transporting materials for electrophotographic photoreceptors have been reported. These include carbazole-containing enamines [37.176], indolo[3,2-b]carbazole derivatives [37.177], and phenyl-1,2,3,4-tetrahydroquinoline [37.178], among many others.

Charge transport was discussed previously (Sect. 37.2.2). Since transport involves orbital overlap between neighboring charge-transport moieties their concentration needs to be as high as possible. In practice, molecular transport materials are doped, singly or as a mixture, at 40–50% by weight into the binder polymer. The purpose of the binder polymer is to provide an inert, robust, substrate for the transport material. The mobility characteristics of a large number of hole-transport materials have been studied and the results interpreted according to a model where the dissolved transport molecules are disordered in energy and position [37.179–181]. Binder effects on hole transport have been observed. It appears that the presence in the CTL of materials with highly polar substituents decrease hole mobility but in general these effects are not well understood [37.182–187].

Since the CTL is typically the surface that is exposed to the various electrophotographic process elements it must be formulated to resist damage and wear. The glass-transition temperature (T_g) of the CTL is an important characteristic. Too low and the material will be soft and easily damaged, too high and it will be brittle. Generally a T_g around 60 °C is adequate. Polycarbonates and polyesters are two classes of materials commonly used as CTL binder polymers. Exposure of the CTL to the effluents of the corona charging system, UV light, reactive chemicals (ozone and nitrogen oxides), ions, etc., results in surface oxidation and degradation of both the physical and electrical characteristics of the CTL [37.188].

Dual-layer devices in which electron transport dominates have been studied extensively but never commercialized. Examples of commercialized electron-transport-dominated photoreceptors are the single-layer dye–polymer aggregate and the PVK–TNF charge-transfer complex. Electron-transport materials are designed to be easily reduced. The reduction potential

must be lower than that of the photogenerated electron on the charge-generation material so that it is transferred to the transport material. However, it is believed that oxygen may act as an electron trap so the reduction potential of the transport material must be lower than that required to reduce oxygen dissolved in the polymer film. Figure 37.10 shows the chemical structures of some electron-transport materials. As with hole-transport materials acronyms based on molecular functionality are common:

- 1,1-Dioxo-2-(4-methylphenyl)-6-phenyl-4-(dicyanomethylidene)thiopyran (PTS),
- *n*-Butyl 9-dicyanomethylenefluorene-4-carboxylate (BCMF),
- 2,4,7-Trinitro-9-fluorenone (TNF),
- 3,3′-Dimethyl-5,5′-di-*t*-butyl-4,4′-diphenoquinone and 3,5′-Dimethyl-3′,5-di-*t*-butyl-4,4′-diphenoquinone isomer mixture (DPQ).

A more complete table can be found in *Borsenberger* and *Weiss* [37.5]. In general the charge mobilities observed with electron-transport materials are much lower than for hole-transport materials. For this reason dual-layer OPCs with electron-transport-based CTLs have not been commercialized. Analysis of the mobility characteristics of electron transport with the disorder model implicates the highly polar nature of many electron-transport molecules [37.189–192].

Both hole- and electron-transport materials have been prepared with the transport moieties as part of a polymer (main chain or pendant) which would serve as a binder with hole-transport functionality. The advantage of a transport-active polymer is that it is a single material with improved physical characteristics relative to the corresponding molecularly doped polymer. In practice, charge transport is generally not enhanced in these materials and their chemical complexity makes them expensive to synthesize. Also, they are still susceptable to the damaging effects of the charging system in the electrophotographic process. Many polymers have been synthesized utilizing hydrazones [37.193–195] or other hole-transporting functionalities [37.196, 197].

Backing Layer

In a web photoreceptor the substrate–photoreceptor may tend to curl due to the residual stress of the coated layers. Such curl can make it difficult to fabricate the web into loops, may degrade loop tracking in the machine, or cause the loop edge to touch other process elements. Any of these attributes would make the photoreceptor unusable. One way to counter film curl is to coat a polymer layer on the back side to compensate for the stresses in the photoreceptor layers. The back-coat polymer must have adequate physical characteristics (friction, wear, etc.) to withstand cycling in the process. The extra coating adds expense but its addition is relatively commonplace. Any suitable polymer, such as a polycarbonate, may be used.

37.4.7 Overcoat Layer

Overcoat layers have received increased attention to lengthen the photoreceptor life by preventing wear, minimizing the effects of surface contacts, the effects of corona effluents (ozone and nitrogen oxides), and liquid attack in liquid-toner-based printers. As with the charge-blocking layer, the simplest approach is to coat a thin insulating polymer onto the photoreceptor surface. The thickness cannot be more than a few μm if one wants to avoid large residual potentials. Several approaches have been developed. One approach is to coat a second CTL with a changed composition to maximize polymer toughness (often by lowering the concentration of transport material or adding inorganic filler particles). Other approaches are to overcoat the photoreceptor with a silsesquioxane sol-gel several μm thick [37.198, 199], or with a submicron refractory layer of diamond-like carbon [37.200] or AlZrN [37.201]. However, the thinness of the refractory materials limits their utility for scratch and wear resistance. Furthermore, depending on their chemical make up they may have sensitivity to corona gasses.

Silsesquioxane overcoats applied in a sol–gel process have received attention [37.202, 203]. A commercial application utilized a sol–gel to overcoat a photoconductor with an uppermost CGL (positive-charging OPC). Because the CGL is sensitive to wear and corona chemicals an overcoat was essential to its implementation in a commercial photoreceptor. The sol is prepared and subsequently hopper-coated and cured at elevated temperature to effect crosslinking. To avoid a residual potential some conductivity is necessary but this cannot be so high that the latent image is degraded particularly under high humidity conditions [37.204]. The conductivity can be controlled with an ionic dopant [37.202] or by the incorporation of a hole-transporting functionality into the sol-gel matrix [37.203, 205].

A polyurethane overcoat in a positive-charging dual-layer OPC has been described for use in a liquid-toner-based printer [37.206]. The CGL was based on TiOPc pigment and, to avoid disruption of the CGL during the overcoat coating operation, an aqueous polyurethane dispersion was used.

A tough, durable, overcoat layer is described in a Konica Minolta Research Report [37.207]. The overcoat is a curable resin chemically bonded to inorganic nanoparticle filler. After one million prints at high

humidity in an electrophotographic printer the OPC thickness decreased by 1.5 μm, but the printed images showed no degredation in quality relative to a new OPC.

37.5 Photoreceptor Fabrication

As discussed above the two most common photoreceptor configurations are as a loop or a metal drum. After coating the layers of a drum photoreceptor it is ready to use in the process. Generally the drums are inspected for visible defects and samples are taken for process testing and quality control. Since the substrate is conductive the ground contact is easily made by means of a conductive brush contacting the edge or inside of the drum when it is mounted in the machine. On the other hand, after the appropriate layers are coated on a web several more steps are required for fabrication of the photoreceptor. The web is rolled onto a spool at the end of the coating process and subsequently slit to the desired width and rewound. The coated roll is then inspected for visible defects and defective areas are marked for removal. Defective areas are removed when the photoreceptor is cut to the desired length. The cut sheets are then ultrasonically welded to produce a photoconductor loop. Because the conductive layer is buried between the substrate and the coated layers, making a ground contact is not trivial. It is possible to leave one edge of the ground layer uncoated but, because the thin metal would be readily damaged or worn away with use, one typically finds a conductive stripe coated on one edge of the photoreceptor. The only requirement is that the conductive stripe penetrate the coated layers and contact the metal. The ground contact in the machine is often made with a conductive brush contacting the conductive stripe. The printing machine must keep track of the splice for several reasons: cleaning blade, degraded photoconductivity due to the ultrasonic welding, etc. This is sometimes accomplished by applying marks to the back of the photoreceptor, which are detected by the machine.

Fabricating a photoreceptor loop entails several operations not required in the fabrication of drum photoreceptors (slitting, cutting, conductive striping, welding, backside marking, etc.). Web-coating a photoreceptor is an expensive process but many thousands of feet of photoreceptor can be produced in a single coating event. Furthermore all the loop-processing elements are relatively straightforward and inexpensive. The key factor is that web-coating is a continuous process while drum-coating is a batch process. Photoreceptor loops are generally about ten times less costly to produce than drums.

There are advantages and disadvantages to both seamed loop and drum configurations in a printing machine. Loops can be made small for desktop printers or large for high-speed commercial printers. A large web (current commercial webs are as large as ≈ 10 ft in circumference) provides more surface area for imaging (several images per loop cycle) and more space for the various electrophotographic process elements. In addition, exposures through a semitransparent conductive layer are possible. Disadvantages are the presence of a seam which must be tracked and makes some processes, such as cleaning with a blade, problematic. Also, the tendency of a web to flutter or move necessitates both tracking and positioning to achieve adequate print registration. Metal drums are seamless and rigid, making it easier to control drum position. However, drums typically have a diameter of 35–300 mm and have limited imaging area and space for process elements. All things being equal a loop which produces several images per cycle will produce more images over its lifetime than a drum. Ultimately, the choice of loop or drum is a printing system issue.

37.6 Summary

Organic photoreceptors have been utilized in electrophotography since 1970. In this chapter we have briefly reviewed the development of organic photoreceptors from the standpoint of the device architecture, materials formulation, and electrical characteristics with emphasis on how the materials used impact on specific device functions.

The use of organic materials has enabled the development of electrophotographic technologies into a multi-billion-dollar business. Today's organic photoreceptor is a large-area photoelectric device capable of very high spatial resolution in the formation of a large-area image, with pixel resolution as small as 20 μm (1200 dpi), to meet demanding image-quality re-

quirements. It is truly an amazing success story. Many of the principles and indeed many of the same materials are being applied to today's highly publicized new technologies including organic light-emitting diodes (OLEDs), organic photovoltaic devices (OPV), and organic transistors. In this chapter we have described the device requirements and shown how organic photoreceptor development has progressed through a combination of architecture manipulation and materials design.

Organic photoreceptors have to satisfy many diverse requirements to be successfully employed in electrophotography as it is practiced today. These requirements have been met in large part by the principles of: (1) functional separation, and (2) materials design for the enhancement of specific electrical and mechanical characteristics. The concept of functional separation was key to organic photoreceptor development. Rather than try to produce a device with all the desirable characteristics in a single layer it is more productive to have a multilayer architecture with each layer being optimized for a specific characteristic. Not surprisingly these layers are commonly named after those characteristics which are paramount: the charge-generation layer (CGL), the charge-transport layer (CTL), the charge-blocking layer, the protective overcoat layer, etc. In this chapter we have described the characteristics of each of these layers and demonstrated how materials have been chosen and new materials synthesized to optimize their characteristics.

It is worthwhile to take a minute to review the electrophotographic process and consider the characteristics which have been built into the device:

- Spatial uniformity. The thickness of each of the coated layers (each varies from submicron to a few tens of μm) and the total thickness (controlled mainly by the CTL) must be very uniform so that the device capacitance (a major factor in determining surface charging characteristics) is uniform (on the order of a few percent variability). The CGL generation characteristics must be uniform, which means that the optical density of the CGL at the exposure wavelength must be uniform, to produce a uniform surface potential after exposure (on the order of a few percent variability). Thickness must be uniform for the smallest pixel (20 μm for 1200 dpi imaging) over the entire area of the device ($> 1000\,cm^2$). The ability to coat large areas of such thin layers to this degree of uniformity is a great technological achievement.
- Chemical resistance. Photoreceptors must resist chemical attack. Because corona charging is the most common method of applying a surface potential, the photoreceptor must be stable to the acid and oxidizing species produced in the corona. These chemicals (ozone, NO_x, and HNO_x) are highly reactive and the layer that is exposed (usually the CTL) must not be degraded. This is achieved by judicious choice of materials, the addition of stabilizers (antioxidants) to the CTL, or a protective overcoat.
- Electrical uniformity and stability. The photoreceptor dark electrical and photoelectrical characteristics (surface potentials with no exposure, imaging exposure, and erase exposure) must be very uniform and stable to prolonged electrophotographic cycling. The initial (dark) and exposed potentials must be the same for each pixel over the entire device area and must remain stable with cycling. If these characteristics drift uniformly with cycling, machine process control must be implemented to maintain image quality. If these characteristics drift nonuniformly the photoreceptor must be discarded when image artifacts (ghosting) appear.
- Photosensitivity. The sensitivity of the photoreceptor to light, often expressed as the energy needed to produce a defined decrease in surface potential, must be mated with the exposure used in the process in terms of exposure energy and wavelength. This has been achieved by the synthesis and pigment form manipulation of charge-generation materials. Today's high-sensitivity photoreceptors can approach a quantum efficiency of unity for charge generation (at a typical applied field of $\approx 20\,V/cm$). But, most importantly photoreceptors with lower sensitivity can be fabricated depending on the needs of the imaging system.
- Photodischarge rate (switching time). The time it takes for photogenerated carriers to transit the device limits the printing process speed. With the synthesis of highly stable hole-transport materials and the principle of molecularly doped polymers it has been possible to prepare devices with hole transit times that permit printing speeds approaching 200 pages/min.
- Mechanical strength. The surface of the photoreceptor that is exposed to the abrasive process elements (often the development and cleaning systems), must not wear too rapidly or unevenly and must be stable to crazing or other forms of damage. Typically the CTL is the surface layer, and considering that it is typically a polymer with as much as 50% by weight of charge-transport molecules, it is remarkable that materials can be chosen such that significant wear occurs only after tens of thousands of cycles. Where warranted, very tough protective overcoats have been developed which have little effect on the overall OPC device performance.

Today multilayer organic photoreceptors that meet all of the requirements listed above are made commercially on a huge scale. This success is due in large measure to the skill of the scientists and engineers who design the materials and processes for photoreceptor fabrication, and who then integrate it into the electrophotographic printing system such that acceptable and consistent image quality is obtained for a photoreceptor life, which is routinely 200 000 imaging cycles or longer if protective overcoat layers are used. This is an amazing story, an organic photoreceptor device with *adjustable* sensitivity at any desired wavelength from the visible to the near-infrared, with stable dark and photoelectrical characteristics over many thousands of imaging cycles, such that the characteristics of a 40 μm pixel area are identical over an area which might be greater than 1000 cm^2.

Acknowledgments. Martin A. Abkowitz received his Ph.D. in Physics from Syracuse University in 1964. In 1965 he joined the Xerox Corp. Webster Research Center where he was a Principal Scientist until his retirement in 1969. After retirement he was a Visiting Scientist at the University of Rochester. He was a Fellow of the American Physical Society, had 174 publications including 35 U.S. patents, and made over 250 contributed and invited presentations at international conferences. Martin passed away on January 30, 2014. The scientific community has lost an outstanding physicist and I, his co-author, have lost a dear friend.

38. Luminescent Materials

Andy Edgar

This chapter surveys the field of solid-state luminescent materials, beginning with a discussion of the different ways in which luminescence can be excited. The internal energy-level structures of luminescent ions and centres, particularly rare-earth ions, are then discussed before the effects of the vibrating host lattice are included. Having set the theoretical framework in place, the chapter then proceeds to discuss the specific excitation process for photo-stimulated luminescence and thermally stimulated luminescence before concluding by surveying current applications, including phosphors for compact fluorescent and LED lighting, long-term persistent phosphors, x-ray storage phosphors, and scintillators.

Luminescent materials are substances which convert an incident energy input into the emission of electromagnetic waves in the ultraviolet (UV), visible or infrared regions of the spectrum, over and above that due to black-body emission. A wide range of energy sources can stimulate luminescence, and their diversity provides a convenient classification scheme for luminescence phenomena, which is summarised in Table 38.1. Photoluminescence, where the luminescence is stimulated by UV or visible light, is a widely used materials science technique for characterising dopants and impurities, and finds applications in lighting technologies such as fluorescent and solid state lamps. Radioluminescence involves excitation by ionising radiation, and is used in scintillators for nuclear particle detection; the special case of stimulation by energetic electrons is called cathodoluminescence, the name arising from early atomic physics experiments involving gas discharges. Electroluminescence involves collisional excitation by internal electrons accelerated by an applied electric field, and with a much lower energy than in the case of cathodoluminescence. Electroluminescence finds applications in panel lighting used in some liquid-crystal display (LCD) back-planes, in inorganic light-emitting diodes (LEDs) and organic light-emitting diodes (OLEDs).

There are other forms of luminescence which we mention for completeness but will not discuss further: bioluminescence and chemiluminescence where the energy input is from chemical or biochemical reactions, sonoluminescence (sound wave excitation), and triboluminescence (strain or fracture excitation). Both organic and inorganic systems can display luminescence, but here we focus primarily on inorganic systems.

There are several books which describe the luminescence and spectroscopy of inorganic materials [38.1–4] and applications to phosphors and scintillators [38.5, 6] in more depth than is possible in a short article.

The terms phosphorescence and fluorescence are often used in connection with luminescent materials. This classification is based on the time-domain response of the luminescent system. Figure 38.1 shows a generic

Table 38.1 Types of luminescence

Designation	Excitation	Trigger	Acronym
Photo-luminescence	UV, visible photons	–	PL
Radio-luminescence	X-ray, gamma rays, charged particles	–	RL
Cathodo-luminescence	Energetic electrons	–	CL
Electro-luminescence	Electric field	–	EL
Thermo-luminescence	Photons, charged particles	Heat	TSL
Optically/photo-stimulated luminescence	Photons, charged particles	Visible/IR photons	OSL, PSL

photoluminescent system where incident UV radiation excites a system from a ground state 1 with probability per unit time P_{12} into an excited state 2. The system decays with probability P_{23} to a luminescing level 3, from which there is a probability P_{31R} and P_{31NR} of radiative and nonradiative decay, respectively, to the ground state. Nonradiative decay generally involves phonon emission.

First suppose that the transition probabilities are such that $P_{12}, P_{21} \gg P_{31}(= P_{31R} + P_{31NR})$. If the optical pumping (excitation) is abruptly stopped, the population of the luminescing state 3 decays as,

$$N_3 = N_3(0)\exp(-P_{31}t) \tag{38.1}$$

and the rate of luminescent energy emission is $-(h\nu P_{31R}/P_{31})\mathrm{d}N_3/\mathrm{d}t$ for an energy difference $E_{31} = h\nu$ between states 1 and 3. Hence the luminescence intensity at distance r from the sample is,

$$I = (h\nu)N_3(0)P_{31R}\frac{\exp(-P_{31}t)}{4\pi r^2} \tag{38.2}$$

and the characteristic luminescence lifetime is $\tau = (P_{31})^{-1}$. Thus the lifetime is governed by both radiative and nonradiative processes, whilst the intensity of the luminescence depends on the relative magnitude of P_{31R}.

This discussion provides the basis for understanding the terms fluorescence and phosphorescence applied to luminescent materials. A material is often classified as one or the other according to the relative magnitude of $\tau = (P_{31})^{-1}$, with 10 ns being set in a relatively arbitrary way as the boundary between a *fast* fluorescent system and a *slow* phosphorescent one. For comparison, the theoretical lifetime for spontaneous emission for a strongly allowed hydrogen atom $2\mathrm{p} \rightarrow 1\mathrm{s}$ transition is about 0.2 ns.

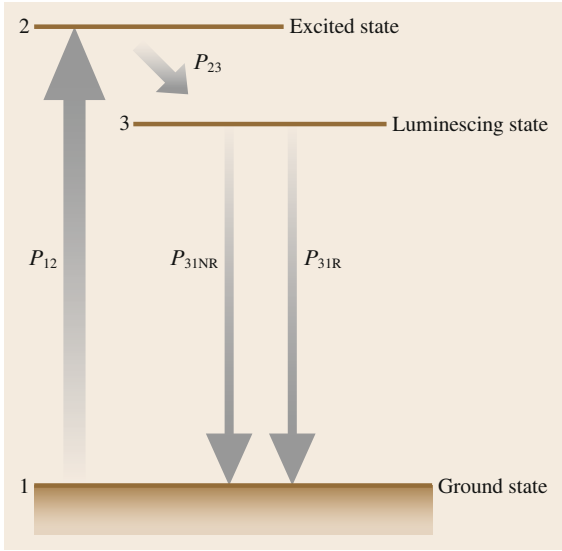

Fig. 38.1 Optical pumping cycle for a generic photoluminescent system

However, by this definition phosphorescence can also arise from luminescent states with short lifetimes which are populated through ones with long lifetimes. In Fig. 38.1, if state 2 is long-lived in the sense that $P_{23} \ll P_{31}$ then the measured lifetime for emission from the luminescing state will be $\tau = (P_{23})^{-1}$, and the system will be labelled phosphorescent, even though the luminescing level itself has a very short lifetime. In consequence, a second classification [38.2] is based on whether or not the luminescing level is fed by a metastable state which sets the lifetime. Sometimes the metastable state is a long-lived intermediate form of energy storage which can be triggered by an external stimulus to undergo a transition to a fluorescent level. Thus in Table 38.1, thermally stimulated and optically stimulated luminescence involve a metastable state consisting of trapped electrons and holes, which can be triggered to recombine by heating or by optical stimulation; the recombination energy is transferred to a fluorescing centre.

Overall, the fluorescence/phosphorescence classification is somewhat nebulous, and it is debateable whether the classification is necessary or desirable.

38.1 Luminescent Centres

A wide variety of centres give rise to luminescence in semiconductors and insulating materials, including rare-earth ions, transition-metal ions, excitons, donor–acceptor pairs, and ions with a d^{10} or s^2 electronic configuration ground state. Organic molecules also display luminescence on two different time scales, fast fluorescence associated with spin-allowed singlet-to-singlet transitions, and slow phosphorescence from triplet-to-singlet transitions. Some luminescence spectra consist of broad emission bands arising from the interaction between the electronic system of the luminescent centre and the vibrations of the atoms or ions, which surround it; the broad bands arise from simultaneous transitions of both electronic and vibrational systems. For others, such as the rare earths, the spectra comprise sharp lines arising from purely electronic transitions, and the effect of the environment is felt mainly through their effects on the lifetimes of the states. Thus in discussing the physical background to luminescence, it is simplest to start with a discussion of rare-earth luminescence, as an example where the effect of vibrations can be initially ignored.

38.1.1 Rare-Earth Ions

The trivalent rare-earth ions have n electrons ($n = 1-14$) in the 4f shell. In a free ion, the eigenstates resulting from the various atomic interactions are labelled by the total spin $\boldsymbol{S}$ and orbital angular momenta $\boldsymbol{L}$. Spin–orbit coupling breaks up each L, S multiplet of degeneracy $(2S+1)(2L+1)$ into sub-multiplets labelled by the total angular momentum $\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S}$, where J can range from $L-S$ to $L+S$. The $4f^n$ orbitals lie within the outer $5s^2$ and $5p^6$ filled shells, which partly shield them from the effects of a crystalline environment. The effects of the latter are quantitatively described by the *crystal field* [38.3, 7], and this term in the Hamiltonian splits the J multiplets into $2J+1$ sublevels, the so-called crystal-field splitting. Some of these crystal-field levels may still be two- or threefold degenerate, depending upon the symmetry of the environment. Odd-electron systems always have at least twofold (Kramers) degeneracy. The resulting energy-level structures are complicated, and are summarised in the classic *Dieke diagram* [38.7]. The original has been updated by *Carnall* et al. [38.8] and is reproduced in many books and papers on rare-earth ion spectroscopy [38.9–11] which should be consulted for a more extensive presentation of the subject than is possible here. In Fig. 38.2, we show a schematic version (not accurately to scale) of the diagram appropriate for Pr^{3+} with $n = 2$, which serves for our discussion. The crystal-field splitting is usually smaller than the spin–orbit splitting, and is illustrated schematically by the vertical extent of the bands in Fig. 38.2. The multiplet labels follow the usual $^{2S+1}L_J$ scheme.

In the figure we also show a generic highest excited band which does not belong to the $4f^2$ configuration. In the specific case of the rare earths this can be the excited-state configuration resulting from promotion of one electron to the 5d state, giving an overall $4f^{n-1}5d^1$ configuration; more generally it could be a so-called charge transfer band, which corresponds to the transfer of one electron from the ligands to the luminescent ion. The relative location and importance of these bands varies with the luminescent ion and the crystalline environment, but they play an important role in the excitation of luminescence.

Excitation and luminescence transitions within the various levels in Fig. 38.2 are governed by the golden rule of quantum mechanics [38.12] for interactions with the electromagnetic field; in summary the probability of a transition between two states i and j is proportional to square of the matrix element $< i|H|j >$,

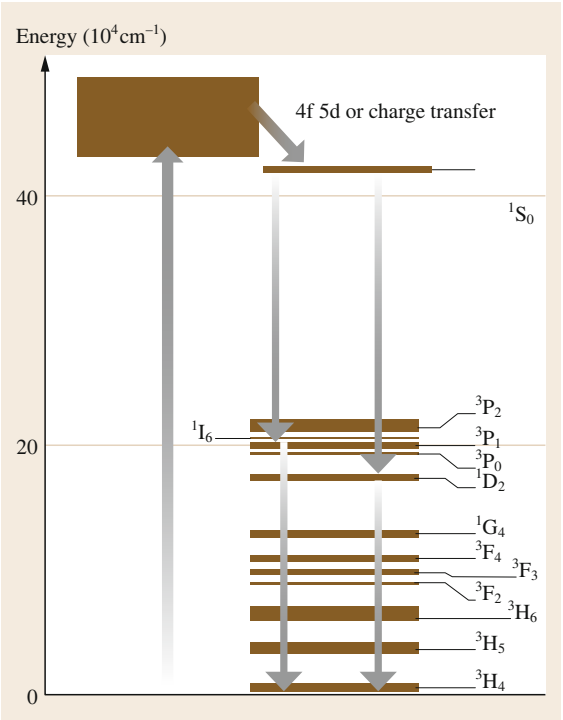

Fig. 38.2 Schematic energy-level diagram for Pr^{3+}

where H is the time-dependent perturbation Hamiltonian representing the interaction of the electrons with the electromagnetic field. The proportionality constant contains the light intensity in the case of excitation. The perturbation can be expanded in a power series involving electric and magnetic multipoles of the electronic system, but of these the electric dipole term is dominant, with the magnetic dipole term being much smaller by a factor of more than five orders of magnitude. Since the electric dipole operator $\boldsymbol{er}$ has odd parity, the matrix element for transitions $r_{ij} = < i|\boldsymbol{er}|j >$ is necessarily zero unless i and j have opposite parity. This is the most important selection rule governing luminescence: transitions between states of the same parity have zero transition probability and so are *forbidden* (Laporte's rule). In the case of the rare earths, all states of a single $4f^n$ configuration have the same parity, and so all optical transitions within the configuration are strictly forbidden. But this rule is relaxed by several considerations. First, if the crystalline environment lacks inversion symmetry, the crystal field admixes a small fraction of the excited configurations (e.g., $4f^15d^1$ for Pr^{3+}) of opposite parity into the ground configuration, which makes such transitions weakly allowed. Secondly, the selection rule for magnetic dipole transitions is that they are allowed between states of the same parity, although they are typically about five orders of magnitude weaker than for electric dipole ones. Finally, odd-parity vibrations and an electron–phonon interaction produce a similar configuration admixture effect to static lattice odd-parity mixing although this effect is more important for 3d ions than for 4f ones.

With only weak transitions possible within the 4f configuration, one might wonder how it would be possible to optically excite any significant luminescence. The answer lies in the 5d or charge-transfer bands which either lie at higher energies, or overlap with the upper levels of the 4f configuration. These give rise to strong absorption and efficient pumping. Relaxation can occur via the parity-allowed transitions to the upper levels of the 4f configuration, and from there via single or multiple radiative emissions back to the ground state. Because these intra-configurational transitions are only weakly allowed, the lifetimes are generally quite long, of the order of μs–ms. Figure 38.2 shows some of the observed transitions in the case of the Pr^{3+} ion. There are further constraints on possible transitions which arise from an analysis of the angular momenta of the initial and final states. For example, a transition between two states both of which have $J = 0$ is forbidden since there is no angular momentum change as required for a photon; similarly for dipole transitions we require $\Delta J = 0, \pm 1$.

The transition probability per second for spontaneous emission [38.13] is given by

$$P_{ij} = \frac{64\pi^4\nu^3}{3hc^3}\left|r_{ij}\right|^2 , \tag{38.3}$$

where ν is the frequency of the transition, h is Planck's constant, c is the velocity of light, and $|r_{ij}|$ is the matrix element of the electric dipole operator $\boldsymbol{er}$ between the two states i and j, and e is the electronic charge. For absorption, this must be multiplied by N, the mean number of photons with energy $h\nu$, which thus incorporates the effect of the incident beam intensity. Experimentally, one measures an absorption coefficient k as a function of energy $k(E)$ [38.13] which is linked to P_{ij} through,

$$\int k(E)\mathrm{d}E = N_i\left(\frac{\pi e^2 h}{nmc}\right)\left(\frac{n^2+2}{3}\right)^2 f_{ij} , \tag{38.4}$$

where n is the refractive index of the crystal environment, m is the electronic mass, N_i is the concentration of the luminescent centres, and f is the *oscillator strength* for the transition. For both absorption and emission, the dimensionless oscillator strength f_{ij} defined as [38.13]

$$f_{ij} = \frac{8\pi^2 m\nu}{3he^2}\left|r_{ij}\right|^2 \tag{38.5}$$

is often quoted to compare the relative transition probabilities. For an electron harmonic oscillator, $\sum f_{ij} = 1$, and so oscillator strengths of the order of 0.1–1 are strongly allowed transitions.

38.1.2 Transition-Metal Ions

Transition-metal ions from the 3d series are characterised by a much stronger interaction with the crystalline environment than the 4f ions since there is no equivalent of screening by the 5s, 5p outer shells. In addition, the spin–orbit coupling is weaker, and so the order of perturbation is reversed: the atomic L, S multiplets are split by the crystal field, with spin–orbit coupling being a smaller interaction. Intra-configurational transitions are again strictly forbidden, but become weakly allowed by inter-configurational mixing through odd-parity crystal fields, and by odd-parity vibrations. The result of this is that the strongest selection rule after parity is that transitions should have $\Delta S = 0$, since the electric dipole operator does not involve spin. The other major difference, again due to the strength of the crystal-field interaction, is that transitions which are purely electronic, the so-called zero-phonon lines, are rarely observed. Rather what are seen

are broad bands which correspond to the simultaneous excitation of an electronic transition and vibrational transitions, which overlap to give the broad observed bands. In particular, transitions involving odd-parity vibrations have a high transition probability through the effect of configuration admixing. This will be considered in a following section. The most commonly observed luminescent ions are those from the d^3 configuration (Cr^{3+}, Mn^{4+}) and from the d^5 configuration (Mn^{2+}). *Avram* and *Brick* [38.14] give a recent and comprehensive account of transition metal ion spectroscopy and fluorescence.

38.1.3 s^2 Ions

The $5s^2$ (e.g., Sn^{2+} and Sb^{3+}) ions and $6s^2$ (e.g., Tl^{+}, Pb^{2+}, Bi^{3+}) ions are of considerable importance because transitions to and from the excited s^1p^1 states are Laporte-allowed. The interaction of the p state with the crystalline environment can be very strong, and so broad spectra are often observed.

38.1.4 Semiconductors

Luminescence in inorganic semiconductors is dominated by near-band-gap luminescence arising from recombination of electrons and holes. This process is most efficient in direct-band-gap materials such as ZnS and GaP rather than indirect-gap materials such as Si and Ge because the transition probability requires conservation of wavevector, but the photon wavevector is ≈ 0 on the scale of the Brillouin zone. Hence creation or destruction of a phonon is required for band-to-band luminescence in indirect-gap materials, which is less probable. The near-edge emission may correspond to luminescence from a variety of shallow energy-level structures such as free or trapped excitons, or from donor–acceptor recombination. These are both example of electronic systems with spatially extensive wavefunctions, in contrast to the atomically localised 3d and 4f wavefunctions considered earlier. However, it is also possible to observe *deep-level* luminescence from transition-metal ions and rare earths in semiconductors provided that the electron affinities and band-gap energies are such that the pertinent energy levels fall in the band gap. In recent years, recombination emission in structured PN junctions based on GaN and InGaN which emit in the UV/blue spectral region has become of substantial practical importance in solid state lighting. Since inorganic semiconductors are discussed elsewhere in this volume, we shall not consider them further here, except as pump sources for down-conversion phosphors in Sect. 38.6.2.

Organic semiconductors are the basis for organic light emitting diodes (OLEDs) which are now finding applications in television and mobile phone displays, and in lighting. The advantages of OLEDS are the simple processing required, and ease of large area production and elelctrode patterning, together with a wide range of available emission colours. The operation is in principle similar to that of inorganic diodes but with very different materials. A diode structure is is engineered with an emissive polymer or small molecule layer sandwiched between between a polymer which is a good hole transporting material and one which is a good electron transporting material. The two transport layers inject charge carriers into the emissive layer, where they form excitons, which subsequently decay through luminescent molecular units in the emissive layer. OLEDs are described in more detail in Chap. 51.

38.2 Interaction with the Lattice

For rare-earth ions, the interaction with the vibrations of the crystal lattice can be ignored for most purposes; the observed luminescence spectrum consists of sets of sharp electronic transitions. But for other luminescent ions which interact strongly with the vibrating ions of the surrounding crystal, the incorporation of the latter is critical to explaining the observed spectra. The simplest model of ion–lattice interactions is to consider only the N nearest neighbour ions and their atomic displacements X_n, Y_n, Z_n, $(n = 1, N)$ in Cartesian coordinates. The vibrational Hamiltonian involves cross terms in these coordinates, but may be transformed to harmonic form if symmetry-adapted forms of these coordinates (*normal modes*) are used instead of the actual displacements. For example, the so-called breathing mode Q_b, for an octahedrally coordinated ion takes the form

$$Q_b = \frac{(Z_1 - Z_2 + X_3 - X_4 + Y_5 - Y_6)}{6} . \qquad (38.6)$$

If all the other modes have zero amplitude, the ions move radially towards or away from the central luminescent ion. The key point in considering the influence of the crystal lattice is that the vibrational potential energy is just the variation of the electronic energy with ionic displacement, or equivalently with the normal modes (within the spirit of the Born–Oppenheimer

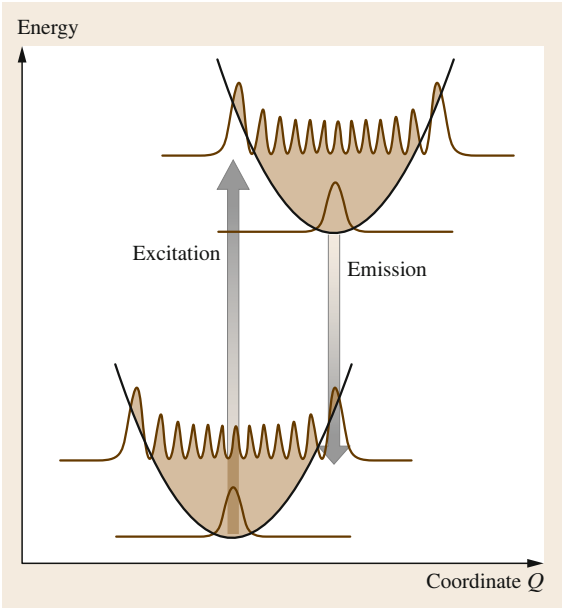

Fig. 38.3 Configuration coordinate diagram for excitation/emission cycle

approximation). Put another way, the crystal field depends on the ion positions so that the electron and lattice quantum-mechanical systems are linked through this electron–lattice coupling. We can therefore expect a difference in the harmonic vibrational potential from one electronic state to another, so that it will in general have the form $(1/2)m\omega_i^2(Q-Q_{0i})^2$; i. e., both the magnitude of the potential and the position of the minima Q_{0i} will depend on the electronic state i. The vibrational states in the harmonic approximation are just the usual simple harmonic oscillator states with energies $(n+1/2)h\nu_i$, with n an integer. Thus we arrive at a *configuration coordinate* diagram such as that shown in Fig. 38.3, with the potential energies for a ground state g and excited state e being offset parabolas of different curvature. The square of the vibrational wavefunction is shown for the ground state and that with $n=11$. We note that for a classical oscillator there would be a peak in the probability function at the extreme lengths of travel, corresponding to the maxima for $n=11$ at the outer limits of the wavefunction in Fig. 38.3.

We consider first luminescence from the excited electronic state/lowest vibrational state. The transition probability may be calculated using the Franck–Condon principle, that is we assume that the duration of the electronic transition is much shorter than a vibrational period, so that the Q remains constant during a transition. The transition is therefore taken to be *vertical* on the configuration coordinate diagram. The transition probability is just $\langle\phi_e|\phi_g\rangle^2$, the square

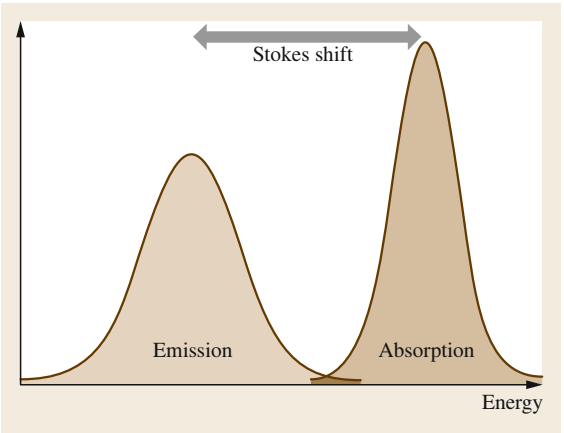

Fig. 38.4 Absorption and emission line shapes for strong electron–lattice coupling

of the vibrational wavefunction overlap, multiplied by the electronic transition probability considered earlier. From Fig. 38.3, this overlap will be a maximum for some vibrational state other than the ground state, unless the positions of the minima of the two potential energy curves coincide accidentally. (In Fig. 38.3, this maximum would be for the $n=11$ ground vibrational state). Put another way, the maximum transition probability is not for the zero-phonon transition (no change in vibrational state), but corresponds to the creation of a finite number of phonons. A range of transitions is allowed, and the result in a semiclassical analysis, allowing for finite line widths, is a Gaussian-shaped band. The analysis has to be extended to include finite temperatures and other modes, as described in detail by *Struck* and *Fonger* [38.15], but the overall result is that the emission line shape is approximately a Gaussian centred at an energy lower than that of the difference between the minima of the two potential curves. The same argument can be applied to the excitation process, and again an approximately Gaussian line shape results but this time centred on an energy above that of the difference in potential-energy minima. Figure 38.4 shows the overall result; the difference between the maxima of the two curves, known as the Stokes shift, is an indicator of the degree of electron–lattice coupling.

It is clear from the diagram that, in cases where there is strong electron–lattice coupling of this type, that: (a) there will be very little intensity in the zero-phonon line, and (b) there will be a large Stokes shift between the energies for maximum absorption and maximum emission. Thus the luminescence spectra of transition-metal ions, colour centres, and closed-shell ground-state ions (s^2, d^0), which have strong interactions with the lattice in the excited states, are typically broad bands with only occasionally weak, sharp zero-

phonon lines being observed. For luminescence from within the 4f states of the rare earths, the reverse is true; we are in the weak-coupling regime, and zero-phonon lines are the predominant features of the spectrum.

38.3 Thermally Stimulated Luminescence

Thermally stimulated luminescence (TSL), or simply thermoluminescence (TL), refers to luminescence induced by thermally stimulated recombination of trapped electrons and holes in materials which have been subject to prior irradiation. The irradiation, which may be in the form of UV light, x-rays, gamma rays, or energetic electrons, creates free electrons and holes, most of which promptly recombine, but some of which are locally trapped at defect centres such as impurities and vacancies. If the trap binding energies are sufficiently large, thermal promotion of the electron or hole to the conduction band or valence band, respectively, is improbable at the irradiation temperature, and so these charge carriers remain trapped after irradiation. However, if the sample is then heated, thermally assisted recombination becomes increasingly probable, and the result is an initially increasing light output with increasing temperature until the traps are depleted, whereupon the light intensity drops. The curve of light intensity versus temperature $I(T)$ is known as a glow curve, and may be analysed to extract the trap depths and concentrations. A comprehensive review of the field has been given by *McKeever* [38.16], and a shorter discussion by *Vij* [38.1].

The process is shown schematically for a simple system comprising a single electron trapping level T and a single recombination centre R in Fig. 38.5.

Irradiation results in a trapped electron at trap T and a trapped hole at R. The trapped hole binding energy is larger than that of the trapped electron, so the latter is depopulated first, with a probability P which has the form,

$$P = s \exp\left(\frac{-E}{k_B T}\right), \tag{38.7}$$

where s and E are the attempt frequency and the activation energy respectively. We have shown the hole trap and recombination centre as being one and the same in Fig. 38.5, but it is also possible that the recombination energy is transferred to a separate luminescent centre.

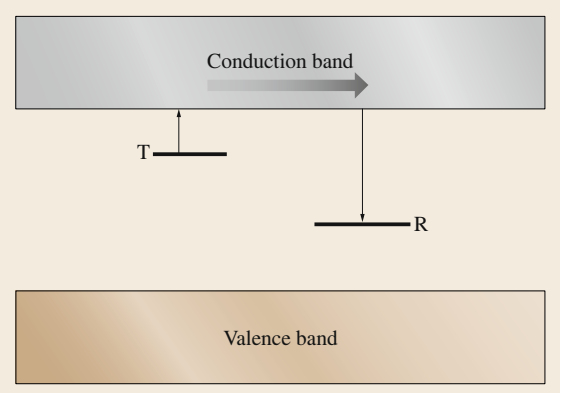

Fig. 38.5 Thermally stimulated luminescence process

In the measurement process, the sample is heated at a fast and linear rate, typically 1–10 K/s, whilst the light emission is monitored by a sensitive filter/photomultiplier combination, or by a monochromator system. The resulting glow curve may be fitted to a theoretical curve to extract the trap parameters. Generally the light output is quite weak, and TSL systems have sensitivity as one of their prime design factors, so cooled detectors and photon counting are commonplace. Above about 400 °C, thermal radiation from the sample/heater is a problem and must be eliminated by filtering or by subtraction of a glow curve recorded using a thermally bleached sample.

The main uses of TSL are in determining trap depths and irradiation doses. In archaeological and geological applications, a comparison is made between accumulated natural dose and a dose from a radioisotope; by combining this with a measurement of the activity of the surroundings, a date since last thermal or optical erasure of the object can be determined. The nature of the traps is often poorly understood for these chemically complex samples. For medical dosimetry, room-temperature stable traps with high thermoluminescent output are required. At present, the material of choice is LiF doped with a few hundred ppm of Mg and Ti.

The mathematical form of the TSL glow curve depends on the physical model used for the TL process. In the simplest case, assuming first-order kinetics [38.1, 16], the light intensity I at temperature T is given by,

$$I(T) = n_0 s \exp\left(\frac{-E}{k_B T}\right) \times \exp\left[-\frac{s}{\beta}\int_{T_0}^{T} \exp\left(\frac{-E}{k_B T}\right) \mathrm{d}T\right], \tag{38.8}$$

where n_0 is the number of occupied traps at time $t = t_0$ when the temperature is T_0, β is the heating rate in K/s,

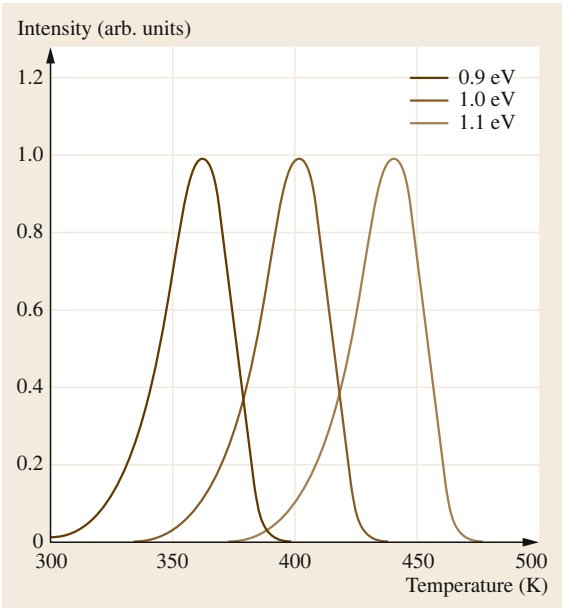

Fig. 38.6 Computed glow curves for first-order kinetics for fixed escape frequency and various trap depths

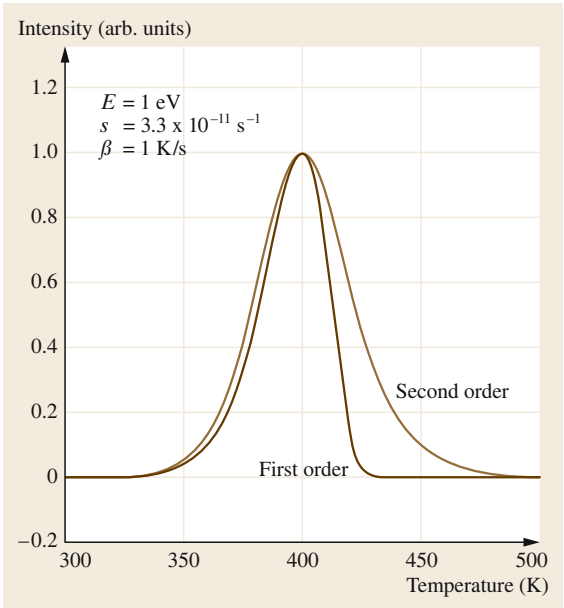

Fig. 38.7 Comparison of first- and second-order glow curves

and k_B is Boltzmann's constant. The result is a glow curve whose peak position varies approximately linearly with trap depth E, as shown in Fig. 38.6 (for fixed escaped frequency $s = 3.3 \times 10^{11}\,\mathrm{s}^{-1}$ and heating rate $1\,\mathrm{K/s}$).

Of course, the peak position also depends on the escape frequency s, but is less sensitive to s than to E. For second-order kinetics [38.1, 16], the glow curve equation becomes

$$I(T) = \frac{\left(\frac{n_0^2 s}{N}\right) \exp\left(\frac{-E}{k_B T}\right)}{\left[1 + \left(\frac{n_0 s}{N\beta}\right) \int_{T_0}^{T} \exp\left(\frac{-E}{k_B T}\right) \mathrm{d}T\right]^2} , \qquad (38.9)$$

where N is the number of available traps. The two forms both give glow curves of similar shape, but the first-order form shows an asymmetric form with a sharp fall off on the high-temperature side of the peak, whilst the second-order form is more symmetric as shown in Fig. 38.7. The parameters are extracted by least-squares fitting of these expressions to the experimental glow curves, which is cumbersome due to the integral, but *Kitis* et al. [38.17] have given analytical approximations to (38.8) and (38.9). In practice, many glow curves do not follow first- or second-order kinetics precisely. *Furetta* [38.18] describes the simulation of glow curves for a variety of TL analytical models.

38.4 Optically (Photo-)Stimulated Luminescence

Thermally stimulated luminescence is sometimes also accompanied by optically stimulated luminescence (OSL), in which one of the trapped carriers is excited by optical stimulation to a level from which it can recombine with the conjugate carrier by tunnelling, or completely to one of the bands so that recombination is achieved through what is essentially a photoconductivity effect. For OSL to be significant, there must be an appreciable optical transition probability, so not all TSL centres are OSL active. The stimulation energy measured in OSL generally differs from that determined from TSL because of the Franck–Condon principle. The OSL effect finds practical application in dosimetry, e.g., [38.19, 20] and in x-ray storage phosphors used for medical imaging, as described later.

38.5 Experimental Techniques – Photoluminescence

A typical traditional photoluminescence measuring system involves a broad-spectrum source, either a combined tungsten filament for the visible spectrum and deuterium lamp for the UV, or a xenon flash lamp. The lamp emission is passed through a grating monochromator and so selectively excites the luminescence. Band-pass or band-edge filters are generally required to eliminate unwanted second- and higher-order diffraction maxima from the grating. The luminescence is efficiently gathered by low-f/number optics and fed to a second grating monochromator, also equipped with filters, to monitor and analyse the luminescence. The final detector may be a photomultiplier, or preferably a charge-coupled device or photodiode array for improved data collection efficiency at multiple wavelengths.

This arrangement relies on good monochromation/filtering to remove what is sometimes a relatively strong component of scattered light from the beam analysed by the emission monochromator. An alternative method of removing scattered light is to use time discrimination, by replacing the source by a xenon flash lamp. The flash has a duration of about 10 μs, so any scattered light has decayed away to an insignificant level when the emitted beam is sampled some time (0.1−10 ms) after the flash. A timed electronic gate is used to sample the emission immediately after a flash and just before the next flash; the difference between these two sampled signals gives the short-term luminescence whilst the second sample alone gives the long-term luminescence with *long* and *short* being relative to the flash repetition period. Of course, luminescence with lifetimes shorter than the pulse width ($\approx 10\,\mu s$) cannot be readily measured with this system. The luminescence intensity is normalised with respect to the excitation intensity by steering a sample of the excitation beam to a rhodamine dye cell which has a quantum efficiency of essentially unity for wavelengths below about 630 nm. The fluorescence from the dye is measured with a second photomultiplier.

To minimise the effect of scattered light, a conventional laser with its intrinsically narrow linewidth and high intensity is a very convenient replacement for a broad-spectrum lamp, but suffers from the disadvantage of a fixed wavelength. Typical lasers of interest are nitrogen (pulsed), argon (UV lines, or frequency-doubled visible lines), krypton, and the new generations of GaN/GaInN blue/violet/UV laser diodes. For rare-earth spectroscopy, or other systems which are characterised by narrow absorption lines, it is very useful to have a scanning dye laser as the excitation source. This *selective excitation* facility enables *tagging* of particular luminescent levels with excited states belonging to the same centre, so that a picture of the energy-level structure of each luminescent centre can be built up in cases where several such centres contribute to the overall luminescence.

For decay kinetics on faster time scales, fluorimeters such as those developed initially by the Spex company (now Horiba) use a fast modulator and phase-sensitive detection to measure the phase shift between fluorescence and excitation; it is claimed that fluorescence decays can be measured with a resolution of 25 ps this way. An alternative is the time-correlated single-photon-counting technique which can measure decay constants in the ps–ns range. In this method, the excitation comes from a fast laser pulse, and the light level reaching the photomultiplier or micro-channel plate detector is reduced to such a low level that less than one photon per excitation pulse is detected. The time delay between the photon detection and the time of the pulse is measured, and a histogram produced of numbers of detected photons versus arrival time taken over a large number of excitation pulses. For efficient data collection, a high repetition rate and fast-pulse laser are required, often a Ti–sapphire laser. The wavelength for Ti–sapphire is too large for stimulating many materials directly with single-photon excitation, but stimulation is nonetheless possible by a two-photon excitation process, or by the use of a nonlinear crystal acting as a frequency doubler to produce laser output at one half the wavelength of the basic laser. Alternatively, a range of fixed wavelength LEDs and laser diodes with pulse widths in the range of ns to ps have become available.

There are a number of specialist techniques, such as hole-burning, fluorescence line-narrowing, and photon echo methods associated with the use of lasers with either very narrow line widths or short pulse duration which have developed in a parallel way to techniques first introduced in nuclear magnetic resonance, and which are mainly used to investigate the dynamics and quantum mechanics of the luminescent species rather than the material in which they are contained. *Meijerink* includes a short discussion of these specialist techniques in the book edited by *Vij* [38.1].

38.6 Applications

The largest market for luminescent materials has traditionally been in the areas of lighting, through fluorescent tubes, and in cathode-ray-tube screen phosphors for image display. Both of these areas can now be regarded as mature in terms of materials development, and in the case of cathode ray tubes, in decline as alternative display technologies have appeared. However, new discoveries in the past decade, and the advent of new technologies, have rekindled interest in phosphor materials. Some of the current areas of activity in applications are outlined below.

38.6.1 Compact Fluorescent Lamps

Compact Fluorescent Lamps (CFLs) are simply condensed versions of the traditional fluorescent lamp with a built-in ballast/starter in the lamp base. The tube contains an argon/mercury gas mixture, and an electric discharge between two electrodes results in the emission of (predominantly) 254 nm UV light from the ionised mercury. This light falls on the powder phosphor mixture on the inside surface of the glass tube, and excites luminescence from the rare earth ions contained within the phosphors. Typically Eu^{2+} is used for blue emission, Eu^{3+} for red, and Ce-activated Tb^{3+} for green. In the latter case, the Ce^{3+} ion efficiently absorbs the UV and the energy migrates to the Tb^{3+} ions. A variety [38.6] of host crystals are used, typically alkaline earth aluminates and yttria, selected on the basis of their performance and stability at high temperatures under intense UV irradiation and ion bombardment. A major challenge is that of good colour rendition, that is to achieve a light output that matches the spectrum of a conventional tungsten bulb in the visible region (which is close to the continuous spectrum expected for a black body radiator) with the multiline output of a rare-earth phosphor. Although CFLs offer a substantially higher energy efficiency and lifetime compared to conventional tungsten bulbs, albeit at a much higher cost, they face strong competion from the newer solid state LED technology as described below. The efficiencies of LED and CFL lamps are similar, but CFL's suffer from the disadvantages of having a slow start characteristic (as mercury liquid is progressively converted into gas as the lamp warms up), they are not readily dimmable, and they are an environmental hazard when they come to the end of their useful life due to the (small) mercury content.

38.6.2 Phosphors for Solid State Lighting

The development of blue, violet and UV LEDs based on GaN, InGaN and other semiconductors and alloys has laid the foundation for the new industry of solid state lighting, where high powered blue or UV LED excites intense visible light emission from an adjacent phosphor or phosphors [38.21, 22]. These so called *white-light LEDs* are making large inroads into the domestic and industrial lighting market as high-efficiency replacements for traditional incandescent bulbs, and are at present in direct competition with CFLs. The most common commercial design for a *white LED* uses visible blue LED emission to stimulate yellow luminescence from a single phosphor, so that when that yellow light is mixed with residual blue light from the LED, the result is simulated white light. For UV emitting LEDs, the emission is used to stimulate separate blue, red and green phosphors, or a single phosphor containing red, green and blue emitting centres, whose collective output approximates white light. The phosphors used for white light LEDs are quite different to those used for CFL's because of the need for efficient optical pumping in the range of 370–450 nm rather than 254 nm.

The most common single phosphor/single centre technology is based around a YAG:Ce garnet phosphor powder, embedded in a transparent polymer resin, which converts some of the emission from a 465 nm blue GaInN LED into an orange/yellow emission centred at 550 nm; the combination of blue and yellow simulates white light. A very strong crystal field splitting in the 5d state of Ce^{3+} shifts the lowest emitting level from the UV or blue where it normally occurs, to the yellow/orange region of the spectrum. YAG:Ce satisfies the considerations of optical and thermal stability in high power applications, but the colour rendition is not optimal, particularly in the red spectral region. Other single phosphors [38.21, 22] which have been investigated for this application include compositional variations on YAG:Ce, silicates, borates, sulphides, all with various rare earth dopings. The nitrides, oxynitrides and other complex nitrides [38.23, 24] are of particular interest from a colour rendition and thermal stability perspective. However, the original YAG:Ce has undergone performance improvements which should maintain its dominance in single phosphor white LEDs. The pumping and light extraction efficiency has been improved, for example through the development of nanoparticle forms such as transparent glass ceramics [38.25] which minimise back-scattering.

Whilst the single phosphor/single centre phosphor implementation has many advantages, including simplicity, improved colour rendition is obtained by using more phosphors or centres, with optimised balance between the various emissions, for example with blue diode pumped $SrGa_2S_4$:Eu (green), SrY_2S_4:Eu (red),

complemented by residual blue LED light. Recent developments based on 375 nm UV LEDs have used multiple emissions to achieve even better colour balance; for example *Kim* et al. [38.26] use $Sr_3MgSi_2O_8:Eu^{2+}$, Mn^{2+}, which has blue (Eu^{2+}), yellow (Eu^{2+}) and red emissions (Mn^{2+}). The europium ions presumably occupy two different sites with very different crystal field splittings. A major problem with multi-phosphor white LEDs is finding a satisfactory red emitter – usually Eu^{3+} fills this role, but it is not efficiently pumped by the available LED wavelengths, and so Mn^{2+} or Mn^{4+} are also under consideration [38.27].

Other directions in research include the possible use of photoluminescent quantum dots (QDs) [38.28] so as to improve colour rendition and achieve a warm white light output. QDs are nanometer-sized particles, in this context they are based on a semiconductor such as CdSe or CdS whose band gap lies in the visible region. The quantum confinement effect means that the energy of recombination emission in these direct band gap materials has a wavelength which is dependent on particle size, resulting in a size-tuneable phosphor. The emission colour can also be modified by chemical modification of the nanoparticle surface with luminescent ions such as rare earths; the recombination energy of electron-hole pairs excited by LED emission can migrate to the surface and excite these ions. The surface layer is a significant volume fraction for a nanoparticle, and so the surface emission can dominate the volume emission. The combination of tailored absorption by adjusting the nanoparticle size and composition, and tailored emission by chemical modification of the surface, gives a very flexible design palette. However, the toxicity of cadmium is an issue, and so other semiconductors which can be fabricated as nanoparticles are under active consideration.

The efficiencies of white LEDs are comparable with CFLs and (currently) about five times larger than for incandescent bulbs, and with a lifetime which is about twenty five times longer. The major problems relate to the cost, colour rendition, and stability at the high temperatures produced by incident optical powers of the order of tens of watts/cm^2, but continuing improvements can be expected in all of these aspects in contrast to the mature state of CFL development.

38.6.3 Long-Persistence Phosphors

It has been discovered in the past twenty years that some materials show a very long-lived but intense afterglow, arising from thermal emission of charge carriers from deep traps, followed by electron–hole recombination at or near a luminescent ion, i. e., room-temperature thermoluminescence. The persistence is for periods of several hours, much longer than the well-known ZnS:Cu persistent phosphor. This new class of materials [38.29], have widespread applications in areas such as signage and passive emergency lighting for public buildings, aircraft cabins etc. The material is activated or *charged* by the blue/UV content of solar radiation or fluorescent indoor lighting during normal conditions; in subsequent dark conditions the energy is released as an afterglow. No power supply is required, the operation is entirely passive, and so a high degree of reliability is assured. Generally the phosphor powder ($\approx 10\,\mu$m grain size) is mixed with a resin binder and applied as a thick (≈ 1 mm) coating. The first materials which were used were rare-earth-doped strontium or calcium aluminate [$CaAl_2O_4$:Eu/Nd (blue), $SrAl_2O_4$:Eu/Dy (green), $Sr_4Al_{14}O_{25}$:Eu/Dy (blue–green), and Y_2O_2S:Eu/Mg/Ti (orange)]. Figures 38.8 and 38.9 show the decay and emission/excitation characteristics of a commercial phosphor strip of this type, based on Luminova $SrAl_2O_4$:Eu/Dy powder sourced from the Nemoto company. The decay is clearly non–exponential, but after the initial rapid decay the intensity may be fitted with an exponential with a decay constant of 3.1 h.

The persistent phosphor effect has now been found in a wide variety of materials [38.30, 31] including the nitrides and oxynitrides (also of interest for LED lighting), although the aluminates remain as the most significant materials for all-round performance from a commercial perspective. The mechanism must involve

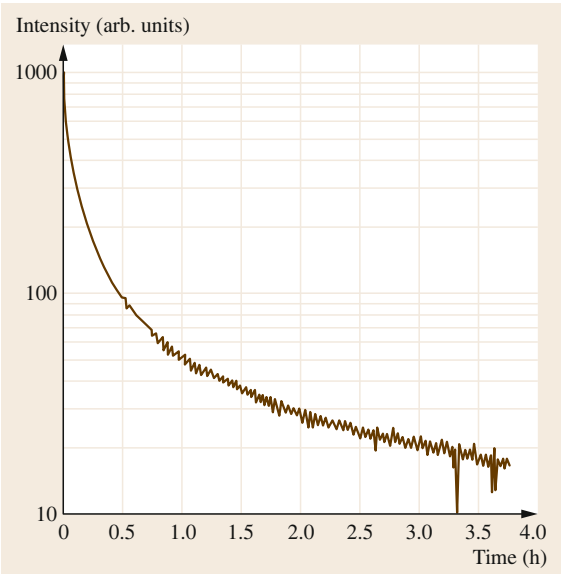

Fig. 38.8 Dark decay of persistent luminescence in a commercial lighting strip based on Nemoto $SrAl_2O_4$:Eu/Dy material

shallow charge carrier traps from which electrons or holes can recombine with the conjugate charge carrier through thermal excitation to the appropriate band, by tunnelling, or by thermally assisted tunnelling. A useful persistent phosphor requires both a substantial brightness, and a time constant for recombination which is of the order of hours. The traps which are responsible for the long-lived decays in these systems have not been clearly identified, and it is likely that there are several involved. It would seem that progress in identifying the mechanisms and traps will require corellated optical, ESR and TSL studies.

38.6.4 X-Ray Imaging

X-ray images have traditionally been recorded with phototographic film since the time of Roentgen, but it was noted in the very early days that photographic film itself was not very sensitive to x-rays. However, if a phosphor is used as an intermediate x-ray to visible photon converter, the sensitivity is increased by approximately two orders of magnitude. Consequently, x-ray film cassettes are usually outfitted with two intensifying screens which sandwich the photographic film. The operating principle of the screens is that an incident x-ray photon generates a large number (tens of thousands) of electron-hole pairs through the photoelectric effect or Compton scattering. When the electrons and holes recombine, the recombination energy can be efficiently transferred to a luminescent centre, resulting in the emission of a large number of visible light photons. The most common phosphor material [38.2] is powdered gadolinium oxysulphide doped with terbium, embedded in an organic binder, and which emits in the green region of the spectrum. However, this long standing technique of phosphor-enhanced film for x-ray radiography is being superceded by a variety of new methods, some of which are phosphor or scintillator based. Among these, optically stimulated or photo-stimulated luminescence is the basis for an x-ray imaging technology known commercially as computed radiography (CR). Several other techniques such as those based on amorphous selenium photoconductor/flat panels and a-Si arrays, and scintillator CCD/complementary metal–oxide–semiconductor (CMOS) arrays have also emerged in recent years, but CR remains as a substantive technology on the basis of numbers of installed units in medical and dental radiography. The many advantages of CR over photographic film, and the principles of the method are detailed in [38.32, 33], but the basic mechanism is that incident x-rays create electron–hole pairs in the material. Most of these promptly recombine, but some are trapped at defects and impurities, and remain trapped for periods of hours after the x-ray source is turned off. In an x-ray storage phosphor (XRSP), one of the trapped carriers is optically stimulable, and can be excited to the conduction band or valence band, or to a level from which it can recombine by tunnelling with the conjugate trapped carrier. The resulting recombination energy is transferred to a luminescent ion, and the intensity of the photo-stimulated luminescence (PSL) is in direct proportion to the incident x-ray intensity. The dominant material used in current XRSP systems is $BaFBr_{1-x}I_x:Eu^{2+}$, where the electron traps are F-centres, the hole traps are unidentified, and the luminescence is the 5d–4f transition of the Eu^{2+} ion. One disadvantage of systems based on this (powder) phosphor is that when the image is extracted with a raster-scanned He–Ne laser beam, light scattering from the powder grains means that material outside the focussed laser spot is also stimulated, limiting the spatial resolution to around 200 μm, which is inadequate for applications such as mammography. Several ways to overcome this are currently under development. CsBr:Eu is also an x-ray storage phosphor [38.34] and can be grown by vapour deposition in a columnar form. The columnar structure has a light-guiding property, restricting the scattering effect, and improving the resolution. A second development is that of glass-ceramic storage phosphors, where PSL active crystals are embedded in a glass [38.35–37]; the combination of particle size, separation and refractive-index mismatch means that these composite materials are semitransparent and the problem of scattering of read-out light

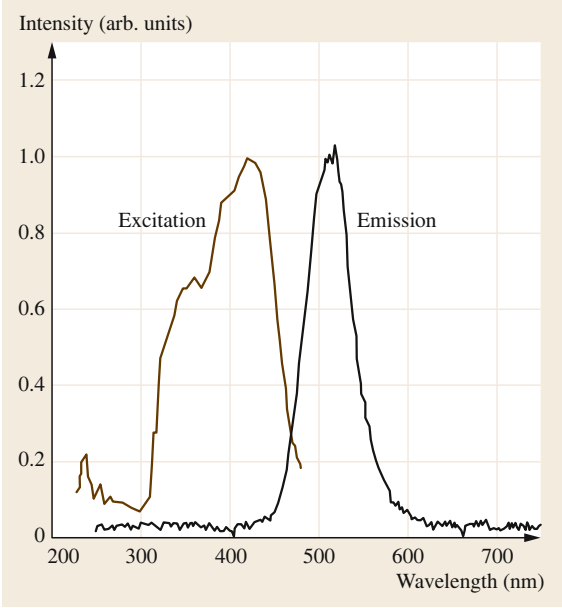

Fig. 38.9 Excitation and emission spectra of a commercial lighting strip based on Nemoto $SrAl_2O_4$:Eu/Dy material

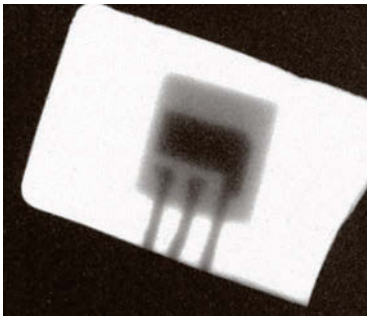

Fig. 38.10 PSL image of a BC549 transistor recorded on a glass-ceramic imaging plate

is reduced. Figure 38.10 shows an image of a BC549 transistor recorded in a glass-ceramic x-ray storage phosphor.

The quest for high resolution x-ray imaging has also led to the development of transparent glasses in which the image is recorded by a quite different luminescent ion technique. Some rare earth ions, particularly Eu and Sm can show a valence change under x-ray or UV irradiation. For example, Sm present in the divalent state in fluorophosphate and fluoroaluminate glasses has been shown to transform in part from the trivalent to the divalent state under x-irradiation [38.38]. The extra electron is sourced from the simultaneous creation of colour centres. The concentration of divalent samarium can be monitored by the Sm^{2+} photoluminescence spectrum, which is readily distinguished from Sm^{3+} as there is minimal overlap, and can be further accentuated by an appropriate choice of excitation wavelength. One-dimensional x-ray imaging based on the monitoring of the Sm^{2+} photoluminescence has been reported by *Okada* and *Morell* et al. [38.38, 39] using the methodology of confocal microscopy to achieve spatial resolutions of the order of ten microns. This particular application of one dimensional imaging was to beam profile monitoring in microbeam therapy, a proposed oncology treatment. *Edgar* et al. have shown [38.40] that two dimensional imaging can be achieved with the same materials using a simple camera technique, and demonstrated resolution of the 25 μm bonding wires on a semiconductor chip. However, the x-ray dose required for the fluorophosphate and fluoroaluminate glasses is too high for conventional medical radiography, and further work on alternative materials or dopants is required to extend the range of applications to the low dose regime.

38.6.5 Phosphors for Displays

Several new technologies have been developed to replace cathode ray tubes for domestic televisions, including plasma display panels (PDPs). In these units, each pixel is a sealed cell containing a mixture of Xe and Ne in a dielectric-shielded electrode structure (for a review, see *Boeuf* [38.41]). An alternating current (AC) voltage applied between the electrodes results in a glow discharge being set up in the gas, and a Xe dimer vacuum UV (VUV) emission predominantly between 147 and 190 nm occurs. (In comparison, the mercury discharge in a conventional fluorescent tube emits primarily at 254 nm.) The UV discharge excites red, blue, or green phosphors coated on one of the cells; each colour is activated by an adjacent electrode. The requirements for efficient output from these phosphors differ from conventional tubes since the latter were chosen on the basis of their luminescence efficiency at a 254 nm pump wavelength, and their resistance to degradation by the UV light and chemical attack by Hg^{+} ions. These requirements are evidently different for the PDP technology; in addition the phosphors must have a significant reflection coefficient in the visible to optimise the light output [38.42], and the surface quality is of greater significance due to the short penetration depth of the VUV. The phosphors which have been used so far include $BaMgAl_{10}O_{17}:Eu^{2+}$ (blue), $Zn_2SiO_4:Mn^{2+}$ (green), and $(Y, Gd)BO_3:Eu^{3+}$ and $Y_2O_3:Eu^{3+}$ (red). The blue phosphor is prone to degradation.

The widespread introduction of Xe excimer excitation in PDPs can be expected to stimulate applications in other lighting technologies. In this regard, the possibility of so-called *quantum cutting* is of much interest. This recognises that the energy of a VUV photon is equivalent to two or more visible photons, so that quantum efficiencies in excess of 100% can in principle be achieved. The difficulty lies in finding a luminescent ion system whose energy-level system provides for both efficient pumping and two-photon luminescence in the visible. One example which has been reported to have a quantum efficiency of up to $\approx 145\%$ is Pr^{3+} in YF_3 and other hosts [38.43, 44], where the excitation is through the allowed $4f^2 \rightarrow 4f^15d^1$ or host transitions. The system then decays to the $^1S_0$ excited state of the $4f^2$ configuration from which two-photon decay is possible through successive $^1S_0 \rightarrow {}^1I_6$ and $^3P_0 \rightarrow {}^3H_J$, ^3F_J transitions, as shown in Fig. 38.2. (The intermediate step from $^1I_6$ to $^3P_0$ is provided by a nonradiative transition.) A difficulty is that the photon for the first transition is in the UV region of the spectrum, and so it is necessary to incorporate a second luminescent ion pumped by this transition to convert the UV to visible output, and the visible quantum efficiency is necessarily reduced.

As at 2016, it would appear that PDP displays are losing ground in comparison with LCD and OLED based display technologies, which are discussed elsewhere in this handbook. In contrast, a rising technology is so-called QLEDs, or quantum dot OLEDs,

in which an OLED structure is modified to incorporate quantum dots within the electron-hole recombination zone [38.28]. The recombination energy migrates to the quantum dots, which can be customised for colour output by adjustments of size, semiconductor, and coating. A significant improvement in efficiency has been achieved by replacing the organic hole-transport layer with an inorganic one. The current application of QLEDs is primarily in backlighting for LCD displays, where the existing cold cathode fluorescent or white LED panels suffer from poor colour rendition.

38.6.6 Scintillators

Although semiconductor detectors of ionising radiation have made large inroads into the particle detection market, traditional scintillators are still widely used and are indispensable for some applications. The operating principle is that an incident gamma ray creates a large number of electrons and holes in the scintillating material directly or indirectly through the photoelectric effect, Compton scattering, or pair production. These energetic electrons and holes lose energy to the lattice on a picosecond time scale through thermalisation processes, and their energy approaches that of the band edges. They can then associate as free or bound excitons, and the energy of these electron-hole pairs is then localised on luminescent ions which have been deliberately doped into the material. The luminescent ion is promoted by this energy into an excited state, from which it can decay by photon emission. One gamma or x-ray photon typically creates tens of thousands of electron-hole pairs, and a similar number of visible region photons which are emitted in one aggregate pulse or *scintillation*. Charged particles such as protons produce electron–hole pairs through the Coulomb interaction with the band electrons. The scintillation or multiphoton bursts which signal the event is detected by a photomultiplier, and the height of the output pulse from the photomultiplier is proportional to the energy of the particle. A pulse-height analyser sorts the pulses according to energy, and so an energy spectrum can be obtained. Key figures of merit for a scintillator material include the light yield, i. e., the numbers of photons per MeV of particle energy, the radiative lifetime of the luminescent ion (since possible pulse overlap limits the maximum count rate which can be measured), and the weighted density ρZ_{eff}^4, which reflects the gamma sensitivity. (Here Z_{eff} is the effective atomic number.) The most widely used scintillator for many years has been NaI:Tl, but many different scintillators are being investigated, driven by the need for improved performance and lower cost for medical applications such as positron emission tomography (PET) and single-photon emission computed tomography (SPECT), and for large-scale elementary-particle facilities such as the Large Hadron Collider at the Centre Européen pour la Recherche Nucléaire (CERN). In the latter regard, the Crystal Clear collaborative project and other programs have resulted in several new materials such as $LaBr_3$, $LaCl_3$, Lu_2SiO_5, Gd_2SiO_5, $Lu_3Al_5O_{12}$ and $LuAlO_3$, all Ce-doped, $CeBr_3$, and undoped $Bi_4Ge_3O_{12}$ and $PbWO_4$, with typical performance figures of 10 000–70 000 photons/MeV and lifetimes of 10–50 ns. For gamma spectroscopy the pulse-height resolution is critical and $LaBr_3$:Ce has twice the resolution of NaI:Tl. The fastest scintillators are based on core-valence luminescence where a hole created in a core level recombines with an electron in the valence band. For example, BaF_2 shows this *cross-luminescence* effect with a lifetime as short as 600 ps. The effect is only shown by materials with a core-valence (CV) band energy gap less than the usual band gap, otherwise CV luminescence is absorbed. Neutron-sensitive scintillators can be made by incorporating an element which has a large cross section for thermal neutron capture such as Li, B, Gd, or Cd; the nuclear decay following neutron capture results in gamma, alpha, or beta emission which again results in electron–hole pair production and scintillation. Plastics are also useful for neutron detection because of the large neutron cross section of hydrogen.

Most scintillator materials are single crystal inorganics, typically halides or oxides, doped with rare earth ions, usually Ce or Eu. However, it has been shown in the past decade that high-performance scintillators can also be made in the form of transparent glass ceramics [38.25] which has advantages in terms of processing and manufacturing flexibility with regard to the geometrical form.

Rodnyi [38.45], *Lecoq* et al. [38.46], and *van Eijk* [38.47] discuss scintillator physics and performance in detail, whilst *Nikl* and *Yoshikawa* [38.48] present a recent update on inorganic single crystal scintillators.

38.7 Representative Phosphors

To conclude, we present in Table 38.2 a list of several luminescent materials of practical significance. The table is intended to be representative rather than comprehensive. It is noticeable from the table that just a few ions are responsible for a large number of applications, and primarily as oxides.

Table 38.2 Some luminescent materials of practical significance

Host	Dopants	Colour	Excitation	Application
$Bi_4Ge_3O_{12}$	–	Blue	Ionising radiation	Scintillator
$Y_3Al_5O_{12}$	Ce^{3+}	Yellow	Blue, violet	White LED
Gd_2SiO_5	Ce^{3+}	UV	Ionising radiation	Scintillator
$Lu_3Al_5O_{12}$	Ce^{3+}	Green	Ionising radiation	Scintillator
$LaBr_3$	Ce^{3+}	UV	Ionising radiation	Scintillator
BaFBr	Eu^{2+}	UV/blue	X-rays	X-ray imaging
CsBr	Eu^{2+}	Blue	X-rays	X-ray imaging
$BaMgAl_{10}O_{17}$	Eu^{2+}	Blue	UV	Fluorescent lamps, plasma displays
Gd_2O_2S	Tb^{3+}	Green	X-rays	Intensifying screens
Sr_3SiO_5	Eu^{2+}	Blue	UV	White LED
$SrGa_2S_4$	Eu^{2+}	Green	UV	White LED
$SrAl_2O_4$	Eu^{2+}, Dy^{3+}	Green	UV, violet	Persistent phosphor
$CaAl_2O_4$	Eu^{2+}, Nd^{3+}	Blue	UV, violet	Persistent phosphor
Y_2O_3	Eu^{3+}	Red	Electrons, UV	Plasma displays, fluorescent lamps
Sr_2SiO_4	Eu^{3+}	Yellow	UV	White LED
$(Y, Gd)BO_3$	Eu^{3+}	Red	UV	Plasma displays
SrY_2S_4	Eu^{3+}	Red	UV	White LED
LiF	Mg^{2+} and Ti^{4+}	UV/blue	Ionizing radiation	TL dosimetry
ZnS	Mn^{2+}	Yellow	Electric field	Panel displays
Zn_2SiO_4	Mn^{2+}	Green	UV	Plasma displays
$CeMgAl_{11}O_{19}$	Tb^{3+}	Green	UV	Fluorescent lamps

39. Nano-Engineered Tunable Photonic Crystals

Harry E. Ruda, Naomi Matsuura

Photonic crystals offer a well-recognized ability to control the propagation of modes of light in an analogous fashion to the way in which nanostructures have been harnessed to control electron-based phenomena. This has led to proposals and indeed demonstrations of a wide variety of photonic-crystal-based photonic devices with applications in areas including communications, computing and sensing, for example. In such applications, photonic crystals can offer both a unique performance advantage, as well as the potential for substantial miniaturization of photonic systems. However, as this review outlines, two-dimensional (2-D) and three-dimensional (3-D) structures for the spectral region covering frequencies from the ultraviolet (UV) to the near-infrared (near-IR) ($\approx 2\,\mu$m) are challenging to fabricate with appropriate precision, and in a cost-effective and also flexible way, using traditional methods. Naturally, a key concern is how amenable a given approach is to the intentional incorporation of selected defects into a particular structure. Beyond passive structures, attention turns to so-called active photonic crystals, in which the response of the photonic crystal to light can be externally changed or tuned. This capability has widespread potential in planar lightwave circuits for telecommunications, where it offers mechanisms for selective switching, for example. This review discusses alternative proposals for tuning of such photonic crystals.

Photonic crystals (PCs) are periodic, dielectric, composite structures in which the interfaces between the dielectric media behave as light-scattering centers. PCs consist of at least two component materials having different refractive indices, and which scatter light due to their refractive-index contrast. The one-, two-, or three-dimensional (1-D, 2-D, or 3-D) periodic arrangement of the scattering interfaces may, under certain conditions, prevent light with wavelengths comparable to the periodicity dimension of the PC from propagating through the structure. The band of forbidden wavelengths is commonly referred to as a *photonic band gap* (PBG). Thus, PCs are also commonly referred to as photonic-band-gap (PBG) structures.

PCs have great potential for providing new types of photonic devices. The continuing demand for photonic devices in the areas of communications, computing, and signal processing, using photons as information carriers, has made research into PCs an emerging field with considerable resources allocated to their technological development. PCs have been proposed to offer a means for controlling light propagation in submicron-scale volumes – the photon-based equivalent of a semiconductor chip – consisting of optical devices integrated together onto a single compact circuit. Proposed applications of PCs for the telecommunication sector include optical cavities, high-Q filters, mirrors, channel add/drop filters, superprisms and compact waveguides for use in so-called planar lightwave circuits (PLCs).

Practical applications of PCs generally require manmade structures, as photonic devices are designed primarily for light frequencies ranging from the ultraviolet to the near-infrared regime (i. e., $\approx 100\,\text{nm}$ to $\approx 2\,\mu\text{m}$ respectively) and PCs having these corresponding periodicities are not readily available in nature. 1-D PCs in this wavelength range may be easily fabricated using standard thin-film deposition processes. However, 2-D and 3-D PC structures are significantly more difficult to fabricate and remain among the more challenging nanometer-scale architectures to realize with cost-effective and flexible patterning using traditional fabrication methodologies. Recently, there has been considerable interest in PC-based devices that has driven advanced fabrication technologies to the point where techniques are now available to fabricate such complex structures reliably on the laboratory scale. In addition to traditional semiconductor nanostructure patterning methods based on advanced patterning/etching techniques developed by the semiconductor industry, novel synthesis methods have been identified for 2-D and 3-D periodic nanostructured PC arrays. There are several excellent reports reviewing these fabrication techniques in the literature [39.1–4] and this growing field has already been the subject of numerous recent reviews, special issues, and books in the area of theoretical calculations (both band-structure and application simulations), 2-D PC structures, 3-D PC structures, and opal-based structures [39.5].

Recently, there has been great interest in exploring the use of PCs for active applications in the field of telecommunications, such as in the area of PLCs (e.g., for optical switching). In such applications, the PC properties should be adjustable to create *tunable* photonic band gaps. This development increases the functionality of all present applications of PCs by allowing the devices in such applications to be adjustable, or tunable. We review recent developments in the engineering of tunable nanometer-scale architectures in 2-D and 3-D. This review aims to organize this ever-changing volume of information such that interested theorists can design structures that may be easily fabricated with certain materials, and such that technologists can try to meet existing fabrication gaps and issues with current systems.

The chapter begins with a brief introduction to PCs, followed by general criteria used to determine appropriate methodologies for the nanoengineering of tunable PCs. Finally, overviews of the most common fabrication methods for tunable 2-D and 3-D PCs will be given.

39.1 PC Overview

39.1.1 Introduction to PCs

The simplest PC structure is a multilayer film, periodic in 1-D, consisting of alternating layers of material with different refractive indices (Fig. 39.1). Theoretically, this 1-D PC can act as a perfect mirror for light with wavelengths within its photonic band gap, and for light incident normal to the multilayer surface. 1-D PCs are found in nature, as seen for example in the iridescent colors of abalone shells, butterfly wings and some crystalline minerals [39.6], and in manmade 1-D PCs (i. e., also known as Bragg gratings). The latter are widely used in a variety of optical devices, including dielectric mirrors, optical filters and in optical fiber technology.

The center frequency and size (i. e., frequency band) or so-called stop band of the PBG depends on the refractive index contrast (i. e., n_1/n_2, where n_1 and n_2 represent the refractive index of the first and second material respectively) of the component materials in the system. Figure 39.1 is an example of a 1-D PC, with a periodic arrangement of low-loss dielectric materials. This multilayer film is periodic in the z-direction and extends to infinity in the x- and y-directions. In 1-D, a photonic band gap occurs between every set of bands, at either the edge or at the center of the Brillouin zone – photonic band gaps will appear whenever n_1/n_2 is not equal to unity [39.7]. For such multilayer structures, corresponding photonic band gap diagrams show that the smaller the contrast, the smaller the band gaps [39.7]. In 1-D PCs, if light is not incident normal to the film surface, no photonic band gaps will exist. It is also important to note that at long wavelengths (i. e., at wavelengths much larger than the periodicity of the PC), the electromagnetic wave does not probe the fine structure of the crystal lattice and effectively sees the structure as a homogeneous dielectric medium.

The phenomena of light waves traveling in 1-D periodic media was generalized for light propagating in any direction in a crystal, periodic in all three dimensions, in 1987 when two independent researchers suggested that light propagation in 3-D could be controlled using 3-D PCs [39.8, 9]. By extending the periodicity of the 1-D PC to 2-D and 3-D, light within a defined frequency range may be reflected from any angle in a plane (in 2-D PBG structures) or at any angle (in 3-D PBG structures).

Since the periodicity of PCs prevents light of specific wavelengths (i. e., those within the photonic band

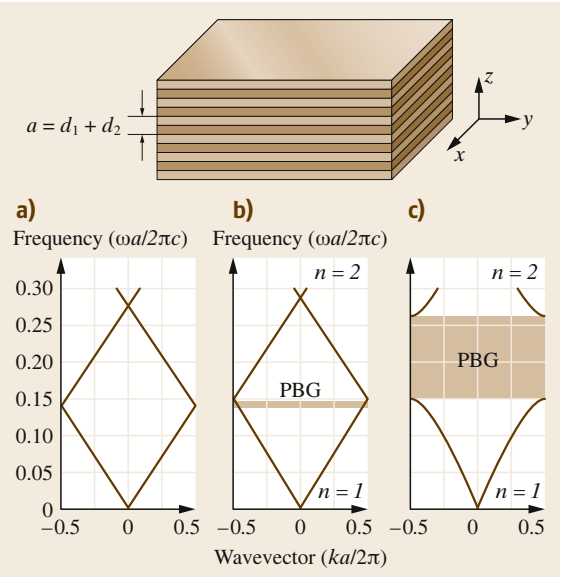

Fig. 39.1a–c Example of a 1-D photonic crystal. For a structure with $d = 0.5a$, the corresponding band gap diagrams are shown for: **(a)** GaAs bulk ($\varepsilon = 13$); **(b)** GaAs/GaAlAs multilayer ($\varepsilon_1 = 13$, $\varepsilon_2 = 12$); and **(c)** GaAs/air multilayer ($\varepsilon_1 = 13$, $\varepsilon_2 = 1$). (After [39.7])

gap) from propagating through them in a given direction, the intentional introduction of *defects* in these structures allows PCs to control and confine light. Propagation of light with wavelengths that were previously forbidden can now occur through such defect states located within the photonic band gap. Defects in such PCs are defined as regions having a different geometry (i. e., spacing and/or symmetry) and/or refractive-index contrast from that of the periodic structure. For example, in a 2-D PC consisting of a periodic array of dielectric columns separated by air spaces, a possible defect would include the removal of a series of columns in a line. Specific wavelengths of light forbidden from propagating through defect-free regions would then be able to propagate through the line defect, but not elsewhere. Indeed, by appropriately eliminating further columns, light may be directed to form optical devices, including, for example, a low-loss 90° bend in a 2-D waveguide, as shown by theoretical simulation [39.7] (Fig. 39.2).

Clearly, photons controlled and confined in small structures, with size on the order of the wavelength of light, using the extremely tight bend radii offered by PCs, would facilitate miniaturization and the fabrication of PLCs [39.7]. In addition, since the periodicity of the PC gives rise to the existence of band gaps that change the dispersion characteristics of light at given frequencies, defect-free PCs give rise to other

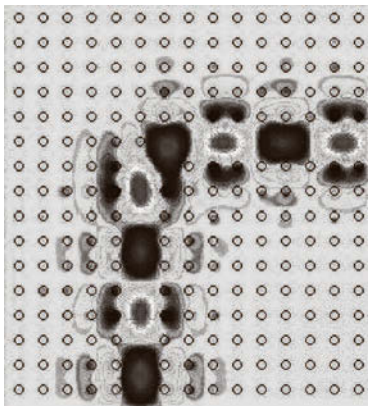

Fig. 39.2 Theoretical simulation of a low-loss 90° bend in a 2-D waveguide. (After [39.7])

interesting phenomena, including highly dispersive elements through the so-called superprism effect [39.10]. Possible designs of PC-based optical devices using such properties have been extensively explored [39.1, 11], generating much excitement in the field of optical telecommunications [39.6].

39.1.2 Nanoengineering of PC Architectures

Most of the promising applications of 2-D and 3-D PCs depend on the center frequency and frequency range of the photonic band gaps. A so-called *complete*, *full*, or *true* PBG is defined as one that extends throughout the entire Brillouin zone in the photonic band structure – that is, for all directions of light propagation for photons of an appropriate frequency. An incomplete band gap is commonly termed a *pseudogap* or a *stop band*, because it only occurs for reflection/transmission along a particular propagation direction. A complete gap occurs when stop-band frequencies overlap in all directions in 3-D. The center frequencies and stop-band locations of the PBGs critically depend on the unit-cell structure [39.7–9, 12, 13]. In particular, the PC properties depend on the symmetry of the structure (i. e., the unit-cell arrangements), the scattering element shape within the unit cell, the fill factor (i. e., the relative volume occupied by each material), the topology, and the refractive-index contrast (Fig. 39.3).

It has been shown that a triangular lattice with circular-cross-section scattering elements in 2-D, or a face-centered-cubic/diamond lattice with spherical scattering elements in 3-D, tend to produce larger PBGs [39.7]. Also, as discussed above, the dielectric contrast is an important determining factor for 2-D and 3-D PC structures. The lower the dimension of the structure, the more readily are PBG manifested, since overlap of the PBGs in different directions is more likely (something which is a certainty in 1-D structures). In 3-D structures, calculations have deter-

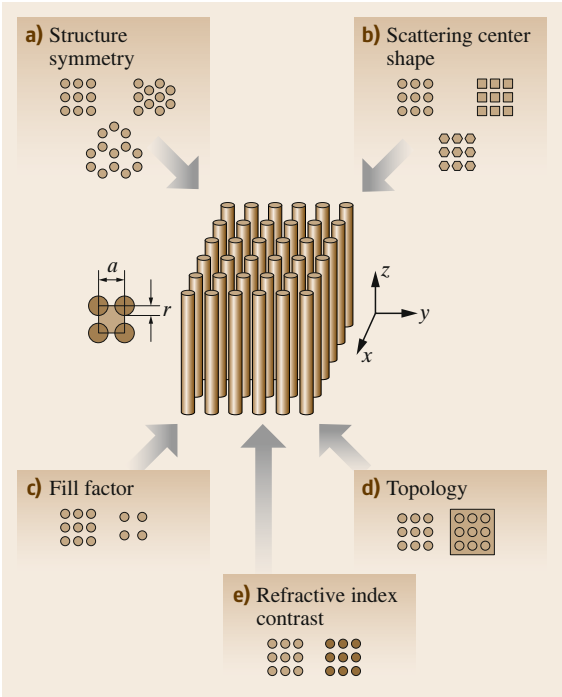

Fig. 39.3 PBG parameters that affect the center frequency and associated stop band (shown in *top view*, in *boxes*) relative to the 2-D periodic arrangement of one material (i. e., the rods, in *gray*) embedded in a second material (i. e., air), periodic in the *x*–*y* plane (shown in the *central figure*)

mined that the minimum dielectric contrast (n_1/n_2) required to obtain a full PBG is about 2.0 [39.2, 12, 14]. For full PBGs, the ideal structure typically consists of a dielectric-air combination, to obtain both the greatest dielectric contrast as well as to reduce losses associated with light propagation in optical materials other than air [39.7].

The relationship between the fill factor, structure symmetry, and scattering element shape on the size and location of the PBG is complex [39.7, 15–18] and will not be discussed in detail here. However, it is clear that the ability to adjust, or tune, one or more of these parameters and thus tune the PC properties, is a very exciting development for future PC device applications.

Real PC structures are of a finite size, and hence differ from the band structure of their infinite counterparts derived by invoking Block's theorem. Instead of having a continuum of allowed modes around the band edges, the finite structures present discrete modes. Developing appropriate models for these structures [39.19] has enabled an understanding of the lifetime of confined modes in specific structures to be achieved. Building on such work enabled engineered high-Q cavities ($\approx 10^6$) with small modal volumes (about $\approx 2(\lambda/n)^3$ for nanowire array cavities) [39.20, 21]. Important to understanding how to design such structures was the realization that for such 3-D PC structures, modal confinement within the PC can be improved by control over the out-of-plane mode profile. In particular, many groups focused on using modes below the light line to satisfy the total internal reflection condition at the interfaces for the top and bottom of the PC slab; however, in such a case, most of the electric field will then concentrate its energy in the dielectric, lowering the modes' frequency as compared with the light line, and decreasing the vertical scattering. To allow for more field energy in the interdielectric space, modes above the light line can provide a better choice. It was found that by a judicious choice of modes, one can identify modes lying above the light line that can still be totally internally reflected and provide for high Q [39.22].

39.1.3 Materials Selection for PCs

The physical architecture of a given PC is just one of the design considerations – another important one is the optical properties of the PC materials. In particular, the refractive index of a given material and its electronic band gap determine the performance and appropriate range of frequencies of PC devices fabricated from such a material.

For large PBGs, component materials need to satisfy two criteria; firstly, having a high refractive-index contrast, and secondly, having a high transparency in the frequency range of interest. This may be a challenge to satisfy at optical wavelengths. Suitable classes of PC materials include conventional semiconductors and ceramics, since at wavelengths longer than their absorption edge (or electronic band gap), they can have both high refractive indices and low absorption coefficients. In addition, these materials have other very useful electronic and optical properties that may complement the functions served by the presence of the PBG.

Another, often overlooked, consideration for PC material selection is the ability to translate the desired bulk single-crystal properties of well-known materials into nanometer-scale PC properties. Such structures typically have extremely large surface areas, and the microstructure of the constituent PC elements must be controlled during fabrication. Consequently, the final properties of the PC elements often vary from those of the bulk properties. This is extremely relevant when considering the functionality of a final PC device, such as those relying on electronic properties (e.g., lasing).

Finally, it is interesting to note that there is a strong correlation between the fabrication methods selected and the component materials. For example, top-down dry etching of semiconductors (e.g., Si, GaAs, InP, etc.)

into nanostructured 2-D arrays is well characterized and relatively commonplace, whereas the same cannot be said for ceramic materials. The opposite is generally true for chemical or bottom-up synthesis using sol-gel technology, in which ceramic PCs are relatively easy to fabricate when sol-gel-based infiltration techniques are used (e.g., in 3-D inverse opal fabrication). It is also clear that the fabrication technique primarily determines the PC structure that can be fabricated, which in turn determines the PC properties.

39.2 Traditional Fabrication Methodologies for Static PCs

Unlike for electrons, where there are natural length scales, for photons there is no such length scale [39.23]. This lack of an absolute length scale ensures that the physics of PCs is scalable: resizing the system rescales the energy in such a way that the spectrum, in units of c/a (where c is the speed of light and a is the lattice parameter of the PC), is independent of the system size [39.23]. Since $\omega/(2\pi c/a) = a/\lambda$, it is customary to use such dimensionless units to measure the photon energy [39.23]. Besides spatial scaling, there is also dielectric scaling – that is, there is no fundamental scale for ε. Two systems whose dielectric functions scale by a factor, $\varepsilon'(\boldsymbol{r}) = \varepsilon(\boldsymbol{r})/s^2$ have spectra that are scaled by the same factor: $\omega' = s\omega$, which means that increasing the dielectric function by a factor of four decreases the photon energy by a factor of two [39.23].

The apparent scalability of PCs is misleading because it suggests that PCs are truly size-independent, which in practice is not the case. As the size of the PC elements decrease, the effect of structural inhomogeneities become increasingly important, leading to inherent size limitations for particular architectures and for particular materials systems. This is most evident in changes in effective refractive index (e.g., due to the formation of intergranular phases, surface oxides, etc.) and functionality.

2-D systems are increasingly being used for microphotonic applications and consist of periodic repetitions of objects in a 2-D arrangement [39.23]. 3-D systems present a modulation in the third direction, such as a stack of spheres [39.23]. To date, 2-D and 3-D PCs have been fabricated using various approaches, including those based on electron-beam lithography, self-assembly and templating. The stringency of the requirements for a fabrication methodology, are dictated by the application of a given PC, in conjunction with associated requirements for material and architecture. Currently, there remains a great need for fabrication methods for mass production of nanometer-scale PCs, offering flexibility in material composition and design, while overcoming the low throughput of serial lithographic patterning, and the low reproducibility and material restrictions of self-assembly methods. Many excellent reports reviewing these fabrication techniques are available in the literature [39.1–4]. For readers unfamiliar with traditional PC fabrication techniques, the following sections review typical 2-D and 3-D PC fabrication methods, based on lithography, self-assembly and hybrid techniques.

39.2.1 2-D PC Structures

Introduction to 2-D PBG Structures

The advantage of the 2-D PC structure is that, due to its planar form, it is easier to fabricate using existing lithographic methods, it retains its original single-crystal properties, and it can be simply integrated into desired PLC designs. However, there are specific design limitations that must be considered for 2-D PC structures. The main problem that has been identified both theoretically and experimentally is diffraction losses in the third dimension (i. e., for light directed out of the plane of the 2-D PC) [39.1, 2].

Calculations often assume a perfect and infinite 2-D material. However, the aspect ratio in experimental structures fabricated using typical micromachining techniques (e.g., reactive-ion etching) tend to be very limited [39.2]. Thus, in order to confine light in the third dimension (i. e., the out-of-plane dimension), the structure must either be large compared to the beam size (i. e., many wavelengths deep), or must be sufficiently confined within a waveguide to experience the full interaction with the periodic lattice [39.1]. As a consequence, 2-D PC structures are now typically fabricated in three principal forms:

1. A 2-D array of air holes in a dielectric (or dielectric pillars of very high aspect ratio in air)
2. A slab waveguide consisting of a 2-D array of holes perforating a thin membrane (with the membrane thickness approximately equal to the hole diameter) and
3. A heterostructure waveguide (i. e., similar to those used for confining light and carriers in semiconductor laser heterostructures) with holes drilled through the heterostructure [39.24].

New fabrication methodologies need to be able to address the fabrication issues for each of these three

types of low-loss 2-D PC structures in order to implement these structures in practical device applications.

2-D Lithographic PC Fabrication Methods

The majority of semiconductor PCs are synthesized using the advanced lithographic and etching capabilities developed for the semiconductor microelectronic industry [39.1, 2, 4, 25]. One major benefit of being able to fabricate PCs from single crystals using top-down lithography is that the properties (e.g., nonlinear electro-optic properties) are typically superior to those for polycrystalline structures produced using bottom-up (e.g., template-based) processes [39.26]. Utilizing the former materials enables significant modulation of the optical properties suitable for developing tunable PC devices. Also, in top-down fabrication, the optical and dielectric properties of the bulk material may be characterized before PC fabrication, allowing them to be more effectively modeled after PC fabrication. Indeed, semiconductor-based PBG structures made using lithographic processes tend to be more reproducible than self-assembled PC structures. Most importantly, there is much greater flexibility in the design and implementation of lithographically fabricated structures, and hence to implementing functional devices. Finally, PC-based PLCs are ideal for optical system integration.

For high refractive-index contrast (i. e., larger photonic stop bands), the preferred PBG structure is a topologically patterned substrate (i. e., an air-solid PC), which may be fabricated using multistep submicron machining based on lithography. In this process, a radiation-sensitive resist is patterned to transfer structures to the bulk material. The patterned resist is developed (i. e., the properties of the exposed material are changed), followed by etching and/or metal thin-film deposition to define features in the bulk material. The majority of submicron machining processes involve exposure of the resist with either electromagnetic radiation (e.g., optical, UV or X-ray photons) or charged particles (electrons, low-energy heavy ions, high-energy light ions) [39.27]. Although resist exposure is essentially a surface micromachining technique and therefore planar, various wet and dry etching techniques have been successfully used to produce topologically varying microstructures in the axial direction [39.27].

Similar to all resist-based processes, the resist itself limits the ultimate minimum size and maximum density of nanostructured patterns [39.28, 29], and organic residues (from processed resist) are often sources of contamination [39.30]. Organic resists are chosen as a compromise between sufficient resilience for selected postprocessing procedures, and having sufficiently high sensitivity and contrast (i. e., a low energy threshold for resist exposure and total resist exposure occurring only above a certain energy threshold with no resist exposure occurring below, respectively) to the incident exposure [39.31] – this tends to be a difficult compromise to satisfy in practice for traditional resist materials.

Lithographic methods provide a simple and straightforward approach for the intentional introduction of defects into these 2-D systems (due to the simple surface patterning), and this top-down method may be the only way to retain the bulk-like semiconducting properties that are required for certain functionalities (e.g., lasing).

Electromagnetic Radiation Patterning. Generally, using electromagnetic radiation to micromachine structures requires masks to expose a resist material in a spatially selective manner, with subsequent development of the exposed resist to produce microstructures. Masks typically incorporate multiple repeat patterns, enabling multiple microstructures to be fabricated in a single exposure, which significantly reduces costs [39.27]. Masks tend to be less useful for patterning with charged particles, since the high energy deposited into the mask during exposure can produce undesirable mask instabilities due to heat expansion, stress and damage [39.27]. Charged-particle micromachining is therefore normally limited to direct-write processes, where a focused charged-particle beam is scanned over a material in a specific pattern to produce microstructures. Such a direct-write process has the advantage of not requiring a mask, but suffers from relatively low throughput as a serial write process, and hence loses its attraction for multiple-component production [39.27].

A main consideration of patterning approaches for PC fabrication is the minimum required feature size. Diffraction effects occurring for wavelengths of light below 100 nm impose a fundamental limitation on achievable structure sizes using optical lithography. Micromachined features smaller than about 250 nm are essentially beyond current readily available optical lithography systems [39.27], although recent advances (e.g., in UV lithography) will probably make this size regime achievable in the near future using a parallel patterning processes. Other techniques such as X-ray lithography that are capable of high-volume production by allowing parallel exposure for larger-area nanometer-scale patterning, are hampered by challenges including making suitable high-resolution masks, as well as the significant capital cost required to achieve the high photon flux suitable for mass production of nanometer-scale components [39.27].

Charged-Particle Beams. Limitations on the minimum feature size using traditional photolithography

have motivated a number of studies using serial patterning with charged-particle beams (e.g., electron-beam lithography (EBL) or, less commonly, focused ion-beam (FIB) lithography) to obtain the small feature sizes required in PC structures.

The advantages of EBL and FIB for defining sub-100 nm feature sizes in a maskless fashion are offset by the fact that high-volume production is commercially impractical using such serial writing techniques [39.27, 32, 33]. Conventional ion implantation, though widely available and robust, has thus far been incapable of patterning densely organized nanostructures due to ion scattering [39.31, 34] and mask limitations [39.35–39].

Another consideration for choosing lithographic techniques for sub-100 nm-scale feature fabrication is that all the steps in this multistep process have their own limitations. Indeed, the finite size of the molecular compound comprising the resist sets the ultimate limit on pattern resolution [39.28, 32]. Since all traditional submicron micromachining techniques except FIB require resist exposure, this is a major factor for determining resolution – for example, the ultimate resolution of EBL is not determined by the electron optical system, which is ≈ 0.1 nm, but by the resolution of the resist and by the subsequent fabrication process [39.40]. Also, electrons in the beam scatter very easily from electrons in the resist material, and both scattered and secondary electrons cause a lateral spread in the patterned material due to diffusion effects (i. e., proximity effects) [39.27]. Thus, the very high spatial resolution achievable at the surface using EBL deteriorates as the beam penetrates into the resist, making EBL unsuitable for high-resolution topographically patterned structures using resist alone [39.27]. The advantage of maskless processing for high-definition surface structures in resist and the inherently slower processing mean that EBL has been limited to mask-making and direct-writing on wafers for specialized applications such as fabrication of 2-D PCs for research purposes only [39.27].

Currently, the most commonly used method to fabricate 2-D PCs in the optical regime is EBL-based mask processing, combined with etching [39.1]. This approach has been used to pattern different semiconductor materials, including Si [39.4] and GaAs [39.1, 4, 7] (Fig. 39.4). Some detrimental effects arising from dry etching have been reported, including damage and ion channeling that increase nonradiative recombination in active microstructures [39.1]. Other post-mask procedures used to fabricate 2-D PC structures include vertical selective oxidation and lift-off techniques [39.1]. In vertical selective oxidation, an *all solid* 2-D PC structure may be fabricated, which maintains the physical integrity of the crystal and allows deposition of electrical contacts afterwards. However, the oxidation process

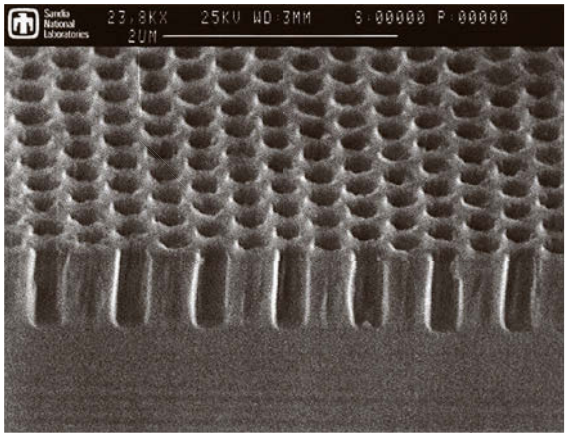

Fig. 39.4 Example of a 2-D PC structure in GaAs. (After [39.7]). The air hole radius is 122.5 nm, the lattice parameter is 295 nm, and the holes are 600 nm deep

usually also occurs laterally, while typical desired configurations for 2-D PC crystals are structured in the vertical direction. Even with improved vertically selective oxidation techniques, the depth-to-diameter aspect ratios of pillars are around 1 : 1, which is significantly less than the 10 : 1 ratios achieved using dry etching techniques [39.1]. Also, volume shrinkage of up to 13% [39.1] can lead to strain, the formation of microcracks and other structural problems. 2-D PC membranes have been fabricated using epitaxial lift-off/substrate removal, but this method is limited to materials with sufficient wet-etch selectivity [39.1].

Despite its extremely low throughput, focused ion beams are presently used for direct, resistless, nanometer-scale surface modification, micromachining, and ion implantation. This is primarily because such patterning cannot be achieved with any other method. However, FIB patterning is inherently slow and expensive, and requires sophisticated optics for ion focusing. Also, the patterning resolution and proximity of nanometer-scale features is greatly limited by the significant FIB tail distribution [39.30, 41] and the highly dose-dependent sputtering yield of FIBs [39.42]. The use of FIB patterning has not been widely used to fabricate PCs.

Light ions collimated by stencil masks can be used to expose resists in a parallel fashion in both ion-projection lithography and masked ion-beam lithography [39.31]. The resist is exposed in a similar manner to X-ray and EBL. Light ions are generally preferred over heavier ions in ion lithography because they have the greatest range in resists (thick resists can be used to give low defect densities [39.35]), but protons also scatter more than heavier ions at the end of the implant range, limiting resolution and nanometer-scale

Table 39.1 Summary of current submicron resist-based machining techniques. (After [39.31])

Technique	Potential sub-100 nm capability	Requires mask	Direct write	Facility availability	High-volume production capability	3-D capability
Optical lithography	No	Yes	No	Widespread industrial use	Yes	No[a]
X-ray lithography	Yes: depends on mask	Yes	No	Scarce and expensive	Yes	Yes
UV lithography	Yes: depends on mask	Yes	No	Scarce	Yes	Yes
Electron-beam writing	Yes: currently achieved	No	Yes	Medium availability	No	No
Low-energy ion beam writing	Yes: depends on focusing	No	Yes	Scarce	No	No[b]
High-energy ion beam writing	Yes: depends on focusing	No	Yes	Very scarce	No	Yes

[a] Optical lithography is a surface technique. However, new supplementary dry etching techniques such as plasma etching are being used to produce submicron 3-D structures from 2-D surface structures in silicon
[b] Low-energy ion-beam micromachining (FIB) relies on sputtering atoms from the surface. 3-D structures can be produced by continuous erosion at a given location although, in practice, this is far too slow for practical 3-D microcomponent production

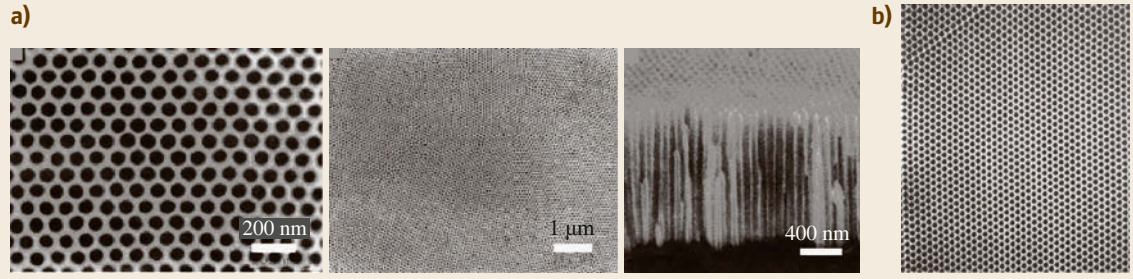

Fig. 39.5a,b Examples of 2-D self-organized PC structures of: **(a)** NCA [39.43], **(b)** NCG. (After [39.44])

feature proximity. However, the use of heavier ions to pattern, following the traditional approach used for semiconductor doping, can lead to mask erosion. This effect is negligible when light ions (e.g., hydrogen) are used, but can become pronounced for higher-dose implantation of heavier ions [39.31]. A summary of current lithography-based submicron micromachining techniques is given in Table 39.1.

2-D Self-Assembled PC Fabrication Methods

For 2-D PC structures, electrochemical methods (i. e., anodic etching and growth) and fiber-pulling have used to prepare extremely high-aspect-ratio ($\gg 50:1$) large-area nanometer-scale hole arrays (Fig. 39.5). These types of structures represent near-ideal infinite 2-D PC structures [39.24]. However, these methods are limited to specific materials (e.g., silicon [39.45] and alumina [39.43] for electrochemical methods, or glass [39.44] by fiber-pulling), and processes such as electrochemical etching are often limited in their capability to control fill factor, structure symmetry and scattering element shape. 2-D PC structures with long-range periodicity obtained by electrochemical etching often require surface prepatterning by serial lithography to obtain lattice dimensions in the visible to near-IR range.

Some examples of easily available, high-aspect-ratio nanoporous arrays include electrochemically grown porous alumina (nanochannel alumina, or NCA) [39.43], electrochemically grown silicon [39.46] and fiber-pulled nanochannel array glass (NCG) (Table 39.2) [39.47, 48].

Nanochannel Alumina. NCA may be fabricated economically with well-characterized properties. Pseudo-ordered regions can be easily fabricated using electrochemical etching, compared with porous silicon, which requires back-side illumination in addition to an applied

Table 39.2 Parameters of current high-aspect-ratio 2-D periodic structures. (After [39.46–48, 50])

Nanotemplate type	Alumina	Silicon	Glass
Pore size (nm)	$1-10^2$	$400-10^4$	> 10
Pore density (cm^{-2})	10^9-10^{12}	10^6-10^9	10^{10}
Pore arrangement	Pseudo-ordered[a]	Disordered[a]	Ordered
Thickness (nm)	10^3	10^3	10^3
Temperature tolerance	$< 450\,^{\circ}C$	$< 900\,^{\circ}C$	$< 600\,^{\circ}C$

[a] May be ordered using prepatterning processes [39.46, 49]

bias. The pore arrangement is completely disordered in silicon if no prepatterning with optical or EBL is used [39.50].

Aluminum is electrochemically oxidized to alumina (Al_2O_3) under positive polarization. For over a century, the growth of disordered pore arrangements has been observed and studied for selected electrolytes that weakly dissolve alumina. However, in 1995 it was first discovered that, after an extended period of anodization, self-ordered porous alumina films with pores arranged in a hexagonal pattern are obtained at the growth front [39.43]. Although knowledge of how to fabricate such NCA templates is now widespread, the formation mechanism of hexagonal NCA has still not been completely elucidated. Mechanical stress between neighboring pores due to the volume expansion of alumina with respect to the aluminum substrate has been proposed as a mechanism for the self-ordering [39.50].

Controlled single-domain porous arrays may be obtained by lithographically prepatterning the aluminum substrate, and applying the optimum potential for the corresponding interpore distance [39.51]. Recently, in addition to the hexagonal lattice, square and honeycomb lattices with square or triangular pore shapes have also been obtained by appropriate prepatterning [39.52].

Extremely high-aspect-ratio NCA templates can be fabricated with periodicities ranging from ≈ 80 to $\approx 600\,nm$. The domain sizes (i. e., areas with the same orientations) are controlled by the anodization conditions and increase with time to micrometer-scale sizes. The thickness of the NCA template can be controlled by the electrochemical etching time, from $\approx 50\,nm$ to $> 10\,\mu m$ thick.

Current Alternative 2-D PC Fabrication Methods. Templating of 2-D Structures. 2-D PCs have been fabricated by templating a secondary material into a PC backbone, that can either remain in the final structure as a composite material or be removed to form a dielectric/air PC structure. In many cases, a dielectric/air PC structure is preferred due to the higher dielectric contrast, but depending on the original PC backbone material, it may not be possible for the secondary materials to be removed after templating.

Over the last decade NCA templates have been commonly used to fabricate various nanostructured arrays by either dry etching or by growth through templates [39.49, 53, 54]. This method of using self-assembled templates for nanostructure patterning has been used to pattern physical topology, resulting in either nanostructured hole arrays (e.g., by dry etching through the templates), or growth of nanostructured *wire* arrays (e.g., by metalorganic chemical vapor deposition – MOCVD, molecular-beam epitaxy, and chemical-solution deposition). The effectiveness of NCA as a templating tool results from the fact that the alumina may be easily selectively chemically etched compared with semiconductor materials, and forms a robust mask for dry etching (compared to, for example, patterned resist materials).

Combining Self-Organized 2-D Structures with Ion Implantation. Ion-beam techniques may be used to pattern, for example, sub-100 nm resolution features on thin membranes, but they are unsuitable for deep subsurface patterning, particularly at the end of the implantation range. One reason for this is that stencil-type masks need to be used, due to the relatively short range of energetic ions compared to, for example, x-rays, which do not require stencil-type masks [39.28, 31]. In the past, high-aspect-ratio stencil masks for ion implantation were fabricated using techniques such as EBL, but such stencil masks were limited by the low pattern density achievable using such fabrication methods, requiring the use of self-complementary masks with multiple offset exposures to create printed patterns [39.38]. Also, the minimum resolution using nanoscale ion implantation through masks is so sensitive to the mask's wall angle [39.36, 37] that advanced photoresists and lithographic techniques need to be used to achieve such ideal masks.

Investigations have been reported on new ways to combine self-organized 2-D PC structures with conventional, broad-beam ion implantation to achieve nanoscale pattern transfer [39.55, 56]. Using self-organized templates as masks significantly simplifies

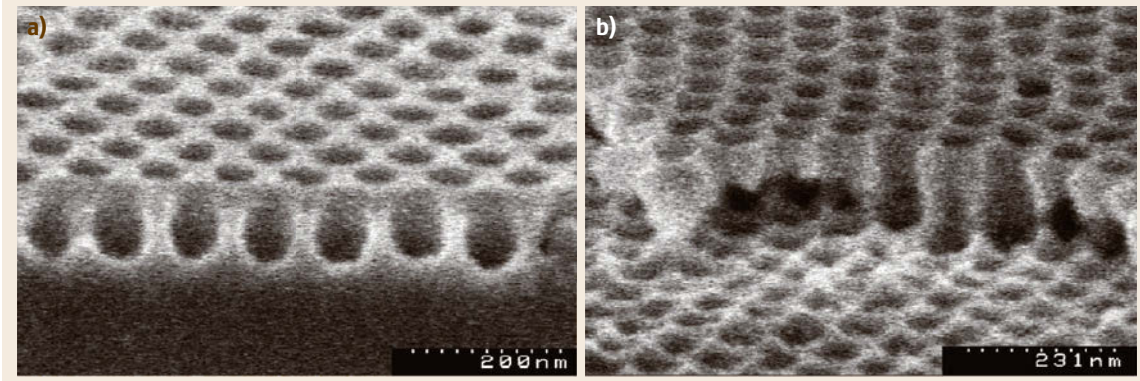

Fig. 39.6a,b Example of nanoscale features formed in a $SrTiO_3(100)$ substrate using conventional ion implantation through high-aspect-ratio masks combined with selective wet etching. (After [39.55, 56]). Scanning electron microscope images for: **(a)** tilt view of single implant and **(b)** multiple energy implants to create membrane structure

the process, as no resolution-limiting resist or no time-intensive serial patterning is necessary, and these ideal, stencil-type masks allow direct nanostructure array transfer with significantly less scattering than solid masks. The use of self-organized masks allows this process to be economically feasible for large-area nanostructure array patterning. This approach transfers the desired pattern from the self-organized template into a desired material that cannot be patterned on the same scale using self-organization.

Despite concerns about mask edge defects [39.57–59], extended radiation damage accumulation extending below the mask edges [39.34, 39] and possible mask distortion from stress and temperature [39.35], it has been shown that nanoscale features could be retained using conventional ion implantation combined with high-aspect-ratio masks to make PC-type structures [39.55, 56] (Fig. 39.6). Energetic, charged particles were accelerated into a substrate using broad-area parallel implantation through NCA templates to pattern 2-D nanostructured arrays of ions in both semiconductor (i. e., InP) and ceramic (i. e., $SrTiO_3$) single crystals [39.55, 56]. The ion-implanted volume was selectively etched away after implantation to form 2-D nanostructured air-hole arrays in the substrate material. The array pattern was successfully fabricated over the entire implant area ($\approx 1\,cm^2$), with resulting minimum feature sizes of $\approx 40\,nm$. Such a direct and parallel method, combining ion implantation with a nanoscale mask, can be immediately beneficial, particularly in applications where using FIB is impractically slow (e.g., for substrate nanostructure array prepatterning for selective or electrochemical etching). In addition, complex profiles (e.g., membrane formation) were shown to be possible using this technique. This method allows ions to be implanted into nanoscale areas, which may result in additional substrate modification, including, but not limited to, micromachining of implanted areas to fabricate topologically patterned nanostructured arrays.

The ability to process structures of different form and shape using ion-implantation techniques offers opportunities for nanomachining, and enables material processing on a nanometer scale – this is applicable to materials that cannot be structured using standard lithography (e.g., samples with pronounced topography [39.42]). This nanoscale patterning method can also be used to directly pattern substrates to create electrochemical initiation sites for fabrication of ordered porous Si and porous GaAs structures for light emission [39.60] and for 3-D PC fabrication in Si [39.61]. In addition, such array pattern transfer is applicable to prepatterning of self-assembled templates themselves, as a substitute for lithographic prepattering for the fabrication of ordered nanochannels in materials such as Si and Al_2O_3 [39.50].

39.2.2 3-D PC Structures

Introduction to 3-D PBG Structures

A main advantage of 3-D PBG structures over 2-D PBG structures is that the 3-D PBG structures can overcome the problem of diffraction losses in the third (out-of-plane) dimension [39.1, 2]. However, this advantage is countered by the significant challenges associated with fabricating 3-D PBG structures. Fabricated 3-D structures reported to date lack the reproducibility and design versatility required for functional devices [39.25].

3-D Lithographic Fabrication Methods

Fabrication of 3-D PCs using top-down micromachining techniques has been more difficult than for 2-D PCs.

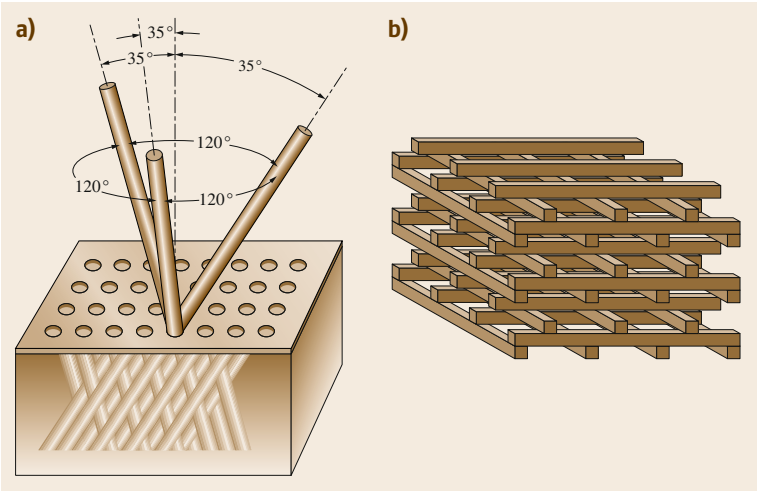

Fig. 39.7a,b Examples of 3-D photonic crystal structures: **(a)** *Yablonovite*, obtained by drilling holes in a homogeneous dielectric material (15 GHz); and **(b)** *woodpile* structure, obtained by stacking micromachined Si rods (500 GHz). (After [39.2])

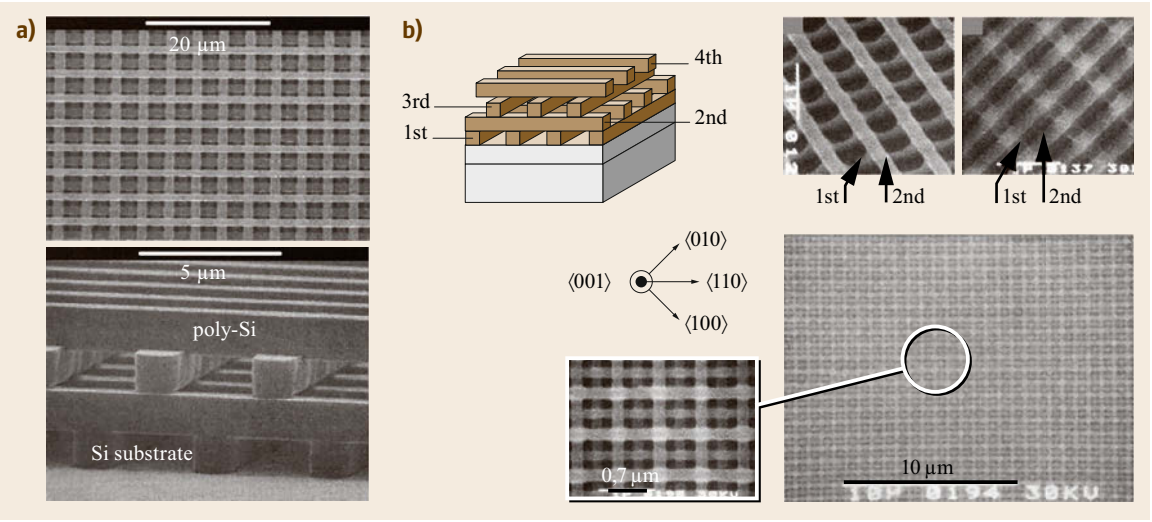

Fig. 39.8a,b Examples of 3-D PBG structures fabricated by micromachining/lithographic techniques: **(a)** advanced lithography. (After [39.62]). **(b)** wafer fusion. (After [39.63])

The first experimental demonstration of a full 3-D photonic band gap was performed in the microwave region (i. e., at 15 GHz, $\lambda \approx 2$ cm), due to the relative ease of fabrication of appropriate structures on the centimeter scale [39.64] (Fig. 39.7). Another case of a full PBG was demonstrated at 500 GHz ($\lambda \approx 600\,\mu$m) with a 3-D structure fabricated by assembling micromachined silicon dielectric rods [39.65] (Fig. 39.7) into log-pile structures [39.66, 67].

In a 3-D lattice, theoretical calculations have determined that the band gap position is generally about one half to one third of the periodicity scale [39.68]. This translates into patterning the dielectric materials with features of 100–300 nm in all three dimensions, with required alignment accuracies among the different layers exceeding tens of nanometers [39.68]. In addition, with air as the second dielectric, the empty volume required for large PBGs is so large ($\approx$ 70–80%) that the mechanical stability of the structure becomes very poor, adding another challenge for the etching procedure [39.2]. Often 3-D PC structures are so full of defects after such etching that the systems no longer exhibit significant PC behavior [39.2].

Due to difficulties in fabricating structures in the optical or near-infrared frequencies [39.2, 68, 69], only a few experimental systems have recently demonstrated the signature of a complete PBG. Lithographically derived 3-D structures require many complex fabrication steps, and it takes many months to make a single structure. Some examples of prototype 3-D PCs in-

clude log-pile structures fabricated using layer-by-layer patterning (i. e., repeated deposition and etching) of Si [39.62] (Fig. 39.8), and structures fabricated using wafer fusion combined with etching in GaAs and InP [39.63] (Fig. 39.8). In the former case, processing difficulties have limited the number of layers in such 3-D periodic structures (i. e., to below ten) and in the latter cases, to materials other than those commonly used in microelectronics [39.68]. Sequential deposition of dielectric films on a patterned substrate may be used to produce 3-D periodic structures in the *autocloning* process [39.70], which is considered to be a relatively cheap and flexible process. However, the range of structures that can be produced with this technique is limited. Also, the technique does not allow the component dielectrics to be continuously connected in 3-D [39.71].

Hole-drilling has also been implemented using x-ray lithography [39.72] and can be scaled to optical frequencies by directional etching through a mask on a semiconductor surface [39.73]. Other fabrication methods include direct laser writing, but its resolution is currently only suitable for infrared structures.

3-D Self-Assembly Methods: Inverse Opals

The technological challenges involved in extending microlithographic techniques to 3-D patterning have made self-assembly methods attractive for 3-D PC fabrication. The benefits of using this type of bottom-up assembly for 3-D fabrication include its low capital cost, and its parallel and rapid nature, which allows the ordered fabrication of 3-D PBG-type structures over macroscopic length scales [39.3, 68, 77, 78]. However, self-assembly methods for 3-D PC fabrication are often material-specific, and templated bottom-up PCs tend to have diluted properties compared to bulk single crystals, typically containing unintentional defects and lacking reproducibility.

Self-organized 3-D colloidal crystal structures in a face-centered-cubic lattice (i. e., artificial opals) can be fabricated through sedimentation of colloidal suspensions (i. e., typically spheres, but other structures, such as micelles formed from rod-coil block copolymers have been used). Previously, colloidal crystals were not considered appropriate for PCs with band gaps in the visible and IR ranges because the colloids (typically SiO_2 or polymer materials such as polystyrene (PS) [39.79, 80] or polymethyl-methacrylate (PMMA)) have refractive indices ≈ 1.5, which are too low to obtain a full PBG [39.81–83]. Such structures have weak refractive-index contrast, but theoretical calculations have shown that the final porosity of the artificial opal is too small to ever obtain a full PBG, even with very high refractive-index contrast [39.1, 3, 77].

These colloidal structures may also be infiltrated with a second material of higher refractive index to potentially improve the dielectric contrast [39.81, 84], while providing the required dimensional control and low solid fraction [39.78]. So-called *inverse* structures can be formed when the original colloidal structure is removed to leave a macroporous structure. Calculations have shown that these inverse structures give rise to larger PBGs for the same refractive-index contrast [39.85]. The porous materials obtained using this approach have also been referred to as *inverse opals* or *inverted opals* because they have an open, periodic 3-D framework complementary to that of the parent opal. Modeling suggests that a porous material consisting of an opaline lattice of interconnected air balls (embedded in an interconnected matrix with a higher refractive index) should produce a full PBG. Optimum photonic effects require that the volume fraction of the matrix material should be 20–30%. Template-based synthesis based on colloids is attractive because the periodicity of this system can be conveniently tuned and a wide variety of materials with relatively high refractive index can be used [39.77]. There have been many examples of inverse opals using materials such as carbon, titania, zirconia, Si and Ge reported in the literature [39.3, 74–78, 86–93] (Fig. 39.9).

The inverse structure is made by infiltrating the interstitial void spaces ($\approx 26\%$ by volume) between the colloidal spheres in the opaline array with a fluid precursor. The fluid may be a pure liquid (e.g., a liquid metal alkoxide or a molten metal), a solution (e.g., a salt solution), a vapor (e.g., using CVD – chemical vapor deposition), or a colloidal dispersion of nanocrystals (e.g., colloidal gold particles) [39.77, 78]. Alternately, suspensions containing nanoparticle precursors (with sizes of ≈ 1–$50\,\mathrm{nm}$) and monodisperse spheres can be coprecipitated into an ordered structure [39.77, 78]. The void spaces between the colloidal spheres has also been filled using a variety of materials by electrochemical deposition [39.77]. The fidelity of this procedure is mainly determined by van der Waals interactions, the wetting of the template surface, kinetic factors such as the filling of the void spaces in the template, and the volume shrinkage of precursors during solidification [39.77].

The choice of wall material depends on the desired optical functionality of the PC, as its properties depend on the transparency region of the dielectric material. The availability of a precursor that can infiltrate the voids between the colloidal spheres without significantly swelling or dissolving the template is critical. For example, high-temperature infiltration techniques exclude the use of polymer templates. The precursor must be carefully chosen to allow for shrinkage occur-

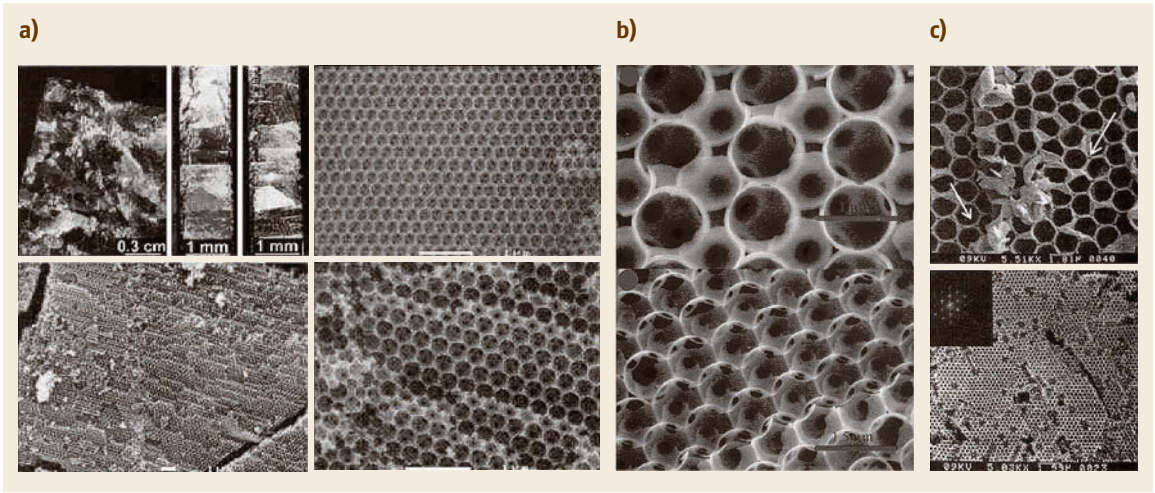

Fig. 39.9a–c Examples of 3-D inverse opal PBG structures: (a) graphite (using CVD infiltration). (After [39.74]), (b) Si (using CVD infiltration). (After [39.75]), (c) titania (using liquid-phase chemical reaction). (After [39.76])

ring during solidification and the final grain size, which affects the smoothness, density, effective refractive index, PC wall structure and the mechanical properties of the final 3-D PC [39.78]. The approach and conditions used for infiltration can affect the filling efficiencies (i. e., the effective wall density) which, in turn, affect the mechanical strength and reduces the average refractive index of the walls [39.78, 86]. Choice of template also depends on the method of solidification of the precursor and whether the template can be selectively removed from the wall material, either chemically or by heating during the final fabrication step.

Porous structures are produced by the removal of the colloidal templates, either by burning, extracting with a solvent, or, in the case of silica colloids, by dissolving with dilute hydrofluoric (HF) acid. The method of template removal depends on the colloid material and on the properties of the infiltrated precursor. Silica sphere template arrays are removed by dissolution in aqueous HF solutions [39.78, 92]. Most metal-oxide inverse opals have typically been synthesized using polymer spheres as templates [39.78]. Polymer sphere template arrays are often removed thermally, with the added benefit of chemically converting the sol-gel precursors in the infiltrated phase to the desired oxide product [39.78, 92]. If precursor solidification is feasible at low temperatures, or if the precursor has components that would be destroyed by thermal template removal, polymer spheres can also be removed chemically using organic solvents, such as toluene, or tetrahydrofuran (THF) and acetone mixtures, or by photodegradation [39.78, 92].

Fabrication of such structures is not trivial: some of the difficulties include incomplete infiltration, structural shrinkage after infiltration, and microstructural variations (affecting the refractive index). A major problem with chemical assembly is that residual disorder drastically reduces the PBG width and the intensity of the reflectance peaks [39.78, 89]. Such disorder can arise from several different sources. Firstly, there are defects in the initial opal template, such as stacking faults or small deviations in sphere size or shape. It is not clear whether the imperfections present in current inverse opals are small enough to observe a complete PBG [39.3]. While progress has been made in reducing such defects, numerical simulations predict that even a 2% deviation in sphere size (or lattice constant) can close a PBG in even high-refractive-index inverted opals [39.3, 78]. Secondly, significant disorder can arise from the infiltration process itself. Even the best samples to date have variations in the amount of guest material filling the lattice [39.3]. Since these inhomogeneities must be much smaller than the optical wavelength, the elimination of residual order remains a challenge with such methods [39.3].

Although 3-D inverse opals are fascinating research objects, they are not amenable for practical photonic applications because of difficulties in integrating them into PLCs. Thus, there is strong interest in fabricating 3-D inverse opals in pseudo-2-D form, or supported on a substrate as an inverse opal film, to be compatible with traditional optoelectronic elements for system integration [39.1, 90, 95–97]. Recently, ordered colloidal crystal films have been formed by convective assembly [39.90] by particle confinement in thin slits between two solid plate boundaries [39.77, 90] and by compacting particles in the dry state [39.90, 95, 97–100]. Recently, patterned substrates were successfully used to

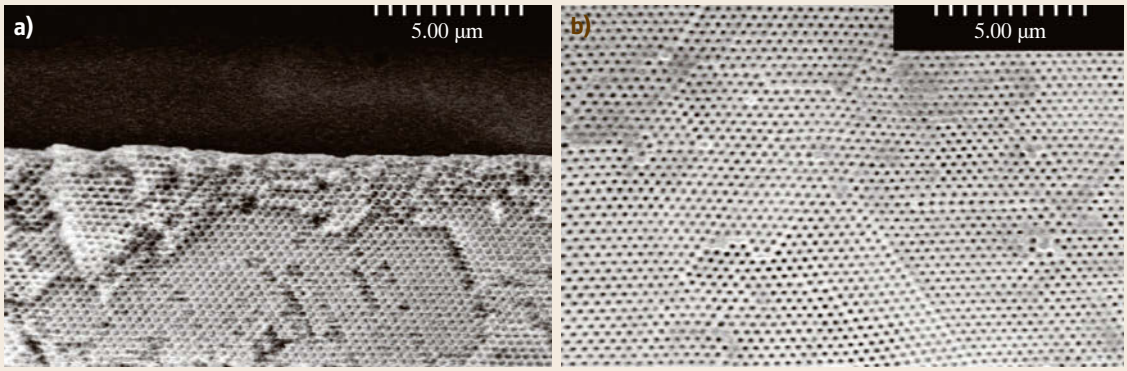

Fig. 39.10a,b Scanning electron microscope images of Pb-doped BST inverse opal thin film: **(a)** cross section; **(b)** top view. (After [39.94])

control slow sedimentation of colloidal particles to improve the long-range order and to induce growth along a specific crystal plane [39.78, 90]. However, growth of defect-free crystalline templates with desired symmetry and orientation remains one of the challenges of the field.

Liquid sol-gel precursors can be used to form a variety of oxide materials and are very convenient for infiltration into artificial opal templates [39.92, 101]. However, the typical high percentage of volume shrinkage (typically 15–30%) involved in the solidification of such sol-gel precursors during the precursor-to-oxide conversion process has often resulted in random cracks in the final inverse opal films [39.77, 78, 92], often preventing the fabrication of large, ordered, inverse opal film structures. Colloidal template films have been infiltrated by soaking the template into the precursor sol-gel solution [39.78, 89, 102], but achieving a dense, complete filling of the void spaces within the 3-D template film has proven to be challenging [39.101]. Another approach used for large-area inverse opal film fabrication involves the crystallization of colloids in a liquid medium containing nanoparticles of the desired material, which are subsequently packed into a dense, 3-D lattice [39.78, 101]. The main limitation of this method is that nanometer-sized particles are not always available for the desired wall material, and so only very specific materials may be made into inverse opals [39.92]. Another method of fabricating high-quality inverse opal films derived from liquid precursors is by infiltrating a sol-gel liquid precursor into a colloidal crystal template film by spin coating, which results in very uniform filling of the template [39.94] (Fig. 39.10). By comparison, solvent-extracted samples shrink about 10% less [39.92]. Thus, for organic polymers, it has been possible to fabricate such 3-D porous structures as free-standing thin films that are several square centimeters in area.

Alternative 3-D PBG Fabrication Methods

Alternative approaches to lithography or self-assembly for 3-D fabrication exist. Some notable examples include laser-guided stereolithography, in which structures can also be written directly layer-by-layer by using a tightly focused laser beam to cause chemical vapor deposition [39.103], and two-photon-induced deposition or polymerization [39.104, 105]. Currently, feature sizes that can be routinely achieved using these methods are on the order of a few micrometers due to focusing and diffraction effects.

A 3-D holographic patterning process using multiple laser beams has recently been investigated; a 3-D laser interference pattern exposes a photosensitive polymer precursor (i. e., a photoresist) rendering the exposed areas insoluble and unexposed areas are dissolved away to leave a 3-D PC formed of cross-linked polymer with air-filled voids [39.106]. This process allows flexible design of the structure of a unit cell and thus of the optical properties of the microstructured material. Of concern is that such structures have relatively weak refractive-index contrast, and the processing approach is quite demanding [39.68].

39.3 Tunable PCs

Although conventional PCs offer an ability to control light propagation or confinement through the introduction of defects, once such defects are introduced, the propagation or confinement of light in these structures is not controllable. Thus, discretionary switching of light, for example, or rerouting of optical signals, is not available with fixed defects in PCs. There are two approaches that have been pursued to tune the properties of PCs: these are by tuning the refractive index of the constituent materials, or by altering the physical structure of the PC. In the latter case, the emphasis has been principally on changing the lattice constant, although other approaches are also relevant (i. e., including for example, the fill factor, structure symmetry and scattering element shape). In the text below, we discuss the state of the art in both of these areas.

39.3.1 Tuning the PC Response by Changing the Refractive Index of the Constituent Materials

We discuss recent progress in using four approaches within this category – namely, tuning the PC response by using: (i) light, (ii) applied electric fields, (iii) temperature or electrical field in infiltrated PCs, and (iv) by changing the concentration of free carriers (using electric field or temperature) in semiconductor-based PCs.

PC Refractive-Index Tuning Using Light

One approach to modifying the behavior of PCs is to use intense illumination of the PC by one beam of light to change the optical properties of the crystal in a nonlinear fashion; this, in turn, can thus control the properties of the PC for another beam of light. An example of a nonlinear effect includes the flattening of the photon dispersion relation near a PBG, which relaxes the constraints on phase matching for second- and third-harmonic generation [39.107]. In addition, light location near defects can enhance a variety of third-order nonlinear processes in 1-D PCs [39.108].

A new approach for PBG tuning has been proposed based on photo-reversible control over molecular aggregation, based on using the photochromic effect in dyes [39.109]. This can cause a reversible change over the photonic stop band. Structures that were studied included opal films formed from 275 nm diameter silica spheres, infiltrated with photochromic dye. Two dyes were considered – namely 1,3-dihydro-1,3,3-trimethylspiro-[2*H*-indole-2,3′-[3*H*]-naphth [2,1-*b*] [1,4]oxazine] (SP) and *cis*-1,2-dicyano-1,2-bis(2,4,5-trimethyl-3-trienyl)ethane (CMTE). For the SP dye opal, a reversible 15 nm shift in the reflectance spectrum was observed following UV irradiation, which was ascribed to changes in the reflective index due to resonant absorption near the stop band. Smaller shifts (of about 3 nm) were observed for the CMTE dye opal. The recovery process on cessation of UV illumination was quite slow, taking about 38 s for the SP dye.

Nonlinear changes in refractive index have also been studied in PCs consisting of 220 nm diameter self-assembly polystyrene spheres infiltrated with water [39.110]. In these studies, the optical Kerr effect was used to shift the PBG. 40 GW/cm^2 [39.2] of peak pump power at 1.06 μm (35 ps pulses at 10-Hz repetition rate) was used to shift the PBG 13 nm. The large optical nonlinearity originates from the delocalization of conjugated π-electrons along the polymer chains, leading to a large third-order nonlinear optical susceptibility. The time response was measured as a function of the delay time between pump and probe, and confirmed a response time of several picoseconds.

Further to the discussions in Sect. 39.1.2 on high-Q nanowire-based PCs using linear optical field interactions, it was found that such structures have an additional benefit for nonlinear optical response. Their highly anisotropic optical response originates from the dielectric mismatch between the nanowire material and surrounding medium, introducing strong depolarising effects, which introduce anisotropy in the optical electric field in the nanowires, and make the probability of optical transitions strongly dependent on direction, and has led to a giant nonlinear response being observed [39.111, 112].

PC Refractive-Index Tuning Using an Applied Electric Field

There have been a number of studies focusing on using ferroelectric materials to form PCs [39.94, 102, 113, 114]. The application of an electric field to such materials can be used to change the refractive index and tune the PC optical response. A recently published review of electrically responsive PCs can be found in [39.115]. For example, lead lanthanum zirconate titanate (PLZT) inverse opal structures have been fabricated by infiltration using 350 nm diameter polystyrene sphere templates and annealing at 750 °C [39.113]. The films were formed on indium tin oxide (ITO) coated glass to enable electric-field-induced changes in reflectivity to be measured due to the electro-optic effect. Applying voltages of up to about 700 V across films of thickness of about 50 mm only achieved a few nm of peak shift, attributed to the very modest changes in refractive index from the applied field (i. e., from 2.405 to 2.435, as a re-

sult of the bias). It should be noted, however, that the intrinsic response of the electro-optic effect in these materials is known to be in the GHz range and hence highly suitable for rapid tuning. Other reports include the formation of inverse opal barium strontium titanate (BST) PCs using infiltration of polystyrene opals [39.94, 102]. BST is most interesting in that it provides a high-refractive-index material and a factor of at least two times higher breakdown field strength than PLZT, and hence offers a much wider range of applied fields for tuning. Reports of using other ferroelectric materials include a high-temperature infiltration process for the ferroelectric copolymer, poly(vinylidene fluoride-trifluoroethane), infiltrated into 3-D silica opals with sphere diameters of 180, 225 and 300 nm [39.114].

Refractive-Index Tuning of Infiltrated PCs

In this case the approach has been to consider modulation of the refractive index of a PC infiltrated with a tunable medium – in particular, the most popular approach has been to use liquid crystals to infiltrate porous 2-D and 3-D PC structures. Such liquid crystals can behave as ferroelectrics whose refractive index may be tuned using either an applied electric field, or by thermal tuning. Reported results for this approach, using 3-D inverse opal structures, have been restricted to infiltration of ferroelectric liquid-crystal material into a silicon/air PC [39.116]. Reported changes in the refractive index of the liquid crystal are 1.4−1.6 under an applied field [39.116]. However, since the ferroelectric liquid has a higher refractive index than air, the infiltration results in a significant decrease in the refractive index contrast. This means that the original full photonic band gap of the inverse opal silicon PC no longer exists, and the practical utility of the silicon structure as a PC is effectively lost. Theoretical simulations have shown that partial surface wetting of the internal inverse opal surface can retain the full photonic band in silicon [39.116], but it is questionable whether such a complex structure can ever be practically fabricated. Finally, the presence of ferroelectric liquid crystal surrenders one of the main advantages of the original concept for PC structures: that is, permitting light propagation in air [39.117]. Temperature tuning of the liquid-crystal material was shown to result in very small changes in refractive index (changes in $n < 0.01$ over a 70 °C change) and thus only provide minimal shifts in the transmittance through the PC over a large temperature range [39.118]. Aside from opalate PCs, nanowire-based PCs with heterostructured cavities with high Q ($\approx 4\times10^5$) have been shown to be highly tunable over a wide range by infiltration. As an example such structures' peak transmission could be continuously linearly tuned from $\approx$ 1604 to $\approx$ 1622 nm by changing the infiltrating medium refractive index from $\approx$ 1.392 to $\approx$ 1.442 [39.119]; note that the tuning range could be extended by careful control over the pillar array aspect ratio.

PC Refractive-Index Tuning by Altering the Concentration of Free Carriers (Using Electric Field or Temperature) in Semiconductor-Based PCs

An elegant way to rapidly tune the PBG of semiconductor-based PCs is to adjust the refractive index by modulating the free-carrier concentration using an ultrafast optical pulse [39.120]. Using this approach, reflectivity of a two-dimensional silicon-based honeycomb PCs with 412 nm air holes (100 μm in length) in a 500 nm periodic array, was studied with a pump-probe approach [39.120]. By varying the delay between the pump the speed of PBG tuning was measured to be about 0.5 ps. The reflectance relaxation (corresponding to the return of the PBG to its original position) occurred on a timescale of 10−100 ns, characteristic of recombination of excess electrons and holes. Although these results are very encouraging, this approach cannot suppress or correct for light-scattering losses caused by structural imperfections, which remain an important consideration for currently fabricated PCs.

Another elegant application of these ideas is in resonant absorption structures exposed to different levels of optical pumping, to change the response. In particular, lateral grating-based PCs have been demonstrated with arrays of nanometer sized silicon p-i-n detectors in which local optical field enhancement is provided by the periodic detectors and the interference within an air/SiO_2/Si cavity structure [39.121, 122].

39.3.2 Tuning PC Response by Altering the Physical Structure of the PC

The second approach that we discuss for tuning the response of a PC is based on changes to the physical structure of the PC. We discuss the following approaches for tuning using this approach: tuning using

1. Temperature
2. An applied magnetic field
3. Strain/deformation
4. Piezoelectric effects, and
5. Using micro-electromechanical systems (MEMS) (i. e., actuation).

Tuning PC Response Using Temperature

An example of this approach is a study of temperature tuning of PCs fabricated from self-assembled

polystyrene beads [39.123]. The PBG in these structures was fine-tuned by annealing samples at temperatures of 20–100 °C, resulting in a continuous blue shift of the stop band wavelength from 576 to 548 nm. New stop bands appeared in the UV transmission spectra when the sample was annealed above about 93 °C – the glass-transition temperature of the polystyrene beads.

Tuning PC Response Using Magnetism

An example of this approach is the use of an external applied magnetic field to adjust the spatial orientation of a PC [39.101]. This can find application in fabricating photonic devices such as tunable mirrors and diffractive display devices. These authors fabricated magnetic PCs by using monodisperse polystyrene beads self-assembled into a ferrofluid consisting of magnetite particles, with particle sizes below 15 nm [39.101]. On evaporation of the solvent, a cubic PC lattice was formed with the nanoparticles precipitating out into the interstices between the spherical polystyrene colloids. These authors then showed how the template could be selectively removed by calcination or wet etching to reveal an inverse opal of magnetite – such structures being proposed as suitable for developing magnetically tunable PCs.

Also, ordered magnetic particle arrays were fabricated through nanosphere deposition [39.124], which can in principle enable the realization of arbitrary material magnetically reconfigurable PCs.

Tuning PC Response Using Strain

The concept in this case is quite straightforward – deforming or straining the PC changes the lattice constant or arrangement of dielectric elements in the PC with concomitant change in the photonic band structure. Polymeric materials would appear to be most suited to this methodology, owing to their ability to sustain considerable strains. However, concerns of reversibility and speed of tuning would clearly need to be addressed. Theoretical predictions for the influence of deformation on such systems include a report on a new class of PC based on self-assembling cholesteric elastomers [39.125]. These elastomers are highly deformable when subjected to external stress. The high sensitivity of the photonic band structure to strain, and the opening of new PBGs have been discussed [39.125]. Charged colloidal crystals were also fixed in a poly(acrylamide) hydrogel matrix to fabricate PCs whose diffraction peaks were tuned by applying mechanical stress [39.126]. The PBG shifted linearly and reversibly over almost the entire visible spectral region (from 460 to 810 nm).

Modeling of the photonic band structure of 2-D silicon-based triangular PCs under mechanical deformation was also reported [39.127]. The structures considered consisted of a silicon matrix with air columns. The authors showed that while a 3% applied shear strain provides only minor modifications to the PBG, uniaxial tension can produce a considerable shift. Other modeling includes a study of how strain can be used to tune the anisotropic optical response of 2-D PCs in the long-wavelength limit [39.128]. These calculations showed that the decrease in dielectric constant per unit strain is larger in the direction of the strain than normal to it. Indeed, the calculated birefringence is larger than that of quartz. They suggest that strain-tuning of this birefringence has attractive applications in polarization-based optical devices.

To appreciate the sensitivity of such structures to mechanical tuning, it is instructive to refer to some recent work on PMMA inverse opal PC structures that were fabricated using silica opal templates [39.129]. Under the application of uniaxial deformation of these PCs, the authors found a blue shift of the stop band in the transmission spectrum – the peak wavelength of the stop band shifted from about 545 nm in the undeformed material to about 470 nm under a stretch ratio of about 1.6.

Another practical approach that has been applied to physically tuning PC structures is that of thermal annealing. One such study showed how the optical properties of colloidal PCs consisting of silica spheres can be tuned through thermal treatment [39.130]. This was attributed to both structural and physiochemical modification of the material on annealing. A shift in the minimum transmission from about 1000 nm (unannealed) to about 850 nm (for annealing at about 1000 °C) was demonstrated, or about a maximum shift in Bragg wavelength of $\approx 11\%$.

A quite novel application of strain tuning was recently reported [39.131]. The authors studied 2-D PCs consisting of arrays of coupled optical microcavities fabricated from vertical-cavity surface-emitting laser structures. The influence of strain, as manifested by shifts in the positions of neighboring rows of microcavities with respect to each other, corresponded to alternating square or quasihexagonal shear-strain patterns. For strains below a critical threshold value, the lasing photon mode-locked to the corresponding mode in the unstrained PC. At the critical strain, switching occurred between the square and hexagonal lattice modes.

Finally, there has been a proposal for using strain in a PC to tune the splitting of a degenerate photon state within the PBG, suitable for implementing tunable PC circuits [39.132]. The principle applied is analogous to the static Jahn–Teller effect in solids. These authors showed that this effect is tunable by using the symmetry and magnitude of the lattice distortion. Using this

effect, the design of an optical valve that controls the resonant coupling of photon modes at the corner of a T-junction waveguide structure has been discussed.

Tuning PC Response Using Piezoelectric Effects

In this section we discuss using piezoelectric effects to physically change PC structures and hence tune them. A proposal was made for using the piezoelectric effect to distort the original symmetry of a two-dimensional PC from a regular hexagonal lattice to a quasihexagonal lattice under an applied electric field [39.133]. The original bands decomposed into several strained bands, dependent on the magnitude and direction of the applied field. In the proposed structures, the application of $\approx 3\%$ shear strain is shown to be suitable for shifting 73% of the original PBG, which they refer to as the tunable-band-gap regime. An advantage of such an approach is that such structures are suggested to be capable of operation at speeds approaching MHz. Another report [39.134] discusses the design and implementation of a tunable silicon-based PBG microcavity in an optical waveguide, where tuning is accomplished using the piezoelectric effect to strain the PC; this was carried out using integrated piezoelectric microactuators. These authors report on a 1.54 nm shift in the cavity resonance at 1.56 μm for an applied strain of 0.04%.

There have also been reports of coupling piezoelectric-based actuators to PCs. One such report [39.135] discusses a poly(2-methoxyethyl acrylate)-based PC composite directly coupled to a piezoelectric actuator to study static and dynamic stop-band tuning characteristics; the stop band of this device could be tuned through a 172 nm tuning range, and could be modulated at up to 200 Hz.

Tuning PC Response Using Micro-Electromechanical Systems (MEMS) Actuation

There have been a number of interesting developments in this field including PC-based air-bridge devices consisting of suspended 1-D PC mirrors separated by a Fabry–Pérot cavity (gap) [39.136]. When such structures are mechanically perturbed, there can be a substantial shift in the PBG due to strain. The authors discuss how a suite of spectrally tunable devices can be envisioned based on such structures – these include modulators, optical filters, optical switches, wavelength division multiplexing (WDM), optical logical circuits, variable attenuators, power splitters and isolators. Indeed, the generalization of these concepts beyond 1-D was discussed in a recent patent [39.137] that covers tunable PC structures. This report [39.137], as well as others [39.137], consider the extension of these ideas to form families of micromachined devices. These authors [39.138] modeled and implemented a set of micromachined vertical resonator structures for 1.55 μm filters consisting of two PC (distributed Bragg reflector, DBR) mirrors separated by either an air gap or semiconductor heterostructure. Electromechanical tuning was used to adjust the separation between the mirrors and hence fine-tune the transmission spectrum. The mirror structures were implemented using strong-index-contrast InP/air DBRs giving an index contrast of 2.17, and weak-index-contrast (0.5) silicon nitride/silicon dioxide DBRs. In the former case, a tuning range of over 8% of the absolute wavelength was achieved; varying the intermembrane voltage up to 5 V gave a tuning range of over 110 nm. Similar planar structures are discussed in other papers [39.139] where the mirrors are formed from two slabs of PC separated by an adjustable air gap [39.137]. These structures have been shown to be able to perform as either flat-top reflection or all-pass transmission filters, by varying the distance between the slabs, for normally incident light. Unlike all previously reported all-pass reflection filters, based on Gires–Tournois interferometers using multiple dielectric stacks, their structure generates an all-pass transmission spectrum, significantly simplifying signal extraction and optical alignment – also the spectral response is polarization-independent owing to the 90° rotational symmetry of their structure. Some interesting recent work includes the coupling of a single photon source (based on an InAs quantum dot) embedded in a PC, coupled to a microfibre [39.140]. By adjusting the coupling strength of microfibre to microcavity mechanically, the spectral response was shown to be tunable over a 1.5 nm bandwidth. Such work has applicability for on-demand single-photon sources, of great importance for quantum information processing.

39.4 Summary and Conclusions

This chapter discussed the fabrication and properties of PCs, with emphasis on developing tunable structures. New fabrication methodologies and tuning schemes offer a glimpse of the far-reaching prospects for developing photonic devices which can, in a discretionary fashion, control the propagation of modes of light in an analogous fashion to the way in which nanostructures have been harnessed to control electron-based phenom-

ena. Analogous to the evolution of electronic systems, one can anticipate a path toward development of compact active integrated photonic systems, as envisioned based on the technology outlined in this review.

40. Quantum Wells, Superlattices, and Band-Gap Engineering

Mark Fox, Radu Ispasoiu

This chapter reviews the principles of bandgap engineering and quantum confinement in semiconductors, with a particular emphasis on the optoelectronic properties of quantum wells. The chapter begins with a review of the fundamental principles of bandgap engineering and quantum confinement. It then describes the optical and electronic properties of semiconductor quantum wells and superlattices at a tutorial level, before describing the principal optoelectronic devices. The topics covered include edge-emitting lasers and light-emitting diodes (LEDs), resonant cavity LEDs and vertical-cavity surface-emitting lasers (VCSELs), quantum cascade lasers, quantum well solar cells, superlattice avalanche photodiodes, infrared detectors, and quantum well light modulators. The chapter concludes with a brief discussion of new research directions on quantum dot and nanowire structures.

The need for efficient light-emitting diodes (LEDs) and lasers operating over the whole of the visible spectrum and also the fiber optic windows at 1.3 and 1.55 μm drives research into new direct-gap semiconductors to act as the active materials. Since the emission wavelength of a semiconductor corresponds to its bandgap energy, the research focuses on engineering new materials that have their bandgaps at custom-designed energies. This science is called *bandgap engineering*.

In the early years of semiconductor optoelectronics, the bandgaps that could be achieved were largely determined by the physical properties of key III–V materials like GaAs and its alloys such as AlGaAs and InGaAs. Then in 1970 a major breakthrough occurred when *Esaki* and *Tsu* invented the semiconductor quantum well (QW) and superlattice (SL) [40.1]. They realized that developments in epitaxial crystal growth could open the door to new structures that exploit the principles of quantum confinement to engineer electronic states with custom-designed properties. They foresaw that these quantum-confined structures would be of interest both to research scientists who would be able to explore uncharted areas of fundamental physics and to engineers who would learn to use their unique properties for device applications. Their insight paved the way for a whole new breed of devices that are now routinely found in a host of everyday applications ranging from blu-ray players to traffic lights.

The emphasis of the chapter is on the optoelectronic properties of QW and SL structures. We begin by out-

S. Kasap, P. Capper (Eds.), *Springer Handbook of Electronic and Photonic Materials*, DOI 10.1007/978-3-319-48933-9_40

lining the basic principles of bandgap engineering and quantum confinement. We then discuss the electronic states in quantum-confined structures and the optical properties that follow from them. In Sects. 40.3–40.5, we explain the principles of the main optoelectronic devices that employ QWs and SLs, namely emitters, detectors, and modulators. Finally, we indicate a few interesting developments that involve semiconductor nanostructures with higher degrees of electronic confinement than QWs, namely nanowires and quantum dots (QDs). A number of texts cover these topics in more detail [40.2–5], and the interested reader is referred to these sources for a more comprehensive treatment. A description of the purely electronic properties of low-dimensional structures may be found in [40.6].

40.1 Principles of Bandgap Engineering and Quantum Confinement

40.1.1 Lattice Matching

The art of bandgap engineering relies heavily on developments in the science of crystal growth. The bulk crystals grown from the melt usually contain a large number of impurities and defects, and optoelectronic devices are therefore grown by epitaxial methods such as liquid phase epitaxy (LPE), molecular beam epitaxy (MBE), and metal-organic vapor phase epitaxy (MOVPE), which is also called metal-organic chemical vapor deposition (MOCVD) (Chap. 14). The basic principle of epitaxy is to grow thin layers of very high purity on top of a bulk crystal called the substrate. The system is said to be *lattice matched* when the lattice constants of the epitaxial layer and the substrate are identical. Lattice matching reduces the number of dislocations in the epitaxial layer, but it also imposes tight restrictions on the band gaps that can be engineered easily, because only a relatively small number of convenient substrate materials are available.

We can understand this point more clearly by referring to Fig. 40.1. This diagram plots the bandgap energy E_g of a number of important III–V semiconductors as a function of their lattice constant. The majority of optoelectronic devices for the red/near-infrared spectral regions are either grown on GaAs or InP substrates. The simplest case to consider is an epitaxial layer of GaAs grown on a GaAs substrate, which gives an emission wavelength of 873 nm (1.42 eV). This wavelength is perfectly acceptable for applications involving short-range transmission down optical fibers or for free-space infrared communication. However, for long distances we require emission at 1.3 or 1.55 μm, while for many other applications we require emission in the visible spectral region.

Let us first consider the preferred fiber-optic wavelengths of 1.3 and 1.55 μm. There are no binary semiconductors with bandgaps at these wavelengths, and so we have to use alloys to tune the bandgap by varying the composition (Chap. 30). A typical example is the ternary alloy $Ga_xIn_{1-x}As$, which is lattice matched to InP when $x = 47\%$, giving a bandgap of 0.75 eV (1.65 μm). $Ga_{0.47}In_{0.53}As$ photodiodes grown on InP substrates make excellent detectors for 1.3 or 1.55 μm radiation, but to make an emitter at this wavelength, we have to increase the band gap while maintaining the lattice-matching condition. This is achieved by incorporating a fourth element into the alloy – typically Al or P – which gives an extra design parameter that permits bandgap tuning while maintaining lattice matching. Thus, the quaternary alloys $Ga_{0.27}In_{0.73}As_{0.58}P_{0.42}$ and $Ga_{0.40}In_{0.60}As_{0.85}P_{0.18}$ give emission at 1.3 and 1.55 μm, respectively, and are both lattice matched to InP substrates.

Turning now to the visible spectral region, it is a convenient coincidence that the lattice constants of GaAs and AlAs are almost identical. This means that we can grow relatively thick layers of $Al_xGa_{1-x}As$ on GaAs substrates without introducing dislocations and other defects. The bandgap of $Al_xGa_{1-x}As$ at room temperature varies approximately quadratically with x

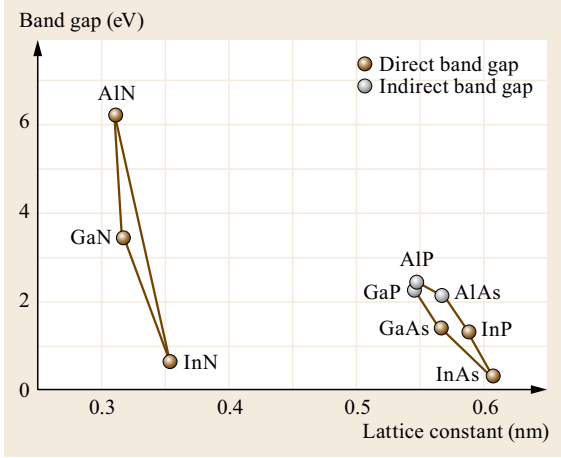

Fig. 40.1 Room-temperature bandgap of a number of important optoelectronic III–V materials versus their lattice constant

according to

$$E_g(x) = (1.42 + 1.087x + 0.438x^2)\,\text{eV}\,, \qquad (40.1)$$

but unfortunately the gap becomes indirect for $x > 43\%$. We can therefore engineer direct bandgaps from 1.42 to 1.97 eV, giving emission from 873 nm in the near infrared to 630 nm in the red spectral range. Much work has been done on quaternary alloys such as AlGaInP (Chap. 30), but it has not been possible to make blue- and green-emitting devices based on GaAs substrates to date, due to the tendency for arsenic and phosphorous compounds to become indirect as the bandgap increases.

The approach for the blue/green end of the spectrum preferred at present is to use nitride-based compounds (Chap. 31). Early work on nitrides established that their large direct gaps made them highly promising candidates for use as blue/green emitters [40.7]. However, it was not until the 1990s that this potential was fully realized. The rapid progress followed two key developments, namely the activation of the p-type dopants and the successful growth of strained $In_xGa_{1-x}N$ QWs that did not satisfy the lattice-matching condition [40.8]. The second point goes against the conventional wisdom of bandgap engineering and highlights the extra degrees of freedom afforded by quantum-confined structures, as will now be discussed.

40.1.2 Quantum-Confined Structures

A quantum-confined structure is one in which the motion of the electrons (and/or holes) is confined in one or more directions by potential barriers. The general scheme for classifying quantum-confined structures is given in Table 40.1. In this chapter, we are concerned primarily with *QWs*, although we will briefly refer to *quantum wires* and *quantum dots* in Sect. 40.6. Quantum size effects become important when the thickness of the layer becomes comparable with the de Broglie wavelength of the electrons or holes. If we consider the free thermal motion of a particle of mass m in the z-direction, the de Broglie wavelength at a temperature T is approximately given by

$$\lambda_{\text{deB}} \sim \frac{h}{\sqrt{mk_BT}}\,. \qquad (40.2)$$

For an electron in GaAs with an effective mass of $0.067\,m_0$, we find $\lambda_{\text{deB}} \approx 42$ nm at 300 K. This implies that we need structures of thickness ≈ 10 nm in order to observe quantum confinement effects at room temperature. Layers of this thickness are routinely grown by the MBE or MOVPE techniques described in Chap. 14.

Figure 40.2 shows a schematic diagram of a GaAs/AlGaAs QW. The quantum confinement is provided by the discontinuity in the bandgap at the interfaces, which leads to a spatial variation of the conduction and valence bands as shown in the lower half of the figure. The Al concentration is typically chosen to be around 30%, which gives a bandgap discontinuity of 0.36 eV according to (40.1). This splits the conduction and valence bands roughly at 2 : 1, so that electrons see a confining barrier of 0.24 eV and the holes see 0.12 eV.

If the GaAs layers are thin enough according to the criterion given above, the motion of the electrons and holes will be quantized in the growth (z) direction, giving rise to a series of discrete energy levels, as indicated by the dashed lines inside the QW in Fig. 40.2. The motion in the other two directions (i. e., the xy plane) is still free, and so we have quasi two-dimensional () behavior.

Table 40.1 Classification of quantum-confined structures. In the case of QWs, the confinement direction is usually taken as the z-axis

Structure	Confined directions	Free directions (dimensionality)
Quantum well	1(z)	2 (x,y)
Quantum wire	2	1
Quantum dot (or box)	3	none

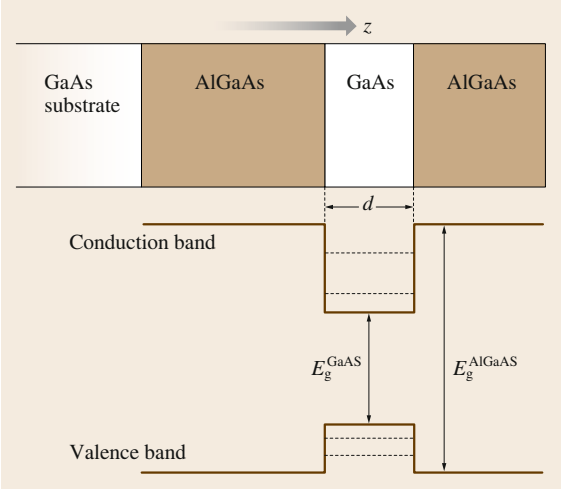

Fig. 40.2 Schematic diagram of the growth layers and resulting band diagram for a GaAs/AlGaAs QW of thickness d. The quantized levels in the QW are indicated by the *dashed lines*. Note that in real structures a GaAs buffer layer is usually grown immediately above the GaAs substrate

The quantization of the motion in the z-direction has three main consequences. Firstly, the quantization energy shifts the effective band edge to higher energy, which provides an extra degree of freedom in the art of bandgap engineering. Secondly, the confinement keeps the electrons and holes closer together and hence increases the radiative recombination probability. Finally, the density of states becomes independent of energy, in contrast to 3-D materials, where the density of states is proportional to $E^{1/2}$. Many of the useful properties of the QWs follow from these three properties.

The arrangement of the bands as shown in Fig. 40.2 in which both the electrons and holes are confined in the QW is called *type I band alignment*. Other types of band alignments are possible in which only one of the carrier types is confined within a specific region (*type II band alignment*). Furthermore, the flexibility of the MBE and MOVPE growth techniques easily allows the growth of SL structures containing many repeated QWs with thin barriers separating them, as shown in Fig. 40.3. SLs behave like artificial one-dimensional periodic crystals, in which the periodicity is designed into the structure by the repetition of the QWs. The electronic states of SLs form delocalized *minibands* as the wave functions in neighboring wells couple together through the thin barrier that separates them. Structures containing a smaller number of repeated wells or with thick barriers that prevent coupling between adjacent wells are simply called *multiple quantum well* (MQW) structures.

In the next section, we shall describe in more detail the electronic properties of QWs and SLs. Before doing so, it is worth highlighting two practical considerations that are important additional factors that contribute to their usefulness. The first is that the bandgap tunability can be achieved without using alloys as the active material, which is desirable because alloys inevitably contain more defects than simple compounds like GaAs. The second factor is that the QWs can be grown as strained layers on top of a lattice with a different unit cell size. A typical example is the $In_xGa_{1-x}N$/GaN QWs mentioned above. These layers do not satisfy the lattice-matching condition, but as long as the total $In_xGa_{1-x}N$ thickness is less than the critical value, there is an energy barrier to the formation of dislocations (Sect. 40.2.1, *Strained Quantum Wells*). In practice, this allows considerable extra flexibility in the bandgap engineering that can be achieved.

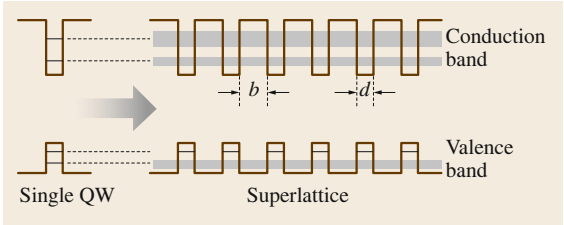

Fig. 40.3 Schematic diagram of an SL, showing the formation of minbands from the energy levels of the corresponding single QW. The structure forms an artificial one-dimensional crystal with period $(d + b)$, where d and b represent the thickness of the QW and barrier regions respectively. The width of the minibands depends on the strength of the coupling through the barriers. It is frequently the case that the lowest hole states do not couple strongly, and hence remain localized within their respective wells, as shown in the figure

40.2 Optoelectronic Properties of Quantum-Confined Structures

40.2.1 Electronic States in Quantum Wells and Superlattices

Quantum Wells

The electronic states of QWs can be understood by solving the Schrödinger equation for the electrons and holes in the potential wells created by the band discontinuities. The simplest approach is the infinite well model shown in Fig. 40.4a. The Schrödinger equation in the well is

$$-\frac{\hbar^2}{2m_w^*}\frac{d^2\psi(z)}{dz^2} = E\psi(z)\,, \tag{40.3}$$

where m_w^* is the effective mass in the well and z is the growth direction. Since the potential barriers are infinite, there can be no penetration into the barriers, and we must therefore have $\psi(z) = 0$ at the interfaces. If we choose our origin such that the QW runs from $z = 0$ to $z = d$, d being the width of the well, the normalized wave functions take the form [40.9]

$$\psi_n(z) = \sqrt{\frac{2}{d}}\sin k_n z\,, \tag{40.4}$$

where $k_n = (n\pi/d)$ and the quantum number n is an integer (≥ 1). The energy E_n is given by

$$E_n = \frac{\hbar^2 k_n^2}{2m_w^*} = \frac{\hbar^2}{2m_w^*}\left(\frac{n\pi}{d}\right)^2\,. \tag{40.5}$$

The wave functions of the $n = 1$ and $n = 2$ levels are sketched in Fig. 40.4a.

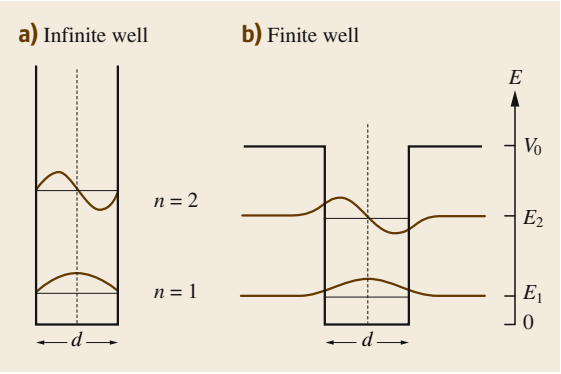

Fig. 40.4a,b Confined states in a QW of width d. **(a)** A perfect QW with infinite barriers. **(b)** A finite well with barriers of height V_0. The wave functions for the $n = 1$ and $n = 2$ levels are sketched for both types of well

Although the infinite well model is very simplified, it nonetheless provides a good starting point for understanding the general effects of quantum confinement. Equation (40.5) shows us that the energy is inversely proportional to d^2, implying that narrow wells have larger confinement energies. Furthermore, the confinement energy is inversely proportional to the effective mass, which means that lighter particles experience larger effects. This also means that the heavy- and light-hole states have different energies, in contrast to bulk semiconductors in which the two types of holes are degenerate at the top of the valence band.

Now, let us consider the more realistic finite well model as shown in Fig. 40.4b. The Schrödinger equation in the well is unchanged, but in the barrier regions we now have

$$-\frac{\hbar^2}{2m_b^*}\frac{d^2\psi(z)}{dz^2} + V_0\psi(z) = E\psi(z)\,, \tag{40.6}$$

where V_0 is the potential barrier and m_b^* is the effective mass in the barrier. The boundary conditions require that the wave function and particle flux $(1/m^*)d\psi/dz$ must be continuous at the interface. This gives a series of even and odd parity solutions that satisfy

$$\tan\left(\frac{kd}{2}\right) = \frac{m_w^*\kappa}{m_b^* k} \tag{40.7a}$$

and

$$\tan\left(\frac{kd}{2}\right) = -\frac{m_b^* k}{m_w^*\kappa} \tag{40.7b}$$

respectively. k is the wave vector in the well, given by

$$\frac{\hbar^2 k^2}{2m_w^*} = E_n\,, \tag{40.8}$$

while κ is the exponential decay constant in the barrier given by

$$\frac{\hbar^2\kappa^2}{2m_b^*} = V_0 - E_n\,. \tag{40.9}$$

Solutions to (40.7a) and (40.7b) are easily found by simple numerical techniques [40.9, 10]. As with the infinite well, the eigenstates are labeled by the quantum number n and have parities of $(-1)^{n+1}$ with respect to the axis of symmetry about the center of the well. The wave functions are approximately sinusoidal inside the well, but decay exponentially in the barriers, as illustrated in Fig. 40.4b. The eigenenergies are smaller than those of the infinite well due to the reduced confinement of the wave functions that follows from their spreading into the barriers. There are only a limited number of solutions, but there is always at least one, no matter how small V_0 might be.

As an example, we consider a typical $GaAs/Al_{0.3}Ga_{0.7}As$ QW with $d = 10\,nm$. The confinement energy is 245 meV for the electrons and 125 meV for the holes. The infinite well model predicts $E_1 = 56\,meV$ and $E_2 = 224\,meV$ for the electrons, whereas (40.7a) and (40.7b) give $E_1 = 30\,meV$ and $E_2 = 113\,meV$. For the heavy (light) holes, the infinite well model predicts 11 meV (40 meV) and 44 meV (160 meV) for the first two bound states, instead of the more accurate values of 7 meV (21 meV) and 29 meV (78 meV) calculated from the finite well model. Note that the separation of the electron levels is greater than k_BT at 300 K, so that that the quantization effects will be readily observable at room temperature.

Strained Quantum Wells

Even more degrees of freedom for tailoring the electronic states can be achieved by epitaxially stacking semiconductor layers with different lattice constants to form *strained QWs*. Examples include $In_xGa_{1-x}As$ on GaAs, $In_xGa_{1-x}N$ on GaN, and $Si_{1-x}Ge_x$ on Si. Large biaxial strain develops within the xy plane of a QW grown on a substrate with a different lattice constant. In order to avoid the build-up of misfit dislocations at the interfaces, the strained layers need to be thinner than a certain critical dimension. For example, a defect-free strained $In_xGa_{1-x}As$-on-GaAs layer requires a thickness less than around 10 nm when $x = 0.2$. Since the band structure is related to the lattice constant, the strain alters several key band parameters. It is due to some of these effects that strained QW structures have become widely exploited in optoelectronic devices.

The most significant effect of the strain in GaAs-based materials is to alter the bandgap and remove the valence band degeneracy near the Γ valley. The split-

ting of the valence band is a consequence of the lattice distortion that reduces the crystal symmetry from cubic to tetragonal [40.11]. There are essentially two types of strain. Compressive strain occurs when the active layer has a larger lattice constant than the substrate, for example, in $In_xGa_{1-x}As$ on GaAs. In this case, the bandgap increases and the effective mass of the highest hole band decreases, while that of the next valence band increases. The opposite case is that of tensile strain, which occurs when the active layer has a smaller lattice constant than the substrate, such as $Si_{1-x}Ge_x$ on Si. The ordering of the valence bands is opposite to the case of compressive strain, and the overall bandgap is reduced.

Superlattices

The analytical derivation of the allowed energy values in an SL is similar to that for a single QW, with the appropriate change of the boundary conditions imposed by the SL periodicity. The mathematical description of an SL is similar to a one-dimensional crystal lattice, which allows us to borrow the formalism of the band theory of solids, including the well-known Kronig–Penney model [40.9]. Within this model, the electron envelope wave function $\psi(z)$ can be expressed as the superposition of Bloch waves propagating along the z-axis. For an SL with a barrier height V_0, the allowed energy is calculated numerically as a solution of the transcendental equation involving the Bloch wave vector

$$\cos(ka) = \cos(kd)\cos(\kappa' b) - \frac{k^2+\kappa'^2}{2k\kappa'}\sin(kd)\sin(\kappa' b)\,, \quad E > V_0\,, \tag{40.10a}$$

$$\cos(ka) = \cos(kd)\cos(\kappa b) - \frac{k^2-\kappa^2}{2k\kappa}\sin(kd)\sin(\kappa b)\,, \quad E < V_0\,, \tag{40.10b}$$

where $a \equiv (b+d)$ is the period, and k and κ are given by (40.8) and (40.9), respectively. The decay constant κ' is given by

$$E - V_0 = \frac{\hbar^2\kappa'^2}{2m_b^*}\,. \tag{40.11}$$

The electronic states in SLs can be understood in a more qualitative way by referring to Fig. 40.3 and making use of the analogy with the tight-binding model of band formation in solids. Isolated atoms have discrete energy levels that are localized on the individual atom sites. When the atoms are brought close together, the energy levels broaden into bands, and the overlapping wave functions develop into extended states. In the same way, repeated QW structures with large values of the barrier thickness b (i. e., MQWs) have discrete levels with wave functions localized within the wells. As the barrier thickness is reduced, the wave functions of adjacent wells begin to overlap and the discrete levels broaden into *minibands*. The wave functions in the minibands are delocalized throughout the whole SL. The width of the miniband depends on the cross-well coupling, which is determined by the barrier thickness and the decay constant κ (40.9). In general, the higher lying states give rise to broader minibands because κ decreases with E_n. Also, the heavy-hole minibands are narrower than the electron minibands, because the cross-well coupling decreases with increasing effective mass.

40.2.2 Interband Optical Transitions

Absorption

The optical transitions in QWs take place between electronic states that are confined in the z-direction but free in the xy plane. The transition rate can be calculated from Fermi's golden rule, which states that the probability for optical transitions from the initial state $|i\rangle$ at energy E_i to the final state $|f\rangle$ at energy E_f is given by

$$W(i \to f) = \frac{2\pi}{\hbar}|\langle f|e\boldsymbol{r}\cdot\mathbf{E}|i\rangle|^2 g(\hbar\omega)\,, \tag{40.12}$$

where $e\boldsymbol{r}$ is the electric dipole of the electron, $\mathbf{E}$ is the electric field of the light wave, and $g(\hbar\omega)$ is the joint density of states at photon energy $\hbar\omega$. Conservation of energy requires that $E_f = (E_i + \hbar\omega)$ for absorption, and $E_f = (E_i - \hbar\omega)$ for emission.

Let us consider a transition from a confined hole state in the valence band with the quantum number n to a confined electron state in the conduction band with the quantum number n'. We apply Bloch's theorem to write the wave functions in the following form

$$|i\rangle = u_v(\boldsymbol{r})\exp(i\boldsymbol{k}_{xy}\cdot r_{xy})\psi_{hn}(z)$$
$$|f\rangle = u_c(\boldsymbol{r})\exp(i\boldsymbol{k}_{xy}\cdot r_{xy})\psi_{en'}(z)\,, \tag{40.13}$$

where $u_v(\boldsymbol{r})$ and $u_c(\boldsymbol{r})$ are the envelope functions for the valence and conduction bands, respectively, $\boldsymbol{k}_{xy}$ is the in-plane wave vector for the free motion in the xy plane, r_{xy} being the xy component of the position vector, and $\psi_{hn}(z)$ and $\psi_{en'}(z)$ are the wave functions for the confined hole and electron states in the z-direction. The photon wave vector is very small, and so conservation of momentum requires that the in-plane wave vectors of the electron and hole are the same.

On inserting these wave functions into (40.12), we find that the transition rate is proportional to both the

square of the overlap of the wave functions and the joint density of states [40.12]

$$W \propto |\langle \psi_{en'}(z)|\psi_{hn}(z)\rangle|^2 g(\hbar\omega)\,. \tag{40.14}$$

The wave functions of infinite wells are orthogonal unless $n = n'$, which gives a selection rule of $\Delta n = 0$. For finite wells, the $\Delta n = 0$ selection rule is only approximately obeyed, although transitions between states of different parity (i. e., Δn odd) are strictly forbidden. The joint density of states is independent of energy due to the quasi-2-D nature of the QW.

Figure 40.5a illustrates the first two strong transitions in a typical QW. These are the $\Delta n = 0$ transitions between the first and second hole and electron levels. The threshold energy for these transitions is equal to

$$\hbar\omega = E_g + E_{hn} + E_{en}\,. \tag{40.15}$$

The lowest value is thus equal to $(E_g + E_{h1} + E_{e1})$, which shows that the optical bandgap is shifted by the sum of the electron and hole confinement energies. Once the photon energy exceeds the threshold set by (40.15), a continuous band of absorption occurs with the absorption coefficient independent of energy due to the constant 2-D density of states of the QW. The difference between the absorption of an ideal QW with infinite barriers and the equivalent bulk semiconductor is illustrated in Fig. 40.5b. In the QW, we find a series of steps with constant absorption coefficients, whereas in the bulk the absorption varies as $(\hbar\omega - E_g)^{1/2}$ for $\hbar\omega > E_g$. Thus, the transition from 3-D to 2-D alters the shape of the absorption curve, and also causes an effective shift in the bandgap by $(E_{h1} + E_{e1})$.

Up to this point, we have neglected the Coulomb interaction between the electrons and holes that are involved in the transition. This attraction leads to the formation of bound electron–hole pairs called excitons. The exciton states of a QW can be modeled as 2-D hydrogen atoms in a material with a relative dielectric constant ε_r. In this case, the binding energy E^X is given by [40.13]

$$E^x(\nu) = \frac{\mu}{m_0}\frac{1}{\varepsilon_r^2}\frac{1}{\left(\nu - \frac{1}{2}\right)^2}R_H\,, \tag{40.16}$$

where ν is an integer ≥ 1, m_0 is the electron mass, μ is the reduced mass of the electron–hole pair, and R_H is the Rydberg constant for hydrogen (13.6 eV). This contrasts with the standard formula for 3-D semiconductors in which E^X varies as $1/\nu^2$ rather than $1/(\nu - 1/2)^2$, and implies that the binding energy of the ground-state exciton is four times larger in 2-D than 3-D. This allows excitonic effects to be observed at room temperature in QWs, whereas they are only usually observed at low temperatures in bulk semiconductors.

Figure 40.6 compares the band edge absorption of a GaAs MQW sample with that of bulk GaAs at room temperature [40.14]. The MQW sample contained 77 GaAs QWs of thickness 10 nm with thick $Al_{0.28}Ga_{0.72}As$ barriers separating them. The shift of the band edge of the MQW to higher energy is clearly observed, together with the series of steps due to each $\Delta n = 0$ transition. The sharp lines are due to excitons,

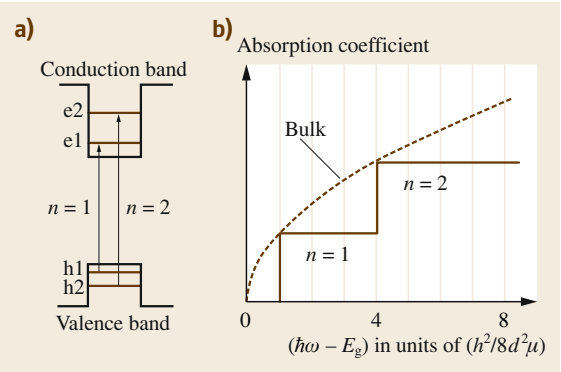

Fig. 40.5a,b Interband optical transitions between confined states in a QW. **(a)** Schematic diagram showing the $\Delta n = 0$ transitions between the $n = 1$ and $n = 2$ subbands. **(b)** Absorption spectrum for an infinite QW of thickness d with a reduced electron–hole mass μ in the absence of excitonic effects. The absorption spectrum of the equivalent bulk semiconductor in shown by the *dashed line* for comparison

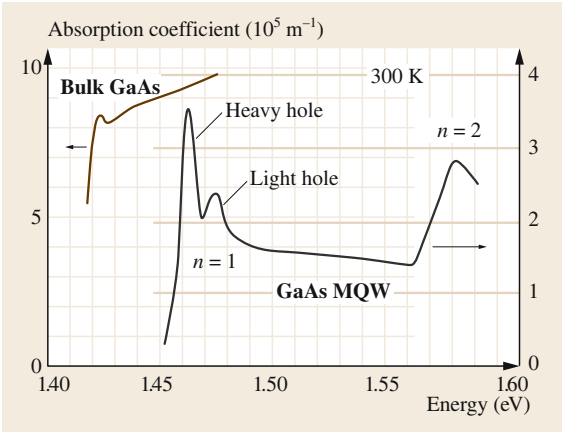

Fig. 40.6 Absorption spectrum of a 77-period GaAs/$Al_{0.28}Ga_{0.72}As$ MQW structure with 10 nm QWs at room temperature. The absorption spectrum of bulk GaAs is included for comparison. (After [40.14], with permission from AIP)

which occur at energies given by

$$\hbar\omega = E_g + E_{hn} + E_{en} - E^X \,. \tag{40.17}$$

Equation (40.16) predicts that E^X should be around 17 meV for the ground-state exciton of an ideal GaAs QW, compared to 4.2 meV for the bulk. The actual QW exciton binding energies are somewhat smaller due to the tunneling of the electrons and holes into the barriers, with typical values of around 10 meV. However, this is still substantially larger than the bulk value and explains why the exciton lines are so much better resolved for the QW than the bulk. The absorption spectrum of the QW above the exciton lines is approximately flat due to the constant density of states in 2-D, which contrasts with the rising absorption of the bulk due to the parabolic 3-D density of states. Separate transitions are observed for the heavy and light holes. This follows from their different effective masses, and can also be viewed as a consequence of the lower symmetry of the QW compared to the bulk.

Emission

Emissive transitions occur when electrons excited in the conduction band drop down to the valence band, and recombine with holes. The optical intensity $I(\hbar\omega)$ is proportional to the transition rate given by (40.12) multiplied by the probability that the initial state is occupied and the final state is empty

$$I(\hbar\omega) \propto W(\mathrm{c} \rightarrow \mathrm{v}) f_c (1 - f_v) \,, \tag{40.18}$$

where f_c and f_v are the Fermi–Dirac distribution functions in the conduction and valence bands respectively. In thermal equilibrium, the occupancy of the states is largest at the bottom of the bands and decays exponentially at higher energies. Hence, the luminescence spectrum of a typical GaAs QW at room temperature consists of a peak of width $\approx k_B T$ at the effective bandgap of $(E_g + E_{hh1} + E_{e1})$. At lower temperatures, the spectral width is affected by inhomogeneous broadening due to unavoidable fluctuations in the well thickness. Furthermore, in QWs employing alloy semiconductors, the microscopic fluctuations in the composition can lead to additional inhomogeneous broadening. This is particularly true of InGaN/GaN QWs, where indium compositional fluctuations produce substantial inhomogeneous broadening even at room temperature.

The intensity of the luminescence peak in QWs is usually much larger than that of bulk materials because the electron–hole overlap is increased by the confinement. This leads to faster radiative recombination, which then wins out over competing nonradiative decay mechanisms and leads to stronger emission. This enhanced emission intensity is one of the main reasons why QWs are now so widely used in diode lasers and LEDs.

40.2.3 The Quantum-Confined Stark Effect

The *quantum-confined Stark effect* (QCSE) describes the response of the confined electron and hole states in QWs to a strong DC electric field applied in the growth (z) direction. The field is usually applied by growing the QWs inside a p–n junction, and then applying reverse bias to the diode. The magnitude of the electric field F is given by

$$F = \frac{V^{\text{built-in}} - V^{\text{bias}}}{L_i} \,, \tag{40.19}$$

where $V^{\text{built-in}}$ is the built-in voltage of the diode, V^{bias} is the bias voltage, and L_i is the total thickness of the intrinsic region. $V^{\text{built-in}}$ is approximately equal to the bandgap voltage of the doped regions (≈ 1.5 V for a GaAs diode).

Figure 40.7 gives a schematic band diagram of a QW with a strong DC electric field applied. The field tilts the potential and distorts the wave functions as the electrons tend to move toward the anode and the holes toward the cathode. This has two important consequences for the optical properties. Firstly, the lowest transition shifts to lower energies due to the electrostatic interaction between the electric dipole induced by the field and the field itself. At low fields, the dipole is proportional to F, and the red shift is thus proportional to F^2 (the quadratic Stark effect). At higher fields, the dipole saturates at a value ultimately limited by the size of the well, and the Stark shift is linear with F. Secondly, the parity selection rule no longer applies due to the breaking of the inversion symmetry about the center of the well. This means that *forbidden* optical transitions with Δn being equal to an odd number become allowed. At the same time, the $\Delta n = 0$ transitions gradually weaken with increasing field as the distortion to the wave functions reduces the electron–hole overlap.

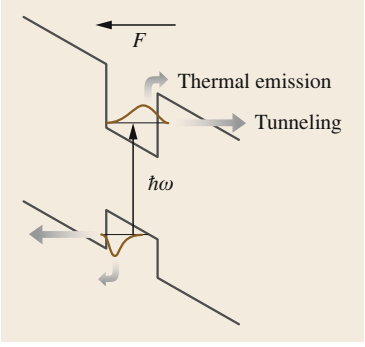

Fig. 40.7 Schematic band diagram and wave functions for a QW in a DC electric field F

Figure 40.8 shows the normalized room temperature photocurrent spectra of a GaAs/$Al_{0.3}Ga_{0.7}As$ MQW p–i–n diode containing 9.0 nm QWs at 0 and −10 V applied bias. These two bias values correspond to field strengths of around 15 and 115 kVcm^{-1}, respectively. The photocurrent spectrum closely resembles the absorption spectrum, due to the field-induced escape of the photo-excited carriers in the QWs into the external circuit (Sect. 40.2.5). The figure clearly shows the Stark shift of the absorption edge at the higher field strength, with a red shift of around 20 meV (≈ 12 nm) at the −10 V bias for the hh1 → e1 transition. The intensity of the line weakens somewhat due to the reduction in the electron–hole overlap, and there is lifetime broadening caused by the field-assisted tunneling. Several parity-forbidden transitions are clearly observed. The two most obvious ones are identified with arrows, and correspond to the hh2 → e1 and hh1 → e2 transitions, respectively.

A striking feature in Fig. 40.8 is that the exciton lines are still resolved even at very high field strengths. In bulk GaAs, the excitons ionize at around 5 kVcm^{-1} [40.12], but in QWs the barriers inhibit the field ionization, and excitonic features can be preserved even up to ≈ 300 kVcm^{-1} [40.15]. The ability to control the absorption spectrum by the QCSE is the principle behind a number of important modulator devices, as will be discussed in Sect. 40.5.

In the case of an SL, such as that illustrated in Fig. 40.3, a strong perpendicular electric field can break the minibands into discrete energy levels local to each QW, due to the bandgap tilting effect represented in Fig. 40.7. The possibility of using an electric field to modify the minibands of an SL is yet another remarkable ability of bandgap engineering to achieve control over the electronic properties by directly using fundamental principles of quantum mechanics.

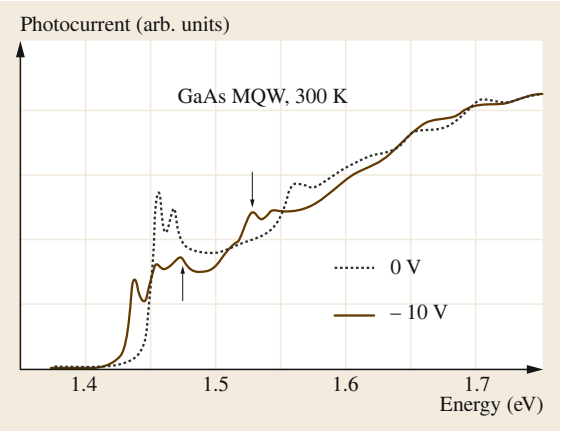

Fig. 40.8 Room-temperature photocurrent spectra for a GaAs/$Al_{0.3}Ga_{0.7}As$ MQW p–i–n diode with a 1 µm-thick i-region at the zero bias and −10 V. The QW thickness was 9.0 nm. The *arrows* identify transitions that are forbidden at zero field. (Adapted from [40.15], © 1991 IEEE)

40.2.4 Intersubband Transitions

The engineered band structure of QWs leads to the possibility of *intersubband* (ISB) *transitions* which take place between confined states within the conduction or valence bands, as illustrated schematically in Fig. 40.9. The transitions typically occur in the infrared spectral region. For example, the $e1 \leftrightarrow e2$ ISB transition in a 10 nm GaAs/AlGaAs QW occurs around 15 µm. For ISB absorption transitions, we must first dope the conduction band so that there is a large population of electrons in the e1 level as shown in Fig. 40.9a. This is typically achieved by n-type doping of the barriers, which produces a large electron density as the extrinsic electrons drop from the barriers to the confined states in the QW. Undoped wells are used for ISB emission transitions, and electrons must first be injected into excited QW states, as shown in Fig. 40.9b.

The basic properties of ISB transitions can be understood by the extension of the principles outlined in Sect. 40.2.2. The main difference is that the envelope functions for the initial and final states are the same, since both states lie in the same band. The transition rate for a conduction band ISB transition then turns out to be given by

$$W^{\mathrm{ISB}} \propto |\langle \psi_{en'}(z)|z|\psi_{en}(z)\rangle|^2 g(\hbar\omega)\,, \qquad (40.20)$$

where n and n' are the quantum numbers for the initial and final confined levels. The z operator within the Dirac bracket arises from the electric–dipole interaction and indicates that the electric field of the light wave must be parallel to the growth direction. Furthermore, the odd parity of the z operator implies that the wave functions must have different parities, and hence that Δn must be an odd number. The use of ISB transitions in infrared emitters and detectors will be discussed in Sects. 40.3.2 and 40.4.3.

40.2.5 Vertical Transport

Quantum Wells

Vertical transport refers to the processes by which electrons and holes move in the growth direction. Issues relating to vertical transport are important for the efficiency and frequency response of most QW optoelectronic devices. The transport is generally classified as either *bipolar*, when both electrons and holes are involved, or *unipolar*, when only one type of carrier (usually electrons) is involved. In this section, we will concentrate primarily on bipolar transport in QW detectors and QCSE modulators. Bipolar transport in light-emitting devices is discussed in Sects. 40.2.6 and 40.3.1, while unipolar transport in quantum cascade (QC) lasers and avalanche photodiodes (APDs) is discussed in Sects 40.3.2 and 40.4.3.

In QW detectors and QCSE modulators, the diodes are operated in the reverse bias. This produces a strong DC electric field and tilts the bands as shown in Fig. 40.7. Electrons and holes generated in the QWs by absorption of photons can escape into the external circuit by the tunneling and/or thermal emission, as illustrated schematically in Fig. 40.7.

The physics of tunneling in QWs is essentially the same as that of the α-decay in nuclear physics. The confined particle oscillates within the well and attempts to escape every time it hits the barrier. The escape rate is proportional to the attempt frequency ν_0 and the transmission probability of the barrier. For the simplest case of a rectangular barrier of thickness b, the escape time τ_T is given by

$$\frac{1}{\tau_T} = \nu_0 \exp(-2\kappa b) \,, \tag{40.21}$$

where κ is the tunneling decay constant given by (40.9). The factor of 2 in the exponential arises from the dependence of the transmission probability on $|\psi(z)|^2$. The situation in a biased QW is more complicated due to the nonrectangular shape of the barriers. However, Equation (40.21) allows the basic trends to be understood. To obtain fast tunneling, we need thin barriers and small κ. The second requirement is achieved by keeping m_b^* as small as possible and by working with a small confining potential V_0. The tunneling rate increases with increasing field, because the average barrier height decreases.

The thermal emission of electrons over a confining potential is an old problem that was originally applied to the heated cathodes in vacuum tubes. It has been shown that the thermal current fits well to the classical Richardson formula

$$J_E \propto T^{\frac{1}{2}} \exp\left(-\frac{e\Phi}{k_B T}\right) , \tag{40.22}$$

with the work function Φ replaced by $(V(F) - E_n)$, $V(F)$ being the height of the barrier that must be overcome at field strength F [40.16]. The emission rate is dominated by the Boltzmann factor that represents the probability that the carriers have enough thermal kinetic energy to escape over the top of the barrier. At low fields, $V(F) \approx (V_0 - E_n)$, but as the field increases, $V(F)$ decreases as the barriers tilt over. Hence, the emission rate (like the tunneling rate) increases with increasing field. The only material-dependent parameter that enters the Boltzmann factor is the barrier height. Since this is insensitive both to the effective masses and to the barrier thickness, the thermal emission rate can dominate over the tunneling rate in some conditions, especially at room temperature in samples with thick barriers. For example, the fastest escape mechanism in GaAs/$Al_{0.3}Ga_{0.7}As$ QWs at room temperature can be the thermal emission of holes, which have a much smaller barrier to overcome than the electrons [40.17].

Superlattices

The artificial periodicity of SL structures gives rise to additional vertical transport effects related to the phenomenon of Bloch oscillations. It is well known that an electron in a periodic structure is expected to oscillate when a DC electric field is applied. This effect has never been observed in natural crystals because the oscillation period (equal to h/eFa, where a is the unit cell size) is much longer than the scattering times of the electrons. In an SL, by contrast, the unit cell size is equal to $(d + b)$ (Fig. 40.3) and the oscillation period can be made much shorter. This allows the electron to perform several oscillations before being scattered. The oscillatory motion of the electrons in an SL was first observed by two groups in 1992 [40.18, 19]. The following year, another group directly detected the radiation emitted by the oscillating electron wave packet [40.20]. The subject has since developed greatly, and a comprehensive review can be found in [40.21].

40.2.6 Carrier Capture and Relaxation

In a QW light-emitting device, the emission occurs after carriers injected from the contacts are transported to the active region and then captured by the QWs. The capture and subsequent relaxation of the carriers is thus of crucial importance. Let us consider the band-edge profile of a typical QW diode laser active region, as illustrated in Fig. 40.10. The active region is embedded between larger bandgap cladding layers designed to prevent thermally assisted carrier leakage outside the active region. Electrons and holes are injected from the n- and p-doped cladding layers under forward bias and

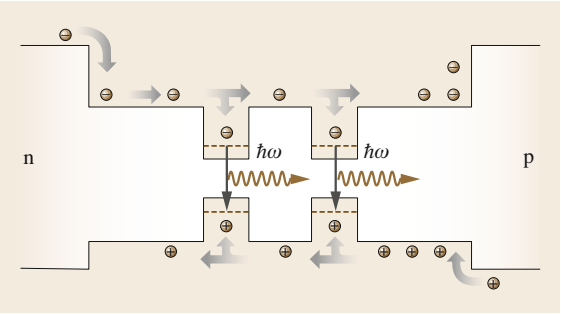

Fig. 40.10 Schematic representation of the drift of injected carriers and their subsequent capture by QWs. Light emission occurs when electrons and holes are captured in the same QW and then recombine with each other

light emission follows after four distinct processes have taken place:

1. Relaxation of carriers from the cladding layers to the confinement barriers (CB)
2. Carrier transport across the CB layers, by diffusion and drift
3. Carrier capture into the QWs
4. Carrier relaxation to the fundamental confined levels.

The carrier relaxation to the CB layers occurs mainly by longitudinal optical (LO) phonon emission. The CB layer transport is governed by a classical electron fluid model. The holes are heavier and less mobile than the electrons, and hence the ambipolar transport is dominated by the holes. Carrier nonuniformities, such as carrier pile up at the p-side CB region due to the lower mobility of the holes, are taken into account in the design of the barrier layers. The carrier capture in the QWs is governed by the phonon-scattering-limited carrier mean free path. It is observed experimentally that the capture time oscillates with the QW width. Detailed modeling reveals that this is related to a resonance between the LO phonon energy and the energy difference between the barrier states and the confined states within the well [40.22]. As another design guideline, the QW widths must be larger or at least equal to the phonon-scattering-limited carrier mean free path at the operating temperature in order to speed up the carrier capture. Finally, the relaxation of carriers to the lowest subband occurs on a subpicosecond time scale if the intersubband energy separation is larger than the LO phonon energy. Carrier–carrier scattering can also contribute to an ultrafast thermalization of carriers, on a femtosecond time scale at the high carrier densities present inside laser diodes. Many of these processes have been studied in detail by ultrafast laser spectroscopy [40.23].

Carrier capture and escape are complementary vertical transport mechanisms in MQW structures. In the design of vertical transport-based MQW devices, one process must often be sped up at the expense of making the other as slow as possible. For example, in order to enhance the performance of QW laser diodes, the carrier confinement capability of the MQW active region must be optimized in terms of minimizing the ratio between the carrier capture and escape times [40.24].

40.3 Emitters

40.3.1 Interband Light-Emitting Diodes and Lasers

QWs have found widespread use in light-emitting diode (LED) and laser diode applications for a number of years now. As discussed in Sects. 40.1.2 and 40.2.2, there are three main reasons why this is so:

1. The ability to control the quantum confinement energy provides an extra degree of freedom to engineer the emission wavelength.
2. The change of the density of states and the enhancement of the electron–hole overlap leads to superior performance.
3. The ability to grow strained layers of high optical quality greatly increases the variety of material combinations that can be employed, thus providing much greater flexibility in the design of the active regions.

Much of the early work concentrated on lattice-matched combinations such as GaAs/AlGaAs on GaAs substrates. GaAs/AlGaAs QW lasers operating around 800 nm have now become industry standard for applications in local area networks. Furthermore, the development of high power arrays has opened up new applications for pumping solid-state lasers such as Nd:YAG. Other types of lattice-matched combinations can be used to shift the wavelength into the visible spectral region and also further into the infrared. QWs based on the quaternary alloy $(Al_yGa_{1-y})_xIn_{1-x}P$, are used for red-emitting laser pointers [40.25], while

$Ga_{0.47}In_{0.53}As$ QWs and its variants incorporating Al are typically used for the important telecommunication wavelengths of 1300 and 1550 nm.

The development of strained-layer QW lasers has greatly expanded the range of material combinations that are available. The initial work tended to focus on $In_xGa_{1-x}As/GaAs$ QWs grown on GaAs substrates. The incorporation of indium into the QW shifts the band edge to lower energy, thereby giving emission in the wavelength range 900–1100 nm. An important technological driving force has been the need for powerful sources at 980 nm to pump erbium-doped fiber amplifiers [40.26]. Furthermore, as mentioned in Sect. 40.2.1, *Strained Quantum Wells* the strain alters the band structure and this can have other beneficial effects on the device performance. For example, the compressive strain in the $In_xGa_{1-x}As/GaAs$ QW system has been exploited in greatly reducing the threshold current density. This property is related to the reduced effective mass of the holes and hence the reduced density of states. An extensive account of the effects of strain on semiconductor layers and the performance of diode lasers is given in [40.27, 28].

At the other end of the spectral range, a spectacular development has been the $In_xGa_{1-x}N/GaN$ QWs grown on sapphire substrates. These highly strained QWs are now routinely used in ultrabright blue and green LEDs [40.29], while commercial laser diodes operating around 400 nm [40.8] are used in blu-ray technology and laser projectors (see Chap. 31 for a review of nitride materials). One current research area focuses on developing lasers to fill the *green gap* that lies between the blue spectral regions covered by standard nitride lasers and the red spectral region accessible to GaAs-based compounds. Conventional nitride devices are grown on *c*-plane GaN buffer layers deposited on 0001-oriented sapphire substrates. The crystal is piezoelectric in this direction, and so the QWs experience a large electric field because of the strain associated with the lattice mismatch between $In_xGa_{1-x}N$ and GaN. This in turn causes a decrease in the radiative efficiency due to the reduced overlap of the electrons and holes through the QCSE (Sect. 40.2.3). In order to reach longer wavelengths, the fraction of indium has to be increased, and this therefore leads to a drop in the efficiency, and hence an increase in the threshold current with increasing wavelength. One possible solution to this problem is to grow the devices on semipolar or nonpolar substrates, which have reduced or zero piezoelectricity, respectively [40.30–32]. The use of semi-polar or nonpolar materials may also have benefits in other applications. Nitride LEDs lie at the heart of many white-light LEDs [40.33], but their efficiency droops off at the high current levels required for their use in solid-state lighting. The reason for this efficiency droop is much debated [40.34], but the use of semipolar material has been reported to reduce the effect [40.35].

A major application of QWs is in *vertical-cavity surface-emitting lasers* (VCSELs). These lasers emit from the top of the semiconductor surface, and have several advantages over the more conventional edge emitters. Arrays are readily fabricated, which facilitates their manufacture. No facets are required, which avoids complicated processing procedures. The beam is circular which enhances the coupling efficiency into optical fibers, while their small size leads to very low threshold currents. For these reasons the development of VCSELs has been very rapid, and many local area fiber networks operating around 850 nm currently employ VCSEL devices. This would not have been possible without the high gain coefficients that are inherent to the QW structures.

Figure 40.11 gives a schematic diagram of a typical GaAs-based VCSEL. The device contains an active QW region inserted between two DBR mirrors consisting of AlGaAs quarter wave stacks made of alternating high and low refractive index layers. The structure is grown on an n-type GaAs substrate, and the mirrors are appropriately doped n- or p-type to form a p-n junction. Electrons and holes are injected into the active region under a forward bias, where they are captured by the QWs and produce gain at the lasing wavelength λ. The thickness of the layer containing the QWs is chosen so that the light at the design wavelength is reflected back and forth from the DBR mirrors through the gain medium and adds up constructively, forming

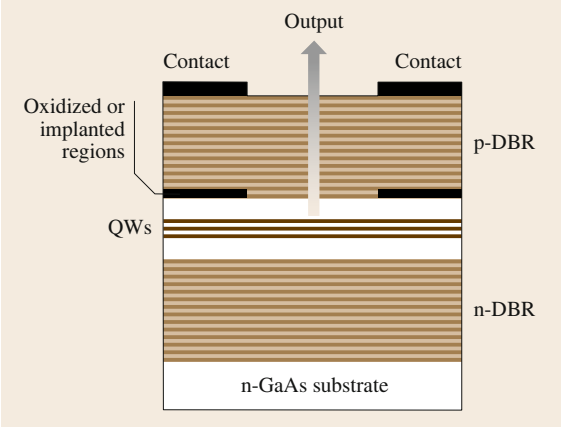

Fig. 40.11 Schematic diagram of a vertical-cavity surface-emitting laser (VCSEL). The QWs that comprise the gain medium are placed at the center of the cavity formed between two distributed Bragg reflector (DBR) mirrors. Oxidized or proton-implanted regions provide the lateral confinement for both the current and the optical mode

a laser resonator. The boundary conditions usually give field peaks close to the edges of the spacer layer, so that a thickness of $\approx \lambda/n_0$, gives an antinode at the center, where the QWs are located. Oxidized or proton-implanted regions provide lateral confinement of both the current and the optical mode. Reviews of the design and applications properties of VCSELs may be found in [40.36, 37].

The conventional VCSEL structures grown on GaAs substrates operate best in the wavelength range between 700 and 1100 nm. Much work is currently focussed on extending the range of operation to the telecommunication wavelengths of 1300 and 1550 nm, and also to shorter wavelengths in the visible spectral range. Unfortunately, it is hard to grow DBR mirrors with sufficient reflectivity on InP substrates due to the low refractive index contrast of the materials, which leads to intense research on new materials such as dilute nitrides, antimonides, and bismides that are compatible with GaAs substrates and hence GaAs/AlAs DBR mirrors [40.38–40]. Alternative approaches based on QDs will be mentioned in Sect. 40.6.

Resonator structures such as the VCSEL as shown in Fig. 40.11 can be operated below threshold as resonant cavity LEDs (RCLEDs). The presence of the cavity reduces the emission linewidth and hence increases the intensity at the peak wavelength [40.41]. Furthermore, the narrower linewidth leads to an increase in the bandwidth of the fiber communication system due to the reduced chromatic dispersion [40.42]. A review of the progress in RCLEDs is given in [40.43].

40.3.2 Quantum Cascade Lasers

The principles of infrared emission by ISB transitions were described in Sect. 40.2.4. Electrons must first be injected into an upper confined electron level as shown in Fig. 40.9b. Radiative transitions to lower confined states with different parities can then occur. ISB emission is usually very weak, as the radiative transitions have to compete with a very rapid nonradiative decay by phonon emission (Sect. 40.2.6). However, when the electron density in the upper level is large enough, population inversion can occur, giving rapid stimulated emission and subsequent laser operation. This is the operating concept of the *QC laser* first demonstrated in 1994 [40.44]. The laser operated at 4.2 μm at temperatures up to 90 K. Although the threshold current for the original device was high, the progress in the field had been very rapid. A comprehensive account of the present state of the art is given in [40.45].

The QW structures used in QC lasers are very complicated, and often contain hundreds of different layers. Figure 40.12 illustrates a relatively simple design based

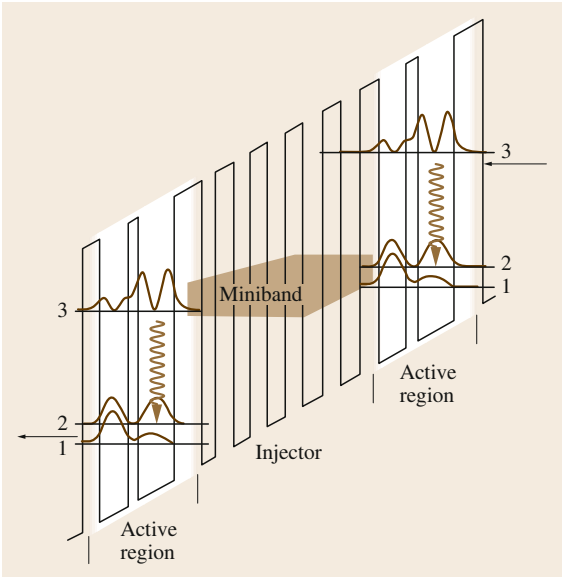

Fig. 40.12 Conduction band diagram for two active regions of an InGaAs/AlInAs QC laser, together with the intermediate miniband injector region. The levels in each active region are labeled according to their quantum number n, and the corresponding wave function probability densities are indicated. Laser transitions are indicated by the wavy arrows, while electron tunneling processes are indicated by the straight arrows. (After [40.46], with permission from IOP)

on lattice-matched $In_{0.47}Ga_{0.53}As/Al_{0.48}In_{0.52}As$ QWs grown on an InP substrate [40.46]. The diagram shows two active regions and the miniband injector region that separates them. A typical operational laser might contain 20–30 such repeat units. The population inversion is achieved by resonant tunneling between the $n = 1$ ground state of one active region and the $n = 3$ upper laser level of the next one. The basic principles of this process were enunciated as early as 1971 [40.47], but it took more than 20 years to demonstrate the ideas in the laboratory. The active regions contain asymmetric coupled QWs, and the laser transition takes place between the $n = 3$ and $n = 2$ states of the coupled system. The separation of the $n = 2$ and $n = 1$ levels is carefully designed to coincide with the LO-phonon energy, so that very rapid relaxation from the $n = 2$ level to the $n = 1$ level occurs, and the system behaves as a four-level laser. This latter point is crucial, since the lifetime of the upper laser level is very short (typically ≈ 1 ps), and population inversion is only possible when the lifetime of the lower laser level is shorter than that of the upper one. The lasing wavelength can be varied by the detailed design of the coupled QW active region. The transition energy for the design as shown in Fig. 40.12

is 0.207 eV, giving emission at 6.0 μm. Further details may be found in [40.46].

Present research on QC lasers focuses on practical systems for chemical sensing and medical imaging, and also on extending their performance at both the short (< 5 μm) and long (> 50 μm) wavelength ends. At short wavelengths, new material systems based on antimonides offer much promise [40.48], while at the long wavelengths, there is much interest in developing sources for THz imaging [40.49, 50].

40.4 Detectors

Photodetectors for the visible and near-infrared spectral regions are generally made from bulk silicon or III–V alloys such as GaInAs. Since these devices work very well, the main applications for QW photodetectors are in the infrared spectral region and for especially demanding applications such as APDs and solar cells. These three applications are discussed separately below, starting with solar cells.

40.4.1 Solar Cells

The power generated by a solar cell is determined by the product of the photocurrent and the voltage across the diode. In conventional single-junction cells, both of these parameters are determined by the bandgap of the semiconductor used. Large photocurrents are favored by small-gap materials, because semiconductors only absorb photons with energies greater than the bandgap, and small-gap materials therefore absorb a larger fraction of the solar spectrum. However, the largest open circuit voltage that can be generated in a p-n device is the built-in voltage, which increases with the bandgap of the semiconductor. This compromise sets a theoretical upper limit to the efficiency of single-junction devices at 31%, with the best silicon devices achieving efficiencies of around 25% [40.51].

QW devices can give better performance than the bulk counterparts because they permit separate optimization of the current and voltage generating factors [40.52]. This is because the built-in voltage is primarily determined by the bandgap of the barrier regions, whereas the absorption edge is determined by the band gap of the QWs. This gives rise to improvements in the efficiency compared to silicon devices, with 28.3% achieved for a GaAsP/InGaAs strain-balanced single-junction QW device in a concentrator cell under 535 sun illumination [40.53]. This enhanced efficiency under high-sun illumination is significant, because the performance of other types of solar cells tends to deteriorate in the higher operating temperatures found in concentrators.

The benefits of QWs become more apparent when they are used in tandem solar cells that incorporate multiple junctions to improve the efficiency. The idea here is to form a solar cell with a series of junctions that are separately optimized to capture energy from different parts of the solar spectrum. The top junction has the widest gap and is designed to absorb the highest energy (shortest wavelength) photons from the sun. This top junction is transparent to lower energy photons, which can then be absorbed efficiently in lower junctions with smaller gaps, making it possible to capture a larger part of the solar spectrum efficiently. In this way, efficiencies surpassing the 31% limit of single-junction cells have been achieved, and the versatility provided by QWs can provide significant benefits in the design of the device. The increased cost of the III–V epitaxy can then become worthwhile in space applications where the use of the highest efficiency devices is paramount to minimize the size and weight of the solar panels. A comprehensive review of the present state of the art in QW solar cells may be found in [40.54], and new research directions on nanowire and QD devices are discussed briefly in Sect. 40.6.

40.4.2 Avalanche Photodiodes

APDs are the detectors of choice for many applications in telecommunications, single-photon counting and imaging. For telecommunication applications, APDs are generally operated in linear gain mode, where the output photocurrent is proportional to the reverse bias applied below breakdown. On the other hand, single-photon detection and high speed imaging applications require APD operation in *Geiger-mode* – when the reverse bias voltage is pulsed above breakdown [40.55].

A variety of semiconductor materials has been researched for optimizing APD design. The material of choice in terms of fabrication process robustness and cost-effectiveness is obviously silicon – but the drawback is the limitation to visible light detection. For example, focal plane arrays of silicon single-photon avalanche diodes (SPADs) have been in development for high-speed image sensor design and fabrication [40.56]. In order to extend the photoresponse into the near infrared, SiGe/Si multiple QW APDs have been developed, based on CMOS process-

ing, and demonstrated to be exhibiting photo-response in the spectral range 800–1500 nm [40.57].

Commercially available III–V semiconductor APDs are typically engineered with different bandgap materials in the absorption and multiplication regions [40.55]. The absorption layer has a relatively narrow bandgap (such as $In_{0.53}Ga_{0.47}As$) to allow for larger absorption, whereas the multiplication region has a wider bandgap (such as InP or $In_{0.52}Al_{0.48}As$) to reduce dark current at the high electric fields required. The avalanche multiplication mechanism plays a critical role in determining the APD photodetection gain, dark current, and gain–bandwidth product. It is the design of the thickness of the multiplication region that makes the fundamental difference between optimizing APDs for linear mode versus Geiger mode. To increase the gain–bandwidth product and reduce noise in linear mode operation, the multiplication region must be thinned down [40.58], whereas for Geiger-mode photon counting the SPAD's multiplication region must be thicker [40.59]. There are many design trade-offs involved, the most critical being the onset of band-to-band tunneling and dark current increase with the thinning of the multiplication region [40.60]. To circumvent this problem, it has been demonstrated that the dark current can be reduced by incorporating adequately designed SLs into the multiplication layer to form an SL-APD as shown in Fig. 40.13 [40.61]. Essentially, the miniband formation (Fig. 40.3) in the SL corresponds to a larger effective bandgap and thus reduces the probability of band-to-band tunneling at the high electric fields required for carrier impact ionization and subsequent carrier multiplication.

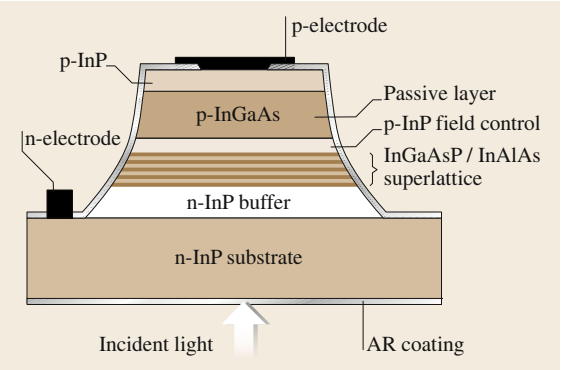

Fig. 40.13 Schematic representation of an InGaAs/InP/InGaAsP/InAlAs superlattice avalanche photodiode (SL-APD). Light is absorbed in the bulk InGaAs layer and the resulting photocurrent is multiplied by the avalanche process in the InGaAsP/InAlAs superlattice region. The spatial periodicity of the SL reduces the dark current

It has been proposed that the excess noise factor can be further reduced by designing multiplication layers with SL [40.62] or *staircase* [40.63] structures to enhance the ionization rate of one carrier type relative to the other due to their different band edge discontinuities [40.64]. However, this proposal is still under active theoretical and experimental scrutiny, because most of the electrons populate the higher energy satellite valleys (X and L) at the high electric fields required for the avalanche gain [40.65]. Monte Carlo simulations [40.66], backed up by experimental evidence [40.67], have shown that the ratio of the electron and hole ionization rates, commonly used as a figure of merit in bulk multiplication layers [40.68], is not critically affected by the bandgap discontinuities. In fact, these models emphasize that it is the spatial modulation of the impact ionization probability, associated with the periodic bandgap discontinuity, which leads to a reduction in the multiplication noise.

40.4.3 Infrared Detectors

The principles of infrared absorption by ISB transitions were described in Sect. 40.2.4. Infrared detectors are required for applications in defence, night vision, astronomy, thermal mapping, gas-sensing, and pollution monitoring. *Quantum well intersubband photodetectors* (QWIPs) are designed so that the energy separation of the confined levels is matched to the chosen wavelength. A major advantage of QWIPs over the conventional approach employing narrow-gap semiconductors is the use of mature GaAs-based technologies, and the avoidance of toxic metals such as mercury and cadmium. Furthermore, the detection efficiency should in principle be high due to the large oscillator strength that follows from the parallel curvature of the in-plane dispersions for states within the same bands [40.69]. However, technical challenges arise from the requirement that the electric field of the light must be polarized along the growth (z) direction. This means that QWIPs do not work at normal incidence, unless special steps are taken to introduce a component of the light field along the z-direction, for example, by using gratings, random scattering or microlenses [40.70]. A major area of current research focuses on developing arrays of QWIPs for applications in imaging [40.71, 72].

Much of the early work on QW infrared detectors was based on the established GaAs/AlGaAs and GaAs/InGaAs material systems. In recent years, however, interest has shifted to other QW materials, especially to type-II InAs/GaSb SL (T2SL) devices [40.73, 74]. In T2SLs, the absorption occurs between hole states at the top of the GaSb valence band and electron miniband states within the InAs conduction band. This

means that they are not actually intersubband devices per se, and hence are not subject to the z-polarization selection rule for ISB absorption. They are therefore sensitive to photons impinging at normal incidence, making the design of the detector arrays much simpler. In Sect. 40.6, we briefly consider another class of III–V nanostructures that also absorb infrared photons at normal incidence based on QDs.

The combination of resonant intersubband (ISB) photodetection and avalanche multiplication (Sect. 40.4.2 above) has been studied to explore the possibility of designing *unipolar avalanche photodiodes* (UAPDs) [40.75]. UAPDs rely on impact ionization involving only one type of carrier in order to achieve gain in photoconductive detectors for mid- and far-infrared light. The unipolar impact ionization occurs when the kinetic energy of the primary carrier exceeds an activation energy E_a defined as the transition energy between the QW ground state and the QW top state (Fig. 40.14). A single QW then releases an extra electron each time it is subject to an impact with an incoming electron.

The impact ionization probability for this process is given by the product between the carrier capture probability and the carrier escape probability under a mechanism of carrier–carrier scattering in the QW. The electron transport occurs through a sequence of escape, drift, and kinetic energy gain under the applied electric field, combined with relaxation, capture and QW ionization. Ultimately, the multiplication gain in a UAPD is governed by the QW capture probability, the number of QWs, and the field uniformity over the QW sequence. The unipolar nature of the multiplication process must be preserved in order to avoid field nonuniformities stemming from spatial charge variation caused by bipolar carrier transport across the multiplication region.

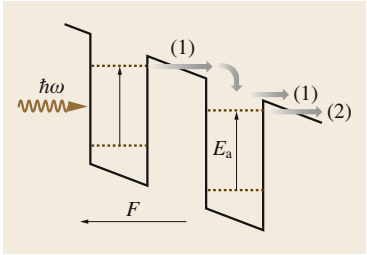

Fig. 40.14 Unipolar carrier multiplication in a multiple QW structure at field strength F: (1) is the primary electron resulting from photodetection, while (2) is the secondary electron resulting from the impact ionisation of the QW by the primary electron

Interest in a purely unipolar multiplication mechanism was originally motivated by the possibility of reduced noise in comparison to bipolar APDs, where band-to-band transitions lead to gain fluctuations manifested as excess noise [40.68]. For this purpose, the QWs in an UAPD structure are typically tailored such that the intersubband activation energy E_a is smaller than the interband impact ionization activation energy that would be responsible for bipolar avalanche multiplication. However, further investigation has shown that unipolar avalanche multiplication is also accompanied by an excess noise factor, such that the noise gain exceeds the photoconductive gain [40.76], thus limiting the practical applications of UAPDs.

40.5 Modulators

In Sect. 40.2.3, we noted that the optical properties of QW diodes are strongly modified by the application of voltages through the quantum-confined Stark effect (QCSE). Referring to Fig. 40.8, we see that at wavelengths below the heavy-hole exciton at 0 V, the absorption increases as the voltage is applied, which provides a mechanism for the modulation of light. For example, the amount of light transmitted at wavelengths close to the bandedge would change with the voltage applied. Moreover, since changes of absorption are accompanied by changes of the refractive index through the Kramers–Kronig relationship, it is possible to make QCSE phase modulators as well [40.77].

Figure 40.15 shows a schematic design of a QW *electroabsorption modulator* (EAM) device incorporated in a waveguide geometry on the same chip as a semiconductor laser. The QCSE modulator transmits the incoming laser light when no voltage is applied and absorbs the beam when the MQW stack is suitably biased. For operation at high speeds, the combination of a continuous laser and a high-speed modulator offers better control of the phase chirp of the pulses than the direct modulation of the laser output itself [40.78]. In particular, the chirp factor is expected to become negative if the photo-generated carriers can be swept out fast enough in the EAM, which is desirable for long-distance data transmission through optical fibers [40.79].

The growth of silicon photonics in recent years has led to a strong interest in QW modulators that can be grown on silicon substrates. Silicon is transparent at

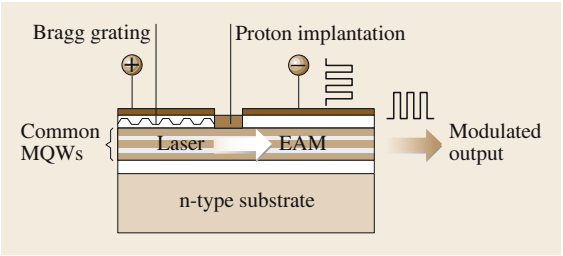

Fig. 40.15 Schematic diagram of an integrated quantum-well waveguide electroabsorption modulator (EAM) and distributed feedback (DFB) laser. The laser is forward biased while the EAM is reverse biased. The p-contacts of the two electrically independent devices are separated by proton implantation. The light emitted by the laser is guided through the EAM region, resulting in a modulated output beam when data pulses are applied to the EAM ►

the technologically important wavelengths of 1300 and 1550 nm, and this enables the development of sophisticated integrated photonic circuits that are compatible with CMOS electronics. Off-chip III–V lasers are coupled into the circuits and are then encoded with data by on-chip modulators. Hybrid devices composed of III–V QCSE modulators grown on silicon substrates have achieved impressive results [40.80]. However, attractive alternative approaches based on germanium QWs have developed following the observation of a strong QCSE around 1400 nm in a Ge/GeSi MQW structure grown on silicon in 2005 [40.81]. Operation at 1550 nm was achieved a year later [40.82], and high-speed devices operating at 23 GHz have now been demonstrated [40.83].

40.6 Quantum Dots and Nanowires

The main emphasis of this chapter has been on outlining the benefits of using QWs and SLs in modern photonic devices. The chapter would not be complete, however, without a brief discussion of semiconductor nanostructures with higher degrees of electronic confinement, namely quantum wires and quantum dots (Table 40.1).

Quantum wires are nanostructures in which the electrons are confined in two dimensions, and free in the third. They can therefore be considered as one-dimensional materials. Laser operation from a GaAs quantum wire formed in a V-groove structure was demonstrated in as early as 1989 [40.86]. However, the direct development of that work was difficult due to the complexity of making quantum wires by the V-groove technique. By contrast, in recent years, there has been very rapid progress in the development of semiconductor nanowires by growth on patterned substrates. Figure 40.16 illustrates the two main approaches [40.84]. In the first method shown in Fig. 40.16a, size-selected metal nanoparticles are deposited on the substrate to act as catalysts for the nanowire growth; the wires then form under the particles by the process of vapor–liquid–solid (VLS) growth. The second method shown in Fig. 40.16b does not make use of catalysts; instead, an array of nanoapertures is patterned into a mask on top of the substrate by e-beam lithography, and the nanowires grow from the holes by the process of selective-area vapor-phase epitaxy (SA-VPE). By these, and similar methods, it is possible to grow large arrays of nanowires for a variety of applications in electronics and photonics. For example, Figs. 40.16c and 40.16d illustrate an array of GaAs nanowires grown by MOVPE on a square array of holes patterned into a SiO_2 mask deposited on a GaAs substrate [40.85]. One particularly interesting potential application is in the development of high-efficiency nanowire-array photovoltaic devices [40.87]. Another major development has been the observation of exotic particles called Majorana fermions in transport studies of InSb nanowires coupled to superconducting electrodes [40.88]. Reviews on the progress of the growth and applications of nanowires may be found in [40.89, 90].

The final member of the family of quantum-confined structures is the QD. These are semiconductor nanostructures in which the electrons are confined in all three directions. This gives rise to zero-dimensional (0-D) physics, in which the continuous electronic bands that are characteristic of bulk semiconductors are broken in discrete quantized states. QDs for photonic applications are usually formed by either epitaxial or colloidal growth. Epitaxial QDs form spontaneously during MBE growth in the Stranski–Krastanow regime, while colloidal QDs are grown in a solution from precursors. Figure 40.17 shows an electron microscope image of an InAs QD grown on a GaAs crystal by the *Stranski–Krastanow* technique [40.91]. The dots are formed because of the very large mismatch between the lattice constants of the InAs and the underlying GaAs. The strain that would be produced in a uniform layer is so large that it is energetically favorable to form small clusters. This then leads to the formation of islands of InAs with nanoscale dimensions, which can then be encapsulated within an optoelectronic structure by the overgrowth of further GaAs layers.

Colloidal QDs can now be obtained commercially from several companies in both aqueous and organic suspensions. The ready availability of these dots makes them highly useful in a variety of applications. One strong area of application is in bio-imaging [40.92, 93]. Here, the dots are attached to a functionalized biomolecule by a chemical bond and introduced into the biosystem to be studied. The tagged biomolecule is then imaged as it moves through the system by exciting fluorescence from the dots. The high brightness and photostability of the dots compared to organic dyes make them particularly well suited for this application. Another active research area is in the development of high brightness organic LEDs [40.94]. Here, the photostability of the dots is again a key advantage compared to organic materials, while their color purity and brightness add further benefit. A third main area of research focuses on photovoltaic devices [40.95, 96]. The low cost of solution-processed material together with their high photostability makes them attractive for use in single-junction cells, with efficiencies approaching 9% reported [40.97], while the wide range of bandgaps that can be achieved by tuning the size and composition of the dots makes them appealing for use in multijunction cells.

The growth of QDs by epitaxy (i. e., MBE or MOVPE) is more expensive than the chemical synthesis of colloidal dots, but has the advantage of incorporating the dots into III–V wafers that can be processed into advanced optoelectronic devices. It has been known for many years that QDs offer significant benefits over QWs in semiconductor lasers – notably that the intrinsic gain is higher [40.98] and that the threshold current is less sensitive to temperature [40.99] – and this has prompted intense research into the development of QD lasers [40.100–102]. As mentioned in Sect. 40.3.1, the production of VCSELs at 1300 and 1550 nm has proven to be difficult for InP-based QW structures due to the low refractive index contrast of the materials that form the DBR mirrors. The use of InAs/GaAs QDs as the active region circumvents this problem and allows the benefits of mature GaAs-based VCSEL technology to be exploited [40.103]. At the same time, significant steps toward QD integra-

tion with silicon foundry process technology have been taken by demonstrating high-performance QD lasers on silicon substrates [40.104, 105]. Another very active area of research is on QD infrared photodetectors (QDIPs). In contrast to QW devices (Sect. 40.4.3), QDIPs are sensitive at normal incidence due to the relaxation of the ISB selection rules for electrons with 3-D confinement [40.106, 107]. This obviates the need for the complicated photon-coupling methods, leading to rapid progress in the deployment of QDs in infrared detectors [40.108–110]. A third intense area of research focuses on exploiting the atom-like nature of the 3-D-confined electronic states for applications in the field of quantum information processing. The emission of antibunched photons from QDs was first demonstrated in 2000 [40.111], and this has led to rapid progress in the development of single-photon sources for use in quantum cryptography and quantum computing [40.112]. At the same time, the use of excitons or carrier spin states in QDs as quantum bits for the processing of quantum information offers much promise [40.113].

40.7 Conclusions

Semiconductor QWs are excellent examples of quantum mechanics in action. The reduced dimensionality has led to major advances in both the understanding of 2-D physics and the applied science of optoelectronics. In some cases, the QWs have enhanced the performance of conventional devices (e.g., LEDs and edge-emitting lasers), and in others, they have led to radically new devices (e.g., VCSELs, quantum cascade lasers, QCSE modulators). At the present time, the main commercial use for QW optoelectronic devices is in LEDs, laser diodes, and QCSE modulators. It remains to be seen whether some of the other devices described here (QW solar cells, SL-APDs, QWIPs) will come to commercial fruition, and whether systems of lower dimensionality (e.g., QDIPs) will eventually replace QWs in the same way that QWs have replaced bulk devices.

41. Glasses for Photonic Integration

Ray DeCorby, Mehrdad Irannejad

Inorganic glasses form the backbone of dielectric materials in optics and photonic applications. In addition to offering a range of transparency windows, intrinsic physical properties of glass materials also offer flexibility of processing for the realization of fibers, films, and shaped optical elements. Traditionally, the main role of glass has been as an optically passive material. However, a significant attribute of glass as an optical medium is to host dopants such as nanoparticles or active ions in a unique chemical environment, which can be engineered via processing, by controlling the geometry to develop active and passive photonic devices, such as laser, amplification, storage media, optical switching, frequency conversion, and sensor media.

For photonic integration, many of the attributes of glasses are particularly compelling. Glasses allow numerous options for thin film deposition and integration on arbitrary platforms. The possibility of controlling the thermal and flow properties, e.g., expansion coefficient, crystallization, and viscosity during film deposition of a glass may allow realization of extremely low-loss microphotonic waveguides, photonic crystals, and microcavities. The metastable nature of glass can enable the direct patterning of photonic elements by energetic beams.

This chapter provides an overview of these unique properties of glasses, from the perspectives of the technology options they afford and the practical limitations they present. Further, an overview is provided of the main families of glassy inorganic films studied for integrated optics. Finally, the main features of rare-earth doped glasses are reviewed, with an emphasis on their potential for implementation in compact integrated light sources and amplifiers.

References 1077

Inorganic glasses have played a central role in optical science and technology, and more generally within the electrical and electronic engineering disciplines [41.1]. Amongst optical materials, the unique advantages of glasses are well known [41.2, 3]. Glasses can be worked relatively easily into various forms, such as bulk lenses, fibers, and thin films. A remarkable example of geometrical control is shown by the manufacture of low-loss silica fibers, in which a hair-thin glass fiber of $\approx 125\,\mu m$ (with tightly controlled geometrical and material properties) is drawn from a heated glass preform at rates as high as 20 m/s or greater [41.4]. Glass can be manufactured with excellent homogeneity and without grain boundaries, so that scattering of light is acceptably low. While perfect crystals typically exhibit even lower levels of scattering, they are difficult to realize in large sizes and with arbitrary shapes. Conversely, optical losses in polycrystalline materials are generally

excessive due to scattering from grain boundaries and other crystal defects. Finally, the standard glass compositions (oxide, halide, and chalcogenide glasses and their hybrids) provide transparency windows from the UV to the mid-infrared (Fig. 41.1). It has been estimated [41.2] that more than 90% of optical components are based on glasses. Given the massive worldwide installation of optical communications fibers since the 1980s [41.5], and depending on the definition assigned to the term *dielectric component*, this statistic might actually be closer to 100%.

Befitting their central role in optical technology, there are numerous excellent reviews covering the optical properties, processing, and photonic functionalities of a range of inorganic glasses [41.3, 6–10] which target bulk glass and fiber optic applications. Further, one of the distinguishing attributes of glasses is their compositional flexibility. Hundreds of commercial glasses are available, and many more have been studied in research laboratories and reported in the literature. Thus, it is not possible to capture the full range of glassy materials (even restricted to inorganic glasses) within a short review paper. A recent monograph by *Yamane* and *Asahara* [41.6] provides a comprehensive and highly recommended treatment of glass technology and its application in photonics. However, reviews on the comparative properties of inorganic glasses for integrated photonics are few and far between. This is an emerging area and for this purpose in this short review our modest aims are as follows:

1. With a focus specifically on *integrated* photonics, the main advantages of glasses are discussed and the most-studied glass systems are reviewed in brief. Integrated photonics (integrated optics) refers to guided wave photonic devices fabricated on planar platforms. Glass substrates (with waveguides defined by ion diffusion) have played an important role in integrated optics. However, the advantages of integrated glass devices compared to crystalline materials such as III–V semiconductors or lithium niobate have been less apparent in applications so far. For this reason, emphasis is placed on glassy thin films that can enable photonic functionality on other substrates. In practice, substrates of interest might be printed circuit boards or semiconductor wafers.
2. For the most part, the discussion is restricted to inorganic glasses. Some reference is made to organic glasses, since their properties and advantages may be comparable with inorganic glasses and polymeric dielectric materials. Good reviews covering polymer materials for integrated photonics are available [41.11].

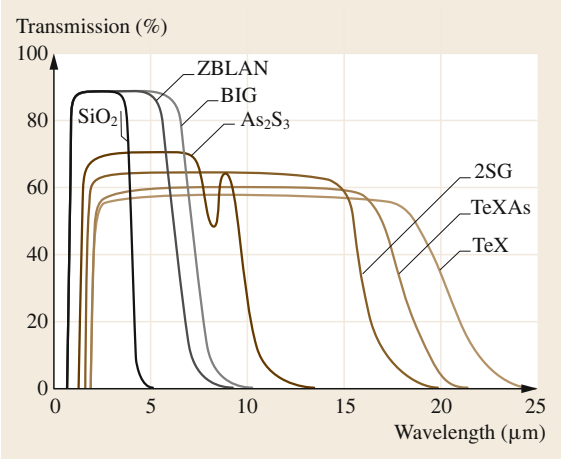

Fig. 41.1 Transmission plots are shown for SiO_2 glass and some representative fluoride and chalcogenide glasses. ZBLAN and BIG are heavy-metal fluoride glasses, 2SG is a selenide glass, and TeXAs and TeX are tellurium-based chalcogenide glasses. (After [41.15])

3. To date, the most important inorganic glass system for integrated photonics is the silica-on-silicon planar lightwave circuit (PLC) platform. We only mention this briefly as the literature [41.12, 13] provides an overview of that technology. Rather, the goal is to provide some insight into the advantages that are globally associated with glassy materials. Further, an emphasis is placed on the unique advantages (lower processing temperatures, higher refractive index contrast, optically active functionality, etc.) enabled by some glass systems.
4. In the context of emerging trends, the review also reports on the application of laser-based deposition and femtosecond laser techniques for waveguide inscription in hybrid and monolithic integration of active-passive functions [41.14]. We also report materials based methodological approaches for integrating photonic crystals (PCs) with high-speed data networks where there is much need for integration on the backplane of printed circuit boards (PCBs). Since the top layer materials present in PCBs for electronic circuits are polymer based, such a choice of material limits the capability of offering active-passive device integration which is essential for high-speed (10 Gb/s) data communication (datacom). Materials issues for active-passive integration are also reviewed.

With these goals in mind, the chapter is organized as follows. In Sect. 41.1, we highlight the main advantages of glasses for photonic integration. These attributes include the unique processing options afforded by the

existence of the glass transition and forming properties in the metastable regime of thermal processing of glasses. Sect. 41.2 provides an overview of the most-studied materials for glass-based integrated optics. This includes the standard glass formers (oxide, halide, and chalcogenide glasses) as well as several materials that are generally classified as ceramics (Si_3N_4, Al_2O_3, etc.) but which can also be formed as amorphous thin films for integrated photonics. In Sect. 41.3, some unique advantages of glasses for realization of integrated light sources are reviewed. Sect. 41.4 provides a summary of emerging trends and some thoughts on future prospects for glass as a material for photonic integration.

41.1 Main Attributes of Glasses as Photonic Materials

One of the most generic features of a glassy material, in contrast with crystalline solids and liquids, is the existence of a characteristic glass transition temperature (T_g). In short, if a viscous liquid is cooled fast enough, the liquid passes through the freezing temperature of the material without undergoing a phase transition to equilibrium or metastable equilibrium solid crystalline states (Fig. 41.2). Rather, it becomes a supercooled liquid, whose rate of change of specific volume (or enthalpy) with decreasing temperature remains constant and equivalent to that of the molten liquid. At T_g, the slope of these curves (for example, specific volume versus temperature) changes abruptly (but in a continuous way) to a value that slowly relaxes with time towards the nearest equilibrium state. Below T_g, the quenched material is an amourph solid or glass.

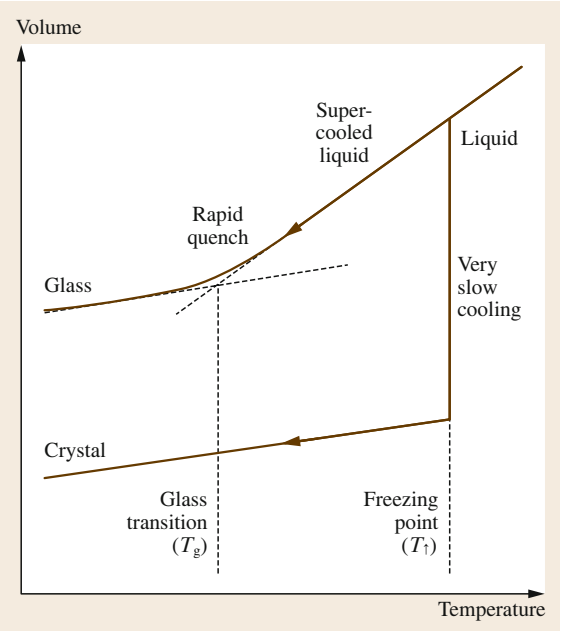

Fig. 41.2 Schematic plot illustrating the change in specific volume of a glass with temperature. (After [41.16])

While glass forming has been a staple of human technological innovation for thousands of years, the physical processes underlying the glass transition are still a matter of some debate [41.16–18]. Several empirical facts are well known, however. The glass transition temperature of a glass is dependent on thermal history, e.g., quench or glass-formation rate (which is the rate of cooling from the melt, or for film formation) and even the age of the glass [41.19]. The quench rate dependence of T_g is given by an Arrhenius-type equation [41.20]

$$Q_i = Q_o \exp\left[-B\left(\frac{1}{T_g} - \frac{1}{T_m}\right)\right], \qquad (41.1)$$

where Q_o and B are constants, and have different values for different glasses. T_m is the melting point.

However, on the basis of empirical observations T_g is in general estimated using the formula: $T_g \approx 2T_m/3$ [41.17]. This rough estimation, however, works only with silicates, phosphates, and borate glasses. For a vast majority of inorganic glasses which are not strongly network forming, the 2/3rd rule does not apply. For glasses that cannot be formed easily by melt quenching, such as amorphous Si [41.18], the direct experimental determination of T_g is not always possible, and indirect methods are sometimes used to estimate an effective T_g.

Central to the technological application of glasses is the ability to control their viscosity by way of temperature [41.5]. For stable glass formers, it is possible to transition between states of very low viscosity (molten liquid), low viscosity (supercooled liquid), and high viscosity (frozen liquid, i. e., glass). This remarkable variation in mechanical properties with temperature, spanning several orders of magnitude in viscosity, underpins both the ancient and modern manufacture of glass products (by molding, extrusion, float processes, etc.). It is interesting to note that T_g can be defined as the approximate temperature at which the shear viscosity attains 10^{12} Pa s. Further, viscosity varies rapidly in the

vicinity of T_g. For so-called strong glass formers (such as SiO_2), the viscosity η varies according to an Arrhenius equation of the form $\eta = A\exp(B/k_BT)$, where A and B are temperature-independent constants and k_B is the Boltzmann constant [41.17]. To form glasses into desired shapes, the temperature is typically controlled such that the viscosity is in the 10^2–10^7 Pa s range, depending on the process and the stability of the particular glass composition [41.6, 21].

It was once held that only certain materials could form glasses, but it is now believed that the glassy state is attainable for all types of materials [41.16]. Accordingly, the literature contains references to various families of glasses, including inorganic (ceramic), organic (polymeric), and metallic glasses.

41.1.1 The Glass Transition and Control of Viscosity

The surface tension of liquids is a well-known enabler of optical quality surfaces. The interfacial or surface tension property of a glass-forming liquid together with viscosity and quench rate determine the optical surface quality [41.22].

The manufacture of modern single-mode fibers is a good example of the enabling nature of the glass transition. In a typical process [41.4, 6, 23], highly purified glass layers are deposited either on the inside walls of a fused silica tube by chemical vapor deposition (CVD) or on the outside surface of a ceramic rod by flame hydrolysis deposition (FHD) or flame oxidation deposition (FOD). The hollow glass cylinder (after removal of the ceramic rod in the latter case) is then heated (sintered) to $\approx 1600\,^{\circ}C$, such that it collapses to form a solid glass preform (typically 1 m in length and 2 cm in diameter). 1600 °C is the approximate softening point of silica glass, typically defined as corresponding to a viscosity of $\approx 10^7$ Pa s [41.6]. The fiber drawing process involves local heating of the preform to a temperature of approximately 2000 °C (corresponding to a viscosity of $\approx 10^5$ Pa s). Thus, viscosity control is critical at nearly all stages of the process. Further, the drawing process allows tremendous control over the optical and geometrical properties of the fiber, in part due to the self-regulating properties of surface tension effects in the supercooled liquid. As an added benefit, inhomogeneities in the original preform tend to be averaged out in the process [41.24]. The amazing properties of silica fibers (tensile strength comparable to that of steel, low loss, and extremely tight tolerances for material and geometrical parameters) are well known, and attest to the technological versatility of (silica) glasses. It is also interesting to note that the standard technique for splicing sections of silica fibers together, which is achieved with less than 0.1 dB loss [41.5], is based on a reflow process wherein surface tension contributes to their alignment.

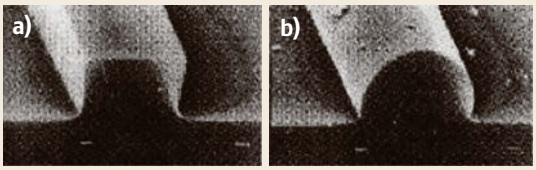

Fig. 41.3 (a) A glass waveguide core is shown before and (b) after a selective reflow process. (After [41.25])

Within integrated optics, the manufacture and optimization of PLC devices relies directly on the glass transition in many cases [41.12, 13]. PLC devices are manufactured in doped SiO_2 glasses deposited (by CVD, FHD, or sol–gel techniques) on a silicon wafer. The undercladding is often pure SiO_2, which can be formed by thermal oxidation of the silicon wafer. Typically, dopants in the core and uppercladding layers act to modify both the refractive index and the thermomechanical properties of the glass. In particular, controlled reflow (by heating the glasses near T_g) of these layers often plays an important part in the process. Reflow is used to consolidate the interface between layers, to smoothen the rough sidewalls of the waveguide core (formed by dry etching processes), and to assist in gap filling and planarization of the cladding layer over the patterned core layer [41.12, 24–26]. Typically, the layers are doped such that the glass transition decreases in the upward direction. In that way, a layer can be reflowed without affecting the underlying layers. As an example, a *pinned based reflow* is shown in Fig. 41.3 [41.25]. The circle-section shaped core arises from selective reflow of the core material while its interface with the undercladding glass remains fixed. The upper boundary of the core is shaped by surface tension.

Surface tension driven manufacturing of more complex designs of optical components such as silica-glass based optical microcavities [41.27–29], nm-scale silica wires [41.30], photonic crystal fibers [41.31], microball lenses [41.32], and microlenses [41.33, 34] have been widely studied. In these cases, the reduction of scattering losses by surface tension-mediated smoothing of interfaces is particularly important.

As discussed further in Sect. 41.2, high-index contrast waveguides, photonic crystals, and microcavities are major themes within integrated optics. High index contrast (between the core and cladding of a waveguide, for example) is desirable because it enables strong confinement of light to small waveguides or small res-

onant cavities. This is essential for the realization of high-density integrated optics [41.12]. The downside of high-index contrast is that scattering at interfaces increases with index contrast. This is clarified by the so-called Tien model for waveguide loss due to interfacial scattering in a symmetric slab waveguide [41.35]

$$\alpha_S = \frac{2\sigma^2 k_0^2 h}{\beta} \Delta n^2 E_S^2 \,, \tag{41.2}$$

where σ is the standard deviation (characteristic amplitude) of the roughness, k_0 is the free-space wavenumber, h is the inverse of the penetration depth of the mode into the cladding, β is the propagation constant of the mode, and E_S is the normalized electric field amplitude at the core-cladding interface. Further, $\Delta n^2 = n_{core}^2 - n_{clad}^2$, where n_{core} and n_{clad} are the core and cladding refractive indices, respectively. This equation explicitly shows the strong dependence of scattering loss on index contrast. A more accurate expression, derived by considering the statistics of roughness (not just the amplitude), is the Payne–Lacey model [41.36]

$$\alpha_S = 4.34 \frac{\sigma^2}{k_0 \sqrt{2} d^4 n_{core}} g f \,, \tag{41.3}$$

where d is the core thickness, g is a function that depends mainly on the core-cladding index offset, and f is a function that depends on the statistics of the roughness. If $r(z)$ is the random function describing the line-edge roughness (i. e., the deviation of the core-cladding interface from a straight line), the autocorrelation of $r(z)$ is often well described by an exponential function [41.37]

$$R(u) = \langle r(z) r(z+u) \rangle \approx \sigma^2 \exp\left(\frac{-|u|}{L_c}\right) , \tag{41.4}$$

where L_c is the so-called correlation length. It can be shown that for waveguide geometries of typical interest, low scattering loss requires both σ and L_c to be low. As a second illustration of the impact of interface roughness, it can be shown that the surface scattering limited quality (Q) factor for whispering gallery modes in a spherical microsphere is approximately [41.29]

$$Q_{SS} = \frac{\lambda^2 D}{2\pi^2 \sigma^2 L_c} \,, \tag{41.5}$$

where D is the microsphere diameter. Again, minimization of scattering losses is correlated with minimization of σ and L_c.

It is interesting to compare recent results for high-index-contrast structures in crystalline materials and glasses. Much of the work on very highly confining waveguides and photonic crystals has focused on semiconductor material systems, especially the silicon-on-insulator (SOI) system [41.35, 36] and III–V semiconductor systems [41.38]. Generally, structures are defined by electron-beam lithography or photolithography, followed by a dry etching process. Each of these steps has limited precision and contributes to the overall roughness [41.37]. With use of sophisticated processes, roughness parameters are typically on the order of $\sigma \approx 5\,\text{nm}$ and $L_c \approx 50\,\text{nm}$, resulting in losses on the order of $3-10\,\text{dB/cm}$ for submicron strip waveguides [41.36]. Significant improvement in these numbers is mostly reliant on advancements in lithography or etching processes. These same issues limit the performance of other high-index contrast structures formed in semiconductors. For example, the Q factor of semiconductor microdisk and microring resonators typically does not exceed 10^5 [41.39], and the loss of photonic crystal defect waveguides in semiconductors remains impractically large [41.40].

By comparison, glasses (at least certain glasses) offer the potential for much smaller characteristic roughness. If a glass is formed from a supercooled liquid state, surface tension effects can produce glass surfaces with nearly atomic-level smoothness. The roughness of a melt-formed or reflowed glass surface is determined by surface capillary waves, which are small amplitude fluctuations at a liquid surface that become frozen in place at T_g [41.31]. The resulting root mean square (RMS) roughness is approximately given by [41.41]

$$\sigma \approx \sqrt{\frac{k_B T_g}{\gamma(T_g)}} \,, \tag{41.6}$$

where $\gamma(T_g)$ is the surface tension of the supercooled liquid at T_g. For silica glass, this equation predicts RMS roughness on the order of 0.1 nm or less, and the correlation length of this inherent roughness is estimated to be as small as 3 nm [41.29]. Note that glasses with lower T_g and/or higher surface tension can in theory exhibit even lower values of surface roughness. Interestingly, sub-nm surface roughness has been experimentally verified for both melt-formed and fractured surfaces of silica glass [41.41] and indirectly from loss measurements in photonic crystal fibers [41.31]. Sub-nm roughness has also been determined for wet-etched surfaces of SiO_2 glass [41.42] and is not untypical for glass films deposited by evaporation.

The smoothness of glass surfaces has important implications for realization of low-loss microphotonic devices, as evidenced by several recently reported results. While little work has been conducted on small core, high-index-contrast planar waveguides in glass,

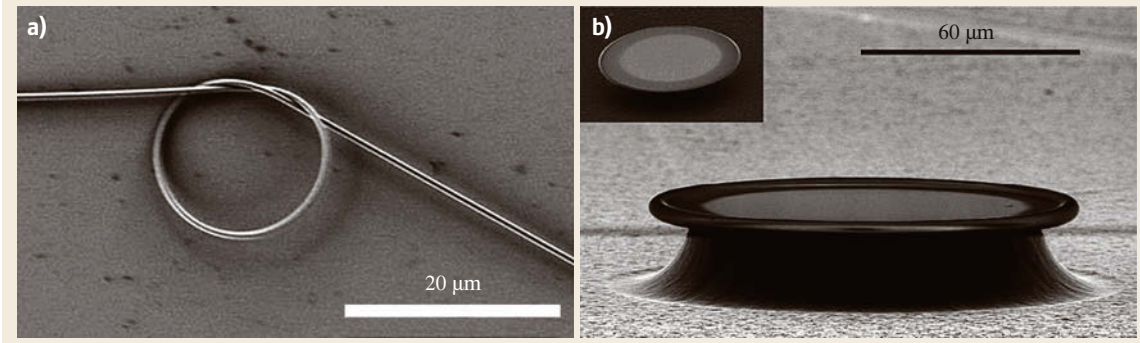

Fig. 41.4 **(a)** A submicron silica glass wire with sub-nm surface roughness is shown. (After [41.30]). **(b)** A silica glass toroid sitting atop a silicon post is shown. The atomic-level smoothness of the toroid surface was achieved using a selective reflow process. (After [41.43])

a method for fabricating submicron silica wires was recently reported [41.30] (Fig. 41.4). The authors estimated the RMS surface roughness of their wires to be less than 0.5 nm, and demonstrated losses on the order of 1 dB/cm at 633 nm for 400 nm diameter wires. Sub-nm surface roughness has also been measured in the case of sol–gel glass microlenses formed by a reflow process [41.33]. Silica-glass-based microsphere cavities, typically formed by melting the end of fused silica fiber, exhibit Q factors of nearly 10^{10} [41.28, 29], the highest for any solid state microcavity. Recently, this concept has been extended [41.27, 43] to the manufacture of silica toroid microresonators on a silicon substrate (Fig. 41.4). The latter devices exhibit Q factors exceeding 10^8. Finally, glass-based photonic crystal fibers have been demonstrated to exhibit scattering loss near fundamental limits set by surface capillary waves [41.31]. This last result contrasts with the situation mentioned above for semiconductor photonic crystals, which to date are significantly compromised by optical scattering.

In summary, processing enabled by the glass transition clearly offers unique benefits for manufacture of microphotonic structures. It is necessary to add a caveat to this discussion, however. Many amorphous materials are conditional glass formers, and do not offer the full range of processing advantages outlined above. As an extreme example, amorphous silicon films typically crystallize at temperatures well below their effective glass transition temperature [41.18], and are not amenable to reflow processes. To varying degrees, this is true of many *glassy* films used in integrated optics, such as silicon oxynitride and alumina. Further, the tendency towards crystallization varies greatly even amongst the traditional glass formers, as discussed below. Thus, chalcogenide and fluoride glasses will not generally support the range of viscosity control that enabled many of the SiO_2-based devices mentioned. Having said that, novel techniques can sometimes circumvent crystallization problems. For example, pressure can be used as a tool for forming glass devices at temperatures below the onset of severe crystallization (but high enough to enable the glass to flow). Chalcogenide glass-based lenses molded by the application of pressure and temperature are now commercially available [41.44, 45]. Another interesting example is the recent work on extruded channel waveguides reported by *Mairaj* et al. [41.46]. Finally, much research has been directed at the fabrication of microphotonic elements in organic glasses by hot embossing [41.11]. In this technique, a hard master (such as a silicon wafer) is pre-patterned with the negative image of the desired photonic circuitry. The glass is heated above T_g and the master is pressed against the glass such that the image of its pattern is transferred to the softened glass. While studied mainly in polymer, this technique might also be applicable to low-cost fabrication of photonic structures in *soft* inorganic glasses.

41.1.2 Metastability

A glass is a metastable material, having been frozen as an amorphous solid possessing excess internal energy relative to the corresponding crystal. Metastability is a double-edged sword. On the one hand, it presents technological limitations with respect to the processing and use of a glass device. As an example, it is well known that commercial introduction of organic glass (polymer)-based optical devices has been hindered by poor stability of many polymers at elevated temperatures or under exposure to high intensity light. On the other hand, metastability offers unique options for fabrication and optimization of photonic microstructures. Specifically, glass properties (optical, mechani-

cal, chemical) can often be tailored or adjusted by the careful addition of energy, in the form of heat, light, electron beams, or ion beams. An example is provided by the commercially important fiber Bragg gratings (FBG), wherein UV light is used to induce a stable refractive index change in the Ge-doped core of a standard SiO_2-based fiber. In the following subsections, the implications of metastability for glass-based integrated photonics are discussed.

Devitrification

Well below its glass transition temperature, a glass sits in a local energy minimum and is impeded by its own viscosity from reaching the lower energy crystalline state. A frequently cited example is that of silicate glass windows in ancient buildings, which have not exhibited any significant crystallization. However, addition of sufficient energy (such as heating a glass to some temperature above T_g) can result in crystallization of a glass. Controlled crystallization is a technologically useful means of modifying the mechanical, thermal, or optical properties of a glass, used in the production of glass-ceramics. However, devitrification produces a polycrystalline material, increases optical scattering loss, and is usually a problem to be avoided in manufacture of photonic devices.

As mentioned in Sect. 41.1.1, crystallization tendencies vary widely between various glass systems. The difference between the onset temperature for crystallization and T_g, $\Delta T = T_x - T_g$, is one of the parameters that define the stability of a particular glass. The high stability against devitrification of silicate glasses is one of numerous reasons that they have traditionally dominated glass technology. This stability underlies the manufacture of the structures discussed in Sect. 41.1.1. Other glass forming systems have lower stability against devitrification, often making their technological application a greater challenge [41.46, 47]. For example, a major research thrust in the field of fluoride and chalcogenide glass fibers is the identification of new compositions that exhibit improved stability against crystallization during the fiber drawing process [41.48].

For integrated optics, this form of stability is not always so critical. Amorphous thin films created by chemical vapor deposition, sputtering, evaporation, etc. can often be processed at temperatures below the onset of any significant crystallization. This enables the use of conditional glass formers, such as Si_3N_4, Al_2O_3 and semiconductors, in their amorphous state. However, it is interesting to review the early development of integrated optics, much of it focused on the identification of suitable thin film materials. Studies [41.49–51] that compared waveguide fabrication in polycrystalline (ZnO, ZnS, Al_2O_3, etc.) and amorphous (Ta_2O_5, polymer, sputtered glass) thin films showed that losses were orders of magnitude higher for the polycrystalline films. The lowest losses were initially obtained for polymer films [41.50], attributed to their amorphous structure and the smoothness of surfaces arising from spin casting of films.

If present, uncontrolled crystallization within films can be a dominant source of propagation loss [41.52]. For conditional glass formers, such as Al_2O_3 and TiO_2, crystallite formation must be carefully avoided during the deposition process [41.53]. While less of an issue for natural glass formers, the possibility for crystallization must always be considered when a glass film is subjected to high-temperature processing steps.

Structural Relaxation

Having been frozen in some metastable configuration at the time of formation, an amorphous solid will always be subject to some degree of aging (changes in the material properties on some time scale). At temperatures below T_g, the glass is usually inhibited from crystallization by a significant internal energy barrier. However, subtler changes in the network structure can occur, such as the transition from the initial state to a more stable (but still amorphous) second state. This so-called structural relaxation is manifested in many ways – experiments often probe the change in time of specific volume, structural signatures (such as by Raman spectroscopy), or optical properties of the glass. The rate of structural relaxation is highly dependent on temperature, being relatively fast at temperatures near T_g and significantly slower for temperatures far below T_g [41.18]. In fact, annealing of glasses at a temperature near T_g is a standard technique used to promote rapid structural relaxation and lessen the dependence of material properties on the processing history [41.6]. In many cases, this annealing step is not practical, and structural relaxation over the in-use lifetime of a glass-based device must be considered.

As the following discussion will illustrate, the rate of structural relaxation at temperature T_1 exhibits a logarithmic dependence on the temperature difference $T_g - T_1$. Thus, T_g is an important parameter in characterizing the long-term stability of a glass component. For example, SiO_2 has a very high T_g ($\approx 1100\,^\circ C$) and does not exhibit significant relaxation at room temperature, either on the time scale of typical experiments or over the typical lifetimes envisioned for glass devices. In fact, aging effects in silica fibers are predominately associated with the growth of defects formed in the glass at the time of manufacture. Environmental moisture is a particular contributor to this aging process. On the

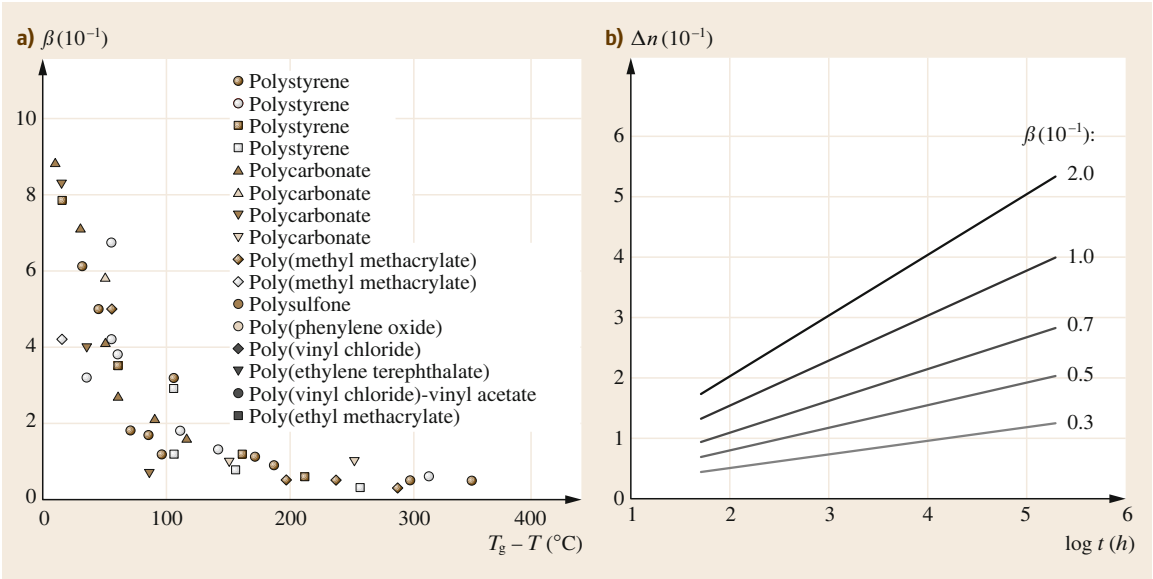

Fig. 41.5 **(a)** A plot of the structural relaxation rate parameter versus the supercooling temperature for a wide range of organic glasses is shown. **(b)** The predicted change in refractive index versus time for an organic glass, with the rate constant β as a parameter. (After [41.54])

other extreme, structural relaxation in low T_g organic glasses is known to be an issue, and intrinsic aging effects in polymers have been widely studied [41.55]. In particular, low T_g glasses exhibit densification with time (relaxation of their specific volume) and a corresponding change in their refractive index. This is a particular concern for interferometric optical devices (gratings, resonators, Mach–Zehnder interferometers), which necessitate tight control of material indices.

Volume relaxation can be characterized by a rate parameter β, defined as

$$\beta = \frac{1}{V}\left[\frac{\partial V}{\partial(\log t)}\right]_{P,T} , \tag{41.7}$$

where V is volume, t is time, P is pressure, and T is temperature. Using the Lorentz–Lorenz expression, the following relationship has been derived from (41.7) [41.54]

$$\left[\frac{\partial n}{\partial(\log t)}\right]_{P,T} = \frac{-\beta\left(\frac{\partial n}{\partial T}\right)_{P,t}}{\alpha} , \tag{41.8}$$

where n is refractive index, $\partial n/\partial T$ is the thermo-optic coefficient, and α is the volume coefficient of thermal expansion. *Zhang* et al. [41.54] further showed that, for polymers, β is approximately a universal function of $T_g - T_1$ as shown in Fig. 41.5. This implies that the time rate of change of refractive index due to structural relaxation is strongly correlated with the parameter $\Delta T_{SC} = T_g - T_1$, termed the supercooling temperature. They also assessed the implications for polymer-based telecommunications devices, concluding that T_g needs to be higher than 300 °C for many applications. This result provides a nice illustration of the impact of T_g on device stability.

While it is not necessarily reasonable to extend the foregoing results directly to inorganic glasses, the essential features of structural relaxation will be similar. The chalcogenide glasses in particular are sometimes called inorganic polymers, partly because of their softness and mechanical flexibility relative to silica-based glasses. Further, the range of T_g for chalcogenide glasses ($\approx$ 50–550 °C) is similar to that of organic polymers, and studies on chalcogenide glasses [41.19] support the conclusion that structural relaxation would present similar restrictions on inorganic and organic glasses. Thus, lifetime restrictions due to relaxation should be considered in the application of any glass having relatively low T_g, including chalcogenide glasses, fluoride glasses, and many nonsilicate oxide glasses [41.6].

Both the processing temperatures (during manufacture) and the in-use temperatures are important considerations in assessing the stability of a glass. Telecommunication devices are typically designed to withstand in-use temperatures between −40 and 85 °C [41.56].

As an example of a more demanding application, it has been proposed that glasses are good candidates for fabrication of integrated photonic elements on future integrated circuit chips [41.57]. In-use temperatures on modern microprocessors can reach 100–200 °C.

Finally, it should be noted that any energy applied to the glass (light, electron beams, etc.) might induce structural relaxation. This has been most widely studied for the chalcogenide glasses, which exhibit a wide array of photoinduced structural changes [41.58]. A fascinating example is the so-called photoinduced fluidity phenomenon [41.59], in which intense sub-bandgap light can reduce the viscosity of a chalcogenide glass by several orders of magnitude (causing the glass to flow or melt). This effect is completely athermal, and in fact is often enhanced at low temperatures. While an extreme example, it illustrates the possibility of aging effects due to nonthermal processes in glass devices. For photonic devices, the main concern is usually the effect of light exposure over the in-use lifetime.

Metastability as Enabler

One highly desirable implication of metastability is the possibility for direct patterning of photonic structures in glasses using energetic beams (electron beams, ion beams, light). These effects can also be exploited for postfabrication trimming of devices [41.60], which is important since many optical components have tolerances beyond the capabilities of practical fabrication processes.

Beam-induced effects in glasses are generally linked to their random network structure. That is, unlike crystals, glasses contain a range of internal *defects* – wrong bonds, dangling (missing) bonds, impurity atoms that act as network modifiers, as well as their inherent variation in bond angles. Addition of energy can cause a glass to undergo a transition from one metastable state to another. This transition is often accompanied by a change in the density of defects or by a structural change – rearrangement or reorientation of bonds. Associated with these structural changes are changes in the physical, chemical, and optical properties of the glass. Most existing knowledge about these induced structural changes is of an empirical nature, whereas the underlying physical mechanisms are still the subject of research.

The ability to induce transitions between metastable states is probably a universal property of amorphous matter. Perhaps for practical reasons, such as the availability of light sources of suitable wavelength, metastability was initially studied in amorphous semiconductors and low-bandgap chalcogenide glasses. It should be added, though, that chalcogenide glasses

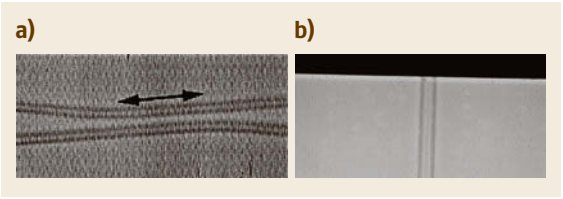

Fig. 41.6 (a) A directional coupler is shown, as written in a multicomponent silicate glass by an ultrafast Ti:sapphire laser. (After [41.64]). The *black arrow* indicates the coupling region. **(b)** Microscope image of a rib waveguide formed by direct exposure of a chalcogenide glass (As_2Se_3) in a UV mask aligner, followed by wet etching. (After [41.65])

seem to be unique with respect to the variety of induced structural changes they exhibit or at least the magnitude of those changes [41.58]. This might be related to the relatively weak, highly polarizable covalent bonds that are characteristic of chalcogenide glasses. Nevertheless, the later discovery [41.61] of photoinduced refractive index changes in Ge-doped silica glass prompted a huge research and development effort because of the technological importance of silicate glasses. The main outcome of this work was the fiber Bragg grating (FBG), which is a critical component in modern telecommunications and sensing networks. FBGs are manufactured by inducing a quasi-permanent index change within the Ge-doped core of a standard silica fiber, by exposure to a UV laser beam. Writing wavelengths are in the 150–350 nm range, corresponding to photon energies below the nominal bandgap of SiO_2. The mechanisms underlying the index increase are still debated [41.12, 61]. However, it is believed that contributing factors are absorption by defects in the glass (possibly generating further defects) and densification due to some sort of structural relaxation [41.62]. Typical index changes for standard fiber cores are in the 10^{-4}–10^{-3} range, but several techniques (addition of other dopants, hydrogen-loading, etc.) have been developed to enable changes as high as 10^{-2}. Given the discussion in the preceding section, it is reasonable to ask whether photoinduced changes are themselves stable. The answer, in some cases, seems to be yes. Researchers have concluded that fiber Bragg gratings can have an operational lifetime of greater than 20 years, even at elevated temperatures of 80 °C [41.63].

Photosensitivity has been widely explored as a means to directly pattern integrated optics devices, especially in silica-based glasses [41.66]. In general, direct patterning is induced using photon energies close to the nominal bandgap energy of the glass or using

intense light of lower photon energy [41.62]. In the latter case, photoinduced effects arise from nonlinear effects such as multiphoton absorption. In particular, the widely available Ti:sapphire laser has been applied to the writing of microstructures in a variety of glasses [41.64]. Because of the nonlinear nature of the writing process, writing with sub-bandgap light allows the direct patterning of 3-dimensional structures (Fig. 41.6).

Photosensitivity has been demonstrated within all of the standard glass families, and in many other amorphous thin films (Sect. 41.2). Because of their large photosensitivity, direct patterning of integrated optics structures in chalcogenide glasses is possible using low-power light sources [41.65, 67].

41.1.3 Glass as Host Material

For completeness, it should be mentioned that glasses are unique in their ability to incorporate a wide range of dopants, sometimes in very high concentration. This is related to the random network structure of a glass. Foreign species are much more likely to find a suitable bonding site, or simply space to reside, inside a glass versus a crystal. These foreign species can be rare-earth ions, transition-metal ions, or semiconductor or metal nanoparticles, for example. As a result, a glass provides significant scope for active functionality. We can transform a passive glass into a laser glass, a nonlinear optical glass, or a magneto-optic glass, for example, by appropriate doping [41.3, 6].

41.2 Glasses for Integrated Optics

In general, thin films can be amorphous, polycrystalline, or crystalline. *Tien* and *Ballman* [41.51] provided an early review of waveguide results achieved for various materials lying within each of these categories. Unless the crystal grain size is sufficiently small relative to the wavelength of interest [41.53], polycrystalline films are too lossy for integrated optics. It should be noted that high attenuation might be tolerable if circuit length is sufficiently short. The present discussion is concerned with amorphous films, which Tien further subcategorized as low index ($n < 1.7$), medium index ($1.7 < n < 2$), and high index ($n > 2$). For convenience, we will follow a similar approach in the following sections. This categorization is somewhat arbitrary, especially when considering material systems (such as the silicon oxynitride system) that enable a range of refractive index. It is interesting to note that 1.7 is the approximate upper limit for the refractive index of organic glasses [41.56]

As noted in Sect. 41.1, increased circuit density is one of the primary goals of integrated optics research [41.12]. Whether employing traditional total internal reflection effects or photonic bandgap materials, increased density relies on high index contrast between at least two compatible materials. Note that the terminology *high index* and *high index contrast* are rather imprecise. For example, in silica PLC technologies core-cladding index differences of $\Delta n \approx 0.02$ have been labeled as *superhigh* index contrast [41.13]. This is a very small value, however, relative to the index contrasts that characterize SOI photonic wire waveguides [41.36].

41.2.1 Low-Index Glassy Films

SiO_2-Based Glasses

As mentioned in the introduction, the SiO_2 on silicon PLC system is the most widely used and developed glass-based integrated optics platform. PLC development (mainly in the 1990s) was driven by fiber-optic long-haul communication systems, especially the emergence of wavelength-division multiplexing (WDM). Various devices, but especially arrayed-waveguide grating (AWG) wavelength demultiplexers, were developed to a very high degree of sophistication by the telecommunications industry. Good early [41.24] and recent [41.12, 13] reviews are available in the literature. A brief overview of the technology is given below, as it illustrates some of the advantages and challenges associated with glass-based photonic integration.

As mentioned in Sect. 41.1.1, commercial PLC waveguides are fabricated primarily by FHD [41.13] or by CVD [41.12]. In addition, considerable research has been conducted on sol–gel synthesis [41.68], with the aim of reducing fabrication costs and providing greater flexibility over the choice of glass compositions. Typically, the undercladding is pure silica glass. To raise its refractive index, the core layer is doped with Ge or P. Ge-doped SiO_2 is known for its photosensitivity, as discussed in Sect. 41.1.2. Addition of P lowers the viscosity and characteristic reflow temperature, enabling the processing options discussed in Sect. 41.1.1. Typical relative index offset Δ between the core and cladding is in the 0.3–2% range, corresponding to minimum waveguide bend radius R in the 2–25 mm range [41.13]. After reactive ion etch-

ing (RIE) to form an approximately square waveguide core, an upper cladding is deposited and subjected to heat treatment. The upper cladding is often a borophosphosilicate glass (BPSG), partly to enable reflow. Further, the B and P dopants have opposite effects on refractive index allowing a nearly symmetric waveguide structure to be obtained.

Given the target applications, it is not surprising that PLC technology placed a great emphasis on efficient coupling between the integrated waveguides and external fiber waveguides. Thus, waveguide cross-sectional dimensions and refractive index contrast between core and cladding layers were tailored to provide a good impedance match (low reflection and good modal overlap) to standard fiber. By employing essentially the same glass (doped SiO_2) as that used to construct fiber, it is even possible to achieve intimate reflowed (fusion type) coupling between the integrated and fiber guides [41.24]. The emphasis on impedance matching is due to the great importance of minimizing insertion loss in fiber systems, but presents some practical limitations:

1. The relatively low index contrast ($\approx 10^{-3}$) between core and cladding necessitates thick glass films. For example, the undercladding or buffer layer, often a thermally grown SiO_2 layer, must typically exceed 12 μm in order to negate radiation losses into the high-index silicon substrate. Further, high-temperature anneals (typically 900–1150 °C) are required to drive out hydrogen impurities and to reflow the core and upper cladding layers. The combination of thick films, high-temperature anneals, and thermal expansion mismatch can result in wafer bending and damage to the glass films. This is partly alleviated in practice by depositing identical layers on both sides of the Si wafer [41.12], which adds cost and complexity.
2. Since modal area and minimum bend radius scale inversely with core-cladding index contrast, traditional PLC waveguides do not support high-density optical integration. As mentioned above, index contrasts in the 0.3–2% range correspond approximately to bending radii in the 25–2 mm range [41.13].

In recent work at Corning [41.69], very low-loss (< 0.1 dB/cm) waveguides and ring resonators were realized in plasma enhanced chemical vapor deposition(PECVD)-grown silica-germania waveguides having an index contrast as high as 4%. Such high index contrasts can accommodate bending radii of less than 1 mm, which is comparable to the range explored recently by IBM researchers using silicon oxynitride materials [41.70].

Amorphous Aluminium Oxide

Sapphire (crystalline Al_2O_3) is amongst the most important solid-state laser hosts. Alumina (polycrystalline or amorphous Al_2O_3) is an important industrial material in its own right, possessing outstanding mechanical and thermal properties [41.21]. Amorphous Al_2O_3 films are of interest for integrated optics for several reasons [41.53]. First, the refractive index is relatively high (although falling within the low index range specified above), typically $n \approx 1.65$. Second, Al_2O_3 is an excellent host for rare-earth and transition-metal dopants. As discussed in Sect. 41.3, rare-earth dopants of interest are typically trivalent, matching the valency of Al ions in Al_2O_3 [41.71]. As a result, rare-earth ions can be incorporated easily into the alumina matrix. In short, Al_2O_3 can homogeneously dissolve large concentrations of rare-earth ions and is therefore of interest for realization of integrated amplifiers and light sources. Finally, Al_2O_3 films typically have excellent transparency from the UV to mid-IR range.

Fluoride Glasses

Heavy-metal fluoride glasses (typically fluorozirconate glasses) such as ZBLAN have been widely studied since their discovery in 1974 [41.48]. One of their outstanding attributes is a wide transparency range, extending from the UV well into the mid-IR (Fig. 41.1). They have received considerable attention as fiber optic materials, because theory predicts a minimum absorption well below that of silica glass. Further, rare-earth ions exhibit the greatest number of useful radiative transitions when embedded in fluoride glasses [41.72]. This is due to their wide transparency window and low characteristic phonon energies (Sect. 41.3).

Fluoride glasses typically have refractive indices in the 1.47–1.57 range, which is advantageous in terms of being well matched to silica glasses. Thin film deposition of these complex multicomponent glasses is difficult, and thermal expansion mismatches with standard substrates create further challenges. For these reasons, fluoride glasses have not been widely explored for applications in integrated optics. The so-called PZG fluoride glasses (PbF_2-ZnF_2-GaF_3) have been successfully deposited using straightforward evaporation techniques, enabling relatively low-loss waveguides and erbium-doped amplifiers on a silicon platform [41.73].

41.2.2 Medium-Index Glassy Films

Silicon Oxynitride

Silicon oxynitride (SiON) films are generally deposited by a CVD technique. The promise of this material system for integrated optics was identified in early

work [41.51]. One of the main attributes of SiON is that it is a standard material system employed in silicon microelectronics, and the thin film technology has been developed accordingly [41.53, 70]. Because of this, SiON is currently being studied as potential material for on-chip interconnects [41.57]. Further, the system enables a continuous range of refractive index from approximately 1.45 (SiO_2) to 2 (Si_3N_4) at 1550 nm wavelength. This index range has been extended to approximately 2.2 by deposition of nonstoichiometric, silicon-rich nitride films [41.74]. SiON and SiN have been amongst the most explored materials for realization of microring resonator structures [41.60, 74].

As an optical material, SiON has some drawbacks. The main one is the presence of hydrogen impurities in films deposited by traditional techniques. Overtones due to hydrogen bonds (mainly N–H and O–H) can produce impractically large values of loss in the 1300 and 1550 nm telecommunications bands [41.69]. Long term, high-temperature annealing (typically at $>$ 1000 °C) is required to reduce this loss. Interestingly, structural relaxation on the time scale of hours and days has been observed in such annealed films [41.53]. Perhaps related to this metastability, UV light has been used as a means to trim the refractive index of SiN-based microring resonators [41.60]. Modified deposition processes that can produce SiON films having low stress and low hydrogen content (without requiring a high temperature annealing step) have been reported recently [41.70, 74]. However, inherent film stress can limit the maximum thickness to a few hundred nanometers in some cases [41.57].

41.2.3 High-Index Glassy Films

Amorphous Metaloxides

Many amorphous metaloxides (Y_2O_3, Nb_2O_5, Ta_2O_5, etc.) have traditionally been used as high index layers in optical thin film stacks [41.56]. It is logical to look at these materials in the hunt for high-index thin films for integrated optics. Often these oxides are miscible with SiO_2, making it possible to tune the refractive index and other material properties over a range of values (as in the case of silicon oxynitride) [41.75].

TiO_2 films are used as dielectric layers, optical coatings, and to protect underlying materials from mechanical damage or corrosion [41.53]. The high dielectric constant of TiO_2 is widely exploited in microelectronics applications. It also has useful optical properties, including a refractive index as high as 2.6 (depending on film deposition details) and good transparency from the UV to mid-IR. The TiO_2-SiO_2 material system has good properties for sol-gel synthesis of thin films [41.68]. Integrated waveguides based on TiO_2 have been studied [41.53, 75], and AWG devices in TiO_2-rich oxide glass with $n \approx 1.9$ were recently reported [41.76].

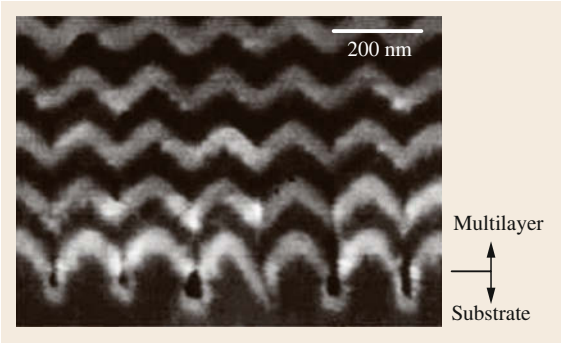

Fig. 41.7 A three-dimensional photonic crystal fabricated using the autocloning growth technique is shown. The *bright* and *dark* layers are TiO_2 and SiO_2 glass, respectively. (After [41.80])

Ta_2O_5 (with $n \approx 2.1$) is another well-studied material, used for example as a high dielectric constant material in microelectronics. It has low absorption in the visible to near infrared wavelength range, and has been recently studied as a material for active integrated optics [41.77, 78]. Further, Ta_2O_5/SiO_2 has been applied to the study of compact microring resonators [41.79].

TiO_2 and Ta_2O_5 have been used in the fabrication of three-dimensional photonic crystals with fundamental bandgaps in the visible and near infrared [41.80, 81]. An example is shown in Fig. 41.7.

Heavy-Metal Oxide Glasses

These glasses are based primarily on the oxides of bismuth (Bi_2O_3), lead (PbO), tellurite (TeO_2) and germanium (GeO_2) [41.9]. Amongst these heavy-metal oxide glass families, except for GeO_2 the majority of glass-forming compositions are conditional glass formers. They have relatively low phonon energies and transmit further into the infrared than most oxide glasses [41.82]. They also have interesting magneto-optic [41.6] and nonlinear optical [41.3] properties.

The major difference between the classical network forming like bismuth, silica and tellurite glass families is the presence of multiple structural units (TeO_3, TeO_4, and $TeO_{3+\delta}$ in tellurite); each of which has a lone pair electron site which may bridge with polyvalent cations and enable network bridging with phosphates, germanates, tungstates, and borates[41.83].

While TeO_2 is a conditional glass former, the addition of other oxides can result in stable glasses with many interesting properties [41.82]. They typically have tunable refractive index in a wide range from 1.68 to greater than 2 [41.84], low phonon energy,

large optical nonlinearities, and a high acousto-optic figure of merit. Further, they have been widely studied as hosts for rare-earth ions. Of particular interest has been the wide bandwidth of the 1550 nm emission exhibited by erbium in tellurite glass [41.85]. Because of these numerous attractive properties, tellurite glasses and amorphous TeO_2 films ($n \approx 2.2$) have received some attention for applications in integrated optics [41.86].

Chalcogenide Glasses

Many chalcogenide alloys, based on S, Se, or Te, are excellent glass formers. In fact, Se is the only element able to easily form a glass on its own [41.19]. These glasses are characterized by very low phonon energies, good transparency in the mid-infrared, and a wide array of beam-induced structural changes [41.58]. Further, chalcogenide glasses are essentially amorphous semiconductors, with an electronic absorption edge typically in the visible to near infrared. Related to this, they have very high refractive indices, ranging from 2.2 for sulfide glasses to greater than 3 for some telluride glasses. They are currently of industrial interest for night-vision optics [41.44, 45], fibers for infrared transmission [41.48], and optical and electronic memory elements [41.58].

Chalcogenide glasses have many appealing features for integrated optics. High-quality thin films can often be deposited by straightforward techniques such as evaporation or sputtering. Their high indices make them suitable for realization of compact waveguides [41.65] and photonic crystals [41.87]. Their beam-induced properties enable many unique processing options. Some chalcogenide alloys have good potential as laser glasses [41.48], with the ability to uniformly dissolve large concentrations of rare-earth ions. Perhaps of greatest interest, the chalcogenide glasses are amongst the most promising materials for nonlinear integrated optics [41.88, 89]. On this last point, several chalcogenide glasses have ultrafast optical Kerr response 2 to 3 orders of magnitude higher than that of SiO_2, while satisfying basic figure of merit criteria for all-optical switching. Results for metal-doped chalcogenide glasses [41.89] suggest even higher nonlinearities might be attainable. Combined with the possibility of realizing highly confining waveguides, this makes chalcogenide glasses one of few material systems that can realistically satisfy long-standing goals for nonlinear processing in integrated optical circuits. For example, it has been estimated [41.88] that 1 pJ pulses of 1 ps duration (≈ 1 W peak power) could induce phase shifts (due to self-phase modulation) greater than π in feasible chalcogenide glass waveguides with length on the order of a few centimeters. This is predicated on realization of low-loss waveguides with modal area of $\approx 1\,\mu m^2$. Recent experimental results suggest that this goal is within reach [41.65].

41.3 Laser Glasses for Integrated Light Sources

Active functionality includes means to generate and detect light (especially stimulated emission and absorption) and means to control (switch, modulate, etc.) light signals. Numerous material properties are employed in active photonics, including thermo-optic, acousto-optic, magneto-optic, electro-optic, and nonlinear Kerr effects. Many glasses have attractive thermo-optic or acousto-optic properties, and a few examples were cited in Sect. 41.2. Also in Sect. 41.2, some glasses with promising nonlinear optical properties were discussed. Elsewhere in this volume, *K. Tanaka* has provided an excellent review of nonlinearities in photonic glasses. A recent, thorough review of magneto-optic glasses is also available [41.6].

Arguably, the most critical element for photonic integration is an integrated light source. Rare-earth-doped glasses are well-established laser media, used especially for the realization of bulk and fiber lasers. Considerable effort has been directed towards development of integrated amplifiers and lasers based on such glasses. In the following, we attempt to highlight some ways in which light sources based on glasses are uniquely enabling, relative to those based on crystalline materials. The performance advantages discussed below combined with the properties discussed in earlier sections (fabrication options) make glasses particularly attractive.

41.3.1 Advantages of Glass-Based Light Sources

Stimulated-emission devices in glass are almost always based on trivalent rare-earth dopants [41.6]. Thus, the term laser glass can usually be equated with the term rare-earth-doped glass. Rare-earth-doped laser glasses have been widely studied and reviewed [41.71, 72]. Further, recent and comprehensive reviews on Nd- and Er-doped integrated glass amplifiers and lasers are available [41.6, 90]. Relative to single crystal hosts, glass hosts result in rare-earth ions exhibiting broadened luminescence lines and lower peak stimulated-emission cross-sections [41.72]. This property is a result of the random network structure of glasses; embedded rare-earth ions exist in a range of local environments. The

broadened, weaker emission is of great importance for the realization of broadband, low-noise fiber amplifiers.

It should be noted that the semiconductor injection laser is an extremely advanced technology, and is the dominant type of integrated light source at present and for the foreseeable future. Semiconductor lasers have important advantages over any glass-based device demonstrated to date. First, semiconductor gain media typically have gain coefficients of the order $\approx 100\,\mathrm{cm}^{-1}$ [41.23]. By comparison, glasses require high rare-earth dopant concentration to achieve gain coefficients exceeding $1\,\mathrm{cm}^{-1}$. Thus, semiconductor optical amplifiers (SOAs) and lasers have cavity lengths measured in tens to hundreds of μm while it is typical for glass waveguide amplifiers and lasers to be measured in cm. Second, semiconductor light sources are pumped electrically while glass devices are typically pumped optically. Electrical pumping is highly desirable for optoelectronic integration of photonic devices on electronic chips. However, as discussed below, integrated glass waveguide lasers have important advantages of their own [41.91].

The lifetime of the metastable lasing level in rare-earth-doped glasses is usually on the order of ms, much longer than the ns lifetimes typical of semiconductor gain media. This long lifetime implies that the gain does not change rapidly with variations in input power (pump or signal). This is an essential feature of the commercially important erbium-doped fiber amplifier (EDFA); the long lifetime ($\approx 10\,\mathrm{ms}$) of the $^4\mathrm{I}_{13/2}$ level of erbium in silicate glass contributes to low-noise operation, high pump efficiency, and low crosstalk between wavelength channels in a WDM system [41.92]. Further, since the relaxation oscillations in glass waveguide lasers occur at relatively low frequency, glass lasers can be mode-locked at correspondingly much lower repetition rates compared to semiconductor lasers [41.91]. This can enable much higher peak intensities from the glass laser.

Related to the discussion in Sect. 41.1, lower cavity loss (higher cavity Q) is generally possible for glass devices. Further, the long metastable lifetime of the rare-earth transition allows glass lasers to have linewidths approaching the Schawlow–Townes limit [41.93]

$$\Delta\nu = \frac{2\pi h\nu_0(\Delta\nu_\mathrm{c})^2}{P}\left(\frac{N_2}{N_2 - N_1}\right), \tag{41.9}$$

where ν_0 is the laser center frequency, P is the laser output power, N_2 and N_1 are the population densities of the upper and lower lasing levels, and $\Delta\nu_\mathrm{c} = (1/(\pi t_\mathrm{c}))$ with t_c the photon lifetime in the cavity. The linewidth ($\Delta\nu$) of a glass laser system and noise figure is underpinned by the uncertainty equation which is given by [41.94]

$$\Delta\varphi\Delta n \geq \frac{h}{4\pi}\,, \tag{41.10}$$

where $\Delta\varphi$ is the phase difference, and Δn is the population difference. The high Q of glass laser cavities coupled with relatively high output powers enables linewidths less than 10 kHz, orders of magnitude below that of semiconductor DFB lasers [41.91]. The high cavity Q and long metastable lifetime is also advantageous for achieving ultrastable passive mode-locking, with low timing jitter and pulse-to-pulse power variation.

Finally, glasses offer the possibility of integration on various substrates. While semiconductor lasers are inherently integrated structures, they are not easily transportable between platforms. For example, III–V semiconductor lasers have not shown great promise (in spite of heroic efforts in some cases) to satisfy the desire for a compact, truly integrated light source on the silicon electronics platform. Glasses (perhaps doped with semiconductor nanocrystals) are viewed by some as the more promising route to achieving such a goal [41.71].

41.3.2 Alternative Glass Hosts

The theoretical maximum gain (cm^{-1}) of a rare-earth-doped glass waveguide amplifier can be expressed [41.90] as $\gamma_\mathrm{p} = \Gamma\sigma_\mathrm{p}N_\mathrm{RE}$, where σ_p is the peak (versus wavelength) stimulated emission cross-section (cm^2) for the transition of interest and N_RE is the volume density (cm^{-3}) of the rare-earth ions. Γ is a dimensionless factor (lying between 0 and 1) that accounts for the spatial overlap of the waveguide mode (at the wavelength to be amplified) and the active ions producing the gain. It can be optimized through waveguide design, irrespective of the glass host, and will not be considered further here. The expression for γ_p neglects all waveguide losses (due to scattering, etc.) and assumes that all of the rare-earth ions have been promoted to the desired lasing level; i. e., a complete population inversion. It is therefore an ideal and unattainable limit, but is useful for framing the following discussion.

Since compactness is a central goal of integrated waveguide lasers, alternative glass hosts can be compared on the basis of the maximum gain (γ_max) that they enable in practice (for a given transition of a given rare-earth ion). Further, since low-noise operation relies on a near complete population inversion [41.90], it is desirable that $\gamma_\mathrm{max} \approx \gamma_\mathrm{p}$. In simple terms, the glass should dissolve a large concentration of the rare-earth ion (high N_RE), should result in a large stimulated-emission cross-section for the desired transition, and should enable the

realization of a nearly complete population inversion. The importance of other practical considerations, such as stability, processing options, and physical properties of the glass, will depend on the intended application. Some hosts provide unique advantages, such as flexible pumping options, as discussed in Sect. 41.3.3.

As mentioned, laser transitions in glasses are generally provided by radiative decay between two energy levels of a trivalent rare-earth ion. Perhaps the most important example is the $^4I_{13/2}$ to $^4I_{15/2}$ transition of Er^{3+}, which produces luminescence in the 1500–1600 nm wavelength range. Once an ion has been promoted (by pumping) to the upper lasing level, it will eventually transition to another state by interactions with the glass, impurities in the glass, the photon fields (at the signal or pump wavelength), or with other rare-earth ions in its vicinity [41.72]. The metastable lifetime of the upper lasing level can be expressed [41.90]

$$\frac{1}{\tau} = A + W_{\mathrm{MP}} + W_{\mathrm{ET}} + W_{\mathrm{IMP}} \,, \tag{41.11}$$

where A is the effective rate of spontaneous radiative decay to all lower lying levels, W_{MP} is the rate of nonradiative decay due to multiphonon energy exchanges with the glass, W_{ET} is the rate of nonradiative energy transfer due to interactions between closely spaced rare-earth ions, and W_{IMP} is the rate of energy transfer to quenching impurity centers in the glass. The first three terms on the right will be discussed below. For the last term, a classic example is the quenching of the 1550 nm luminescence band of erbium due to resonant energy transfer to OH^- impurities in silica glass [41.72].

The choice of a particular glass host will impact several important properties of a given transition: pumping efficiency, peak gain, linewidth, metastable lifetime, etc. Alternative glasses can be compared on the basis of a few key parameters, as discussed in the following subsections. Representative data for erbium in various glasses is given in Table 41.1.

Stimulated-Emission Cross-Section

Stimulated transitions of rare-earth ions in glass tend to be predominately driven by electric dipole interactions [41.72]. For a given transition of interest, the spontaneous-emission probability can be expressed in cgs units as [41.6, 95]

$$A = \frac{64\pi^4 e^2 \chi}{3h(2J+1)\lambda_p^3} S \,, \tag{41.12}$$

where J is the total angular momentum of the upper lasing level, λ_p is the peak emission wavelength, and χ is the local field correction factor. For electric-dipole interactions of an ion in a dielectric medium, $\chi \approx n((n^2+2)^2)/9$, with n the refractive index of the host glass. S is the quantum-mechanical line strength for the transition. Further, the peak stimulated-emission cross-section can be expressed in terms of the spontaneous-emission probability

$$\sigma_p = \left(\frac{\lambda_p^4}{8\pi c n^2 \Delta\lambda_{\mathrm{eff}}}\right) A \,, \tag{41.13}$$

where $\Delta\lambda_{\mathrm{eff}}$ is the effective linewidth of the transition, n is refractive index and c is the vacuum speed of light. From (41.12) and (41.13), the host-dependent factors that influence σ_p are the refractive index, the line strength, the effective linewidth, and to a lesser extent the peak emission wavelength (which typically varies only slightly between different hosts). The local field correction factor is significant in hosts with large refractive index, and can result in an enhancement of the stimulated-emission cross-section and a reduction of the radiative lifetime. This is especially true for chalcogenide glass hosts, which typically have refractive index in the 2–3 range.

Metastable Lifetime

In the limit of low rare-earth-dopant concentration, W_{ET} in (41.11) is zero because the ions are sufficiently well separated to negate their interaction. If the difference in energy between the upper lasing level and the adjacent state is several times the effective phonon energy, then W_{MP} can be neglected to first order. Further neglecting impurity quenching, we can then assert that $\tau_0 \approx \frac{1}{A}$, where τ_0 is the metastable lifetime in the limit of low rare-earth concentration. From Einstein's relations, $A \approx \sigma_p$, so it follows that $\tau_0 \approx \frac{1}{\sigma_p}$. In short, hosts that result in an enhancement of the peak stimulated-emission cross-section (because of an enhancement of the electric-dipole interaction or because of a high local field correction factor) will also result in a reduction in metastable lifetime. In other words, both stimulated and spontaneous emission rates are enhanced.

The inverse scaling of stimulated-emission cross-section and metastable lifetime represents a tradeoff, as it is generally desirable for the lifetime to be as large as possible. Some of the advantages of long lifetime were discussed in Sect. 41.3.1. In addition, the pumping efficiency (gain per applied pump power) of a waveguide amplifier scales directly with τ [41.6, 90] and, therefore, the threshold for continuous wave (CW) lasing scales inversely with τ [41.96].

Concentration Quenching

Glasses differ greatly in the amount of a given rare-earth dopant that they are able to dissolve. To avoid

Table 41.1 Representative parameters for erbium ions embedded in various types of glass. (After [41.68, 71, 72])

Glass host	Refractive index n	Peak stimulated emission cross-section σ_p (10^{-21} cm^2)	Metastable lifetime τ (ms)	Quenching concentration ρ_q (10^{20} cm^{-3})	Effective luminescence bandwidth (nm)
Silica	1.46	7	12	–	11
Amorphous Al_2O_3	1.64	6	7.8	–	55
Aluminosilicate	1.5	5.7	10	3.9–6.0	43
Phosphate	1.56	8	10	3.9–8.6	27
Fluoride	1.53	5	9	3.8–5.3	63
Tellurite	2.1	13	3.3	–	80
Sulfide	2.4	20	2.5	3.2	–

problematic ion–ion interactions, the rare-earth ions should be incorporated homogeneously into the glass structure. In the extreme case of high concentration, the rare-earth ions will form microscopic clusters (phase separation). Such clustering is highly detrimental, as typically all of the ions within a cluster are effectively removed from the desired stimulated-emission process [41.90]. As is well known [41.71, 72], the onset of clustering occurs at quite small values ($\approx 0.1\%$) in pure silica glass. The addition of Al_2O_3 to SiO_2 allows silica-based fibers to dissolve a significantly higher concentration. For example, a value of 10–20 for the Al ion to Er ion concentration ratio has been shown to greatly reduce clustering of Er ions in silica glass [41.96]. Interestingly, the addition of Ga (with similar ratio) to chalcogenide glasses has been shown to provide a similar reduction in rare earth-ion clustering [41.48]. These additives essentially modify the glass network, and create sites for isolated rare-earth ions to be incorporated. For similar reasons, multicomponent aluminosilicate and phosphosilicate glasses have been favored in the development of integrated waveguide amplifiers, where the rare-earth concentration must be orders of magnitude higher than in fibers [41.90].

Even in the absence of significant clustering, ion–ion interactions can occur at high concentrations. This is simply due to the reduction in inter-ion spacing, and is exacerbated by any nonuniform (nonhomogeneous) distribution of the rare-earth ions in the glass host. These interactions are manifested by a reduction in the metastable lifetime, often well described by the semiempirical expression [41.68, 72]

$$\tau(\rho) = \frac{\tau_0}{1 + \left(\frac{\rho}{\rho_Q}\right)^p}\,, \tag{41.14}$$

where ρ is the rare earth-ion concentration, ρ_Q is the so-called quenching concentration, and p is a fitting parameter ($p \approx 2$ for interactions between pairs of ions). The parameter ρ_Q is useful for comparing glasses in terms of their ability to uniformly dissolve a given ion.

Table 41.2 Characteristic maximum phonon energies for a variety of glass hosts. (After [41.6, 72])

Glass host	Phonon energy (cm^{-1})
Borate	1400
Phosphate	1200
Silicate	1100
Germanate	900
Tellurite	700
Heavy-metal fluoride	500
Chalcogenide (sulfide)	450
Chalcogenide (selenide)	350

Phonon Energies

The characteristic phonon energies of a glass depend on the weights of its constituent atoms and the strength and nature (ionic or covalent) of its bonds. Typical values are shown in Table 41.2. The rate of multiphonon decay (W_{MP}) between two energy levels depends exponentially on the number of phonons required to bridge the energy gap. Thus, the phonon energy has a great impact on the ultimate efficiency of a desired radiative transition. Low phonon energy can be a good or bad thing, depending on the transition of interest and the particular pumping scheme.

Mid- to far-infrared transitions of rare-earth ions can exhibit reasonably high quantum efficiency in low phonon energy hosts, such as fluoride, tellurite, and especially chalcogenide glasses. If the same ions are embedded in silicate or phosphate glasses, these transitions are completely quenched by nonradiative processes at room temperature. For this reason, rare-earth-doped chalcogenide glasses are of interest for realization of long-wavelength amplifiers and lasers [41.48, 71]. Also unique to low phonon energy hosts is the possibility of efficient upconversion lasers [41.97]. In simple terms, the long lifetimes of numerous energy levels allows processes such as ion–ion interactions and excited state absorption (ESA) to efficiently populate the higher energy levels. By contrast, these levels are rapidly depopulated by phonons in oxide glasses. Conversely, population of the higher levels is highly detrimental if the desired transition is between two lower levels. For

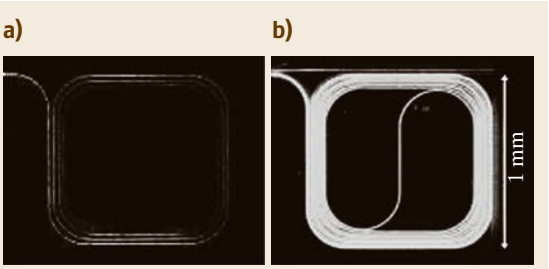

Fig. 41.8a,b Spiral geometry demonstrated for Al_2O_3-based waveguide amplifiers, where erbium was introduced by ion implantation **(a)** and co-sputtering **(b)**. The bright green emission is a result of ion–ion interactions causing up-conversion for the co-sputtered sample. (After [41.99])

example, the efficient pumping of EDFAs using 980 nm wavelength sources relies on the rapid decay (via multiphonon processes) of ions from the $^4I_{11/2}$ pumping level to the $^4I_{13/2}$ lasing level. In fluoride and chalcogenide glass hosts, ions raised above the $^4I_{11/2}$ level tend to become trapped in higher levels (so-called *population bottlenecking* [41.72]). Cerium co-doping has been shown to alleviate this problem [41.73]. Another approach is addition of light elements to the glass network, to increase the phonon energy [41.85].

41.3.3 Progress Towards Integrated Light Sources in Glass

Per the preceding discussion, important goals for glass-based lasers include size reduction and the need for simplified optical or (ideally) electrical pumping schemes. It should be noted that integration brings its own advantages. As is well known, waveguide lasers have greatly enhanced pump efficiency (gain per applied pump power) relative to their bulk solid-state counterparts. This is due to the confinement of the pump beam and the stimulated emission beam within a small volume. As explored recently in [41.98], this benefit scales with confinement. Amplifiers based on very high-index-contrast waveguides can have extremely high pump efficiency, as well as requiring only a small amount of wafer real estate. Thus, while the gain per unit length is limited by concentration quenching in rare-earth-doped glasses, devices can still be very compact through the use of folded spiral waveguide layouts as illustrated in Fig. 41.8 [41.99].

In terms of maximizing gain per unit length, phosphate glasses have produced the best results to date. This is due to their ability to uniformly dissolve large concentrations of rare-earth ions, and the high cross-sections exhibited by those ions. The high phonon energy can also be an advantage as discussed above. Phosphate glass disks (typically ≈ 1 mm thick) have been widely used for realization of compact microlasers [41.100] and ultrafast modelocked lasers with pulse length as short as 220 fs [41.101] and repetition rate exceeding 40 GHz [41.102]. Phosphate glass fiber lasers with a length of only 7 cm have recently generated 9.3 W of output power [41.103]. Sputtered phosphate glass waveguides have produced gains exceeding 4 dB/cm [41.104]. More recently, a phosphate glass co-doped with 8% erbium and 12% ytterbium was used to realize ion-exchange waveguides exhibiting 4.1 dB gain in only 3 mm length [41.105]. At such high concentrations, the rare-earth constituents can hardly be called dopants as they exceed the concentration of some of the host glass constituents.

On the theme of simplified pumping options, so-called broadband sensitizers [41.106] are of great interest. A broadband sensitizer is essentially a co-dopant that is able to efficiently absorb pump energy over a wide wavelength range and subsequently excite nearby rare-earth ions to the desired lasing level. This might enable planar waveguide amplifiers that are pumped transversely using low-cost broadband light sources [41.71]. Silicon nanoclusters (embedded in oxide glass) are receiving the most attention at present. In addition to acting as a broadband sensitizer, there is evidence that these nanoclusters can enhance the stimulated emission cross-section of co-doped rare-earth ions by 1–2 orders of magnitude. *Han* et al. [41.107] have reported a waveguide amplifier (on a silicon platform) exhibiting signal enhancement of 7 dB/cm, in spite of a very low erbium concentration. The same group has also reported gain using transverse pumping by light-emitting diode (LED) arrays [41.108]. Finally, the presence of a large concentration of silicon clusters makes electrical pumping a realistic possibility for some silicon-rich oxide glasses [41.71].

It seems very likely that chip-scale glass-based lasers are on the verge of playing a central role in photonics. These lasers will deliver moderate power in a very small package, and will offer extreme spectral purity or stable, high-repetition rate pulses. They might even satisfy the long-standing desire for a silicon-based laser [41.71, 101], facilitating the convergence of photonics and electronics.

41.3.4 Integration of Dissimilar Materials Using Laser Processing

Integration of an inorganic active glass thin film with a semiconductor and a polymer requires additional control of material properties such as thermal and stress mismatch of the integrated materials. Integration of these dissimilar materials opens up a new avenue for

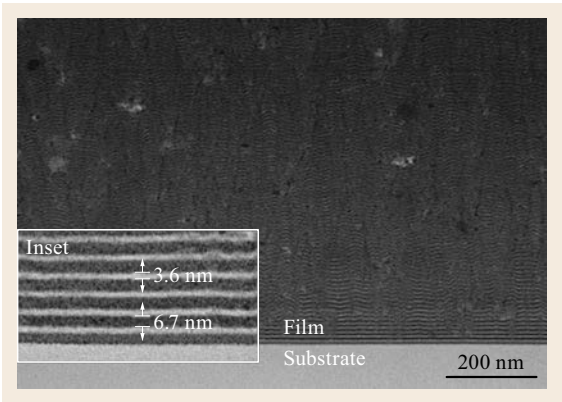

Fig. 41.9 Transmission electron microscopy (TEM) image of a cross-section of the superlattice thin film. The *inset* shows the glass (*dark*) and PDMS (*white*) interlayer thicknesses. (After [41.109], © IOP Publishing, reproduced with permission. All rights reserved)

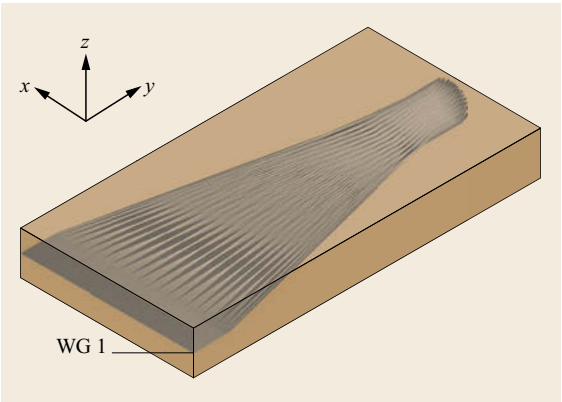

Fig. 41.10 A 3-D waveguide structure. The position of waveguide 1 (WG1) is indicated in the sketch. The waveguide number then increases sequentially along the linear array. (After [41.116], © The Optical Society)

novel photonic integrated device engineering with potential applications in optical and data communication. In photonic integrated device engineering one must consider thermal and stress mismatch as this is crucial for the structural stability of a device, which must be capable of processing signals in an active gain medium. Integration of a nanocrystalline semiconductor on an amorphous dielectric material has been demonstrated in the engineering of optoelectronic devices. Optically active or passive photonics devices, III–V semiconductor on glasses and on Si/SiO_2, and glass on an electro-optic layer such as a III–V semiconductor are some common examples of integration of dissimilar materials [41.110–114].

Recently, the integration of Er^{3+}-ion-doped phosphate-modified tellurite glass thin film with III–V semiconductor and polymer substrates has been reported [41.14, 109]. The active glass thin films were deposited using the pulsed-laser deposition technique and exhibited a refractive index close to the bulk glass target [41.115]. The optical channel waveguides fabricated using a femtosecond laser inscription method offered much smoother channel sidewalls and 2.5 dB internal gain at 1565 nm on using a 150 mW and 1480 nm pump source [41.14]. It was also reported that increasing the deposition temperature up to 400 °C during the pulsed-laser deposition process increases the photoluminescence lifetimes of the active glass thin films up to 4.3 ms, and it has no detrimental effect on the performance of the III–V semiconductor laser fabricated using this approach to integrating dissimilar materials.

Integration of organic and inorganic materials using the laser processing approach allows to control the growth parameters and optoelectronic properties of the integrated devices. For example, superlattice structures of Er^{3+}:Yb^{3+}:Ce^{2+} doped phosphate-modified tellurite glasses and polydimethyl siloxane (PDMS) polymer were successfully grown using pulsed-laser deposition at a deposition temperature of 100 °C with interlayer thicknesses as low as 7 nm for glass and 4 nm for polymer [41.115] as shown in Fig. 41.9.

The successful integration of dissimilar materials illustrates the possibility of engineering structural and thermal compatibility of organic–inorganic materials at nanometer size using the pulsed laser deposition technique. The introduced approach to integrating dissimilar materials opens up a new route to efficient and durable photonic device fabrication with potential applications in a range of optical amplifiers [41.109], and biological sensors [41.117] where integration is impossible using conventional material engineering techniques.

The limited solubility of rare-earth ions in silica glasses and silicon wafers hampers the development of low-loss photonics integrated circuits. Therefore, innovative fabrication methods are required to tackle this limitation which is related to the chemical and physical properties of the host materials and rare-earth ions. *Chandrappan* et al. [41.118] introduced a new technique based on ultrafast laser plasma-assisted hybrid multicomponent material integration of rare-earth-ion-rich tellurite and silica to enhance rare earth-ion solubility in integrated photonic silica-based components. Using this method, high multi-ion rare-earth-doping concentrations of Er^{3+}- and Yb^{3+}-ions (1.63×10^{21} atom/cm^3) were successfully achieved, without any segregation with Er^{3+}:$^4I_{13/2} \rightarrow {}^4I_{15/2}$ and transition lifetime of 9.1 ms in the silica substrate by

controlling the layer thickness of the modified silicate, which is impossible using by conventional methods.

When using conventional mix and melting glass-making methods to produce tellurite-modified silica glasses, phase separation and crystallization affinity increases due to the chemical dissimilarity of the raw materials. Recently, a novel technique based on the ultrafast laser-generated plasma-assisted process was employed for incorporation of rare-earth-ion-doped glasses into silica substrates [41.119]. By implanting the rare-earth ions into a silica glass network using the laser plasma-assisted method a metastable and homogeneous glass structure can be achieved, which is not possible using conventional methods. Increasing the rare earth-ion concentration in the bulk target glass enhances the refractive index and photoluminescence intensity of the modified silica substrate whilst the photoluminescence lifetime of the rare-earth ions decreases due to the quenching effect.

One application of the integration of dissimilar materials in the engineering of photonic components is the photonic lantern, which has potential uses in astrophysics and remote sensing. The photonics lantern is a device that efficiently couples light between a multimode optical fiber and a set of single-mode optical fibers as shown in Fig. 41.10. Ultrafast laser inscription can be used to fabricate two- and three-dimensional integrated optical waveguides that efficiently couple light from a multimode waveguide to a two- or three-dimensional array of single-mode waveguides with a loss of approximately 2 dB [41.116, 120, 121].

41.4 Summary

Glasses have numerous advantages (ease of component fabrication, low scattering loss, flexible atomic structure) that have made them a workhorse material for traditional bulk optics applications. These properties can provide equal or greater advantage in the realization of microphotonic devices and circuits. The glass transition can enable manufacturing techniques unavailable to other materials, and the realization of devices having a surface roughness approaching fundamental limits. Owing to this, glasses have enabled the highest Q microcavities and some of the lowest-loss photonic crystal and microphotonic waveguides reported to date. The metastability of glass enables a rich array of processing and postprocessing options. Direct patterning of waveguides, gratings, and other microphotonic elements by energetic beams is widely studied. These methods of material modification are also promising for postfabrication trimming of devices. Conversely, metastability has implications for processing and aging of glass devices.

Rare-earth-doped glasses offer numerous advantages relative to other solid-state laser media, especially for realization of ultra-low-noise single frequency and ultrafast lasers. Recent advances have greatly increased the maximum gain per unit length, and point to the potential for compact, on-chip glass-based light sources. Progress with respect to 2nd- and 3rd-order nonlinear effects in glasses is ongoing. It is expected that cm-scale switching or pulse-shaping devices based on glasses will become feasible, at least for niche applications.

Overall, it is clear that glasses can contribute greatly to the development of compact, low-loss, multifunction optics integrated with electronics.

Acknowledgments. The authors would like to acknowledge Prof. Animesh Jha for his support and guidance, and helpful technical discussions on the aspects of integrated optics and relevant fabrication. 42. Optical Nonlinearity in Photonic Glasses

Keiji Tanaka

A brief review of optical nonlinearity in photonic glasses is given. For third-order nonlinearity, the relationship between two-photon absorption and nonlinear refractive index is considered using a formalism developed for crystalline semiconductors. Stimulated light scattering and supercontinuum generation in optical fibers and waveguides are introduced. Prominent resonant-type nonlinearity in particle-embedded glasses is described. For second-order nonlinearity, a variety of poling methods are summarized. The nonlinearity also appears in crystallized and ceramic glasses. Finally, it is pointed out that various photoinduced changes can appear when excited by linear and nonlinear optical processes.

References 1092

Developments in optical fibers, integrated waveguides, and pulsed lasers have prompted increasing interest in optical nonlinearity in photonic glasses [42.1–3]. The third-order polarization yields several nonlinear phenomena, such as intensity-dependent absorption and refractive index, which can be utilized in power stabilizers, supercontinuum generation, all-optical switches, and so forth. The main target here is to attain high nonlinearity with fast response. However, in some cases, as mentioned later, the nonlinearity may be a nuisance. On the other hand, the second-order polarization that occurs in poled and crystallized glasses can be utilized in second-harmonic generation, for example. This chapter provides a brief review of optical nonlinearity in *inorganic* glasses.

This chapter begins with an overview of research trends (at the beginning of 2015). Figure 42.1 shows a yearly number of published papers, analyzed using Web of Science, having the topical words *nonlinear, optical, and glass*.

In the total number amounting to ≈ 4000, we see an abrupt rise in 1991 followed by an overall increase with a peak in 2007–2008. What led to these rises? The rise in 1991 seems to be triggered by fundamental interests. Actually, as shown in the statistics, the rise becomes clearer with additional words such as CdS. At the time, we actively examined fundamental properties of commercially available, semiconductor-doped, color-glass filters using pulsed YAG lasers. Such studies have continued to date, though the dopant has been gradually replaced by metallic particles such as Ag, Cu, Au, etc., which are capable of providing greater nonlinearity in combination with plasmonic effects. On the other hand, the origin of the 2007–2008 peak is vague. We see that the additional words such as *photonic crystal*, *Raman*, *ceramic*, *crystalized*, *poling*, or *all-optical* also result in the rise. Probably, many scientific experiments using Ti-sapphire lasers flourished around that time.

The statistics shed light on another noteworthy aspect. As known, there are three kinds of optical glasses namely, oxide, chalcogenide, and halide, of which oxide is the most commonly used one. However, we note that *oxide* and *chalcogenide* papers are comparable, giving the total numbers of ≈ 400, with much fewer being halide related. This relatively intense interest in chalcogenide glasses rests on the higher nonlinearity (Table 42.1), which promises wide applications, as reviewed in recent articles [42.4–6].

Finally, what are the growing topics at the present time? As shown in Fig. 42.1, an additional word *supercontinuum* has been manifesting a rapid growth since ≈ 2005, which might contribute to commercializing supercontinuum fibers. *Photonic crystal fiber* shows a similar trend. It is also mentioned that *integrated*, which appeared in 1992 and fluctuated around 6 [42.7], rapidly rose to 14 in 2014. The topic includes, for example, proposals of polymer-glass hybrid systems [42.8] and also integrated devices [42.5, 9], which may be promising henceforth.

At this point we should note that, in many respects, the glass nonlinearity is competitive with that in organic polymers and crystals [42.1, 2]. Compared to polymers, glass is more stable, while polymers can provide greater nonlinearity with molecular designs. Therefore, these two types of materials are competitors in practical applications. Compared to crystals, the glass nonlinearity, specifically that of the second order, may be smaller than that in the crystal. However, a great advantage of glass is its ability to control its form at three scales. First, the atomic composition of the glass can be tailored continuously. For instance, we can obtain nonlinear optical glass with any refractive index in the range of 1.4–3.2 at a wavelength of $\approx 1\,\mu$m. Second, the atomic structure of the glass can be modified reasonably easily using, for example, light beams. Such modifications may be regarded as photoinduced phenomena, which can be employed in order to add second-order nonlinearity to selected regions and so forth. Finally, macroscopic forms can be changed into arbitrary bulk shapes, fibers [42.3], thin layers, channels, and micro-particles [42.10, 11].

Here, fibers and waveguides are practically important for nonlinear applications for two reasons. One is that the light power density can be increased by reducing the lateral size, for example, the fiber diameter or waveguide dimensions, to wavelength scales [42.12]. In this respect, nanowires [42.13], which are the waveguide with submicron cross sections, may be more promising. The other is fibers can provide long lengths for light–matter interactions that are not limited by diffraction. These scale factors produce apparent enhancements in nonlinear effects in glasses, although the intrinsic nonlinearity may be smaller than that in crystals. In addition, it should be emphasized that structured (holey, photonic crystal) fibers [42.14] are able to control dispersion characteristics, which can tune desired wavelengths. Needless to say, the accuracy in shaping fibers and waveguides, which are fabricated by several methods [42.3, 15, 16], is a key issue for suppressing the light-scattering loss.

Before proceeding further, it would be useful to introduce a nonlinear formula [42.1, 2]. For simplicity, we take the polarization P and the electric field E to be scalar quantities. Then, very simply, P can be written down in the CGS unit as

$$P = \chi^{(1)}E + \chi^{(2)}EE + \chi^{(3)}EEE + \dots , \qquad (42.1)$$

where the first term $\chi^{(1)}E$ depicts the conventional linear response, and $\chi^{(2)}$ and $\chi^{(3)}$ represent the second- and the third-order nonlinear susceptibilities, respectively. $\chi^{(1)}$ is related to the linear refractive index n_0 via $n_0 = (1+4\pi\chi^{(1)})^{1/2}$. On the other hand, the second term provides such time dependence as $\sin(\omega \pm \omega')t$, so that it could produce second-overtone (2ω) and dc signals. In a similar way, the third could modify the fundamental (ω) signal and generate a third-overtone (3ω). Nevertheless, since a refractive index changes with light frequency, it is not straightforward in the overtone generations to satisfy the so-called phase-matching condition, for example, $\varphi_{3\omega} = 3\varphi_{\omega}$, where φ is the phase of electric fields in glasses. Microscopically, the nonlinear terms arise through several mechanisms, such as electronic, atomic (including molecular motions), electrostatic, and thermal processes. Among these, electronic processes can provide the fastest responses, with fs–ps time scales, which will be needed for optical information technologies. Accordingly, we will focus on such processes from this point onward.

The chapter is divided as follows. In Sect. 42.1, we treat conventional glasses. These are optically isotropic, which gives $\chi^{(2)} = 0$, because the isotropic structure

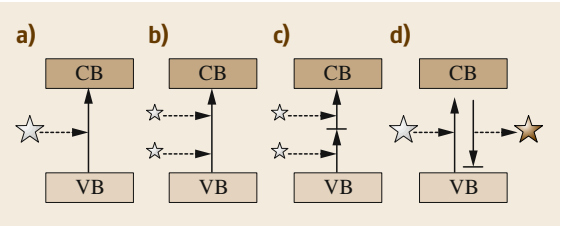

Fig. 42.2a–d Schematic illustrations of **(a)** one-photon absorption, **(b)** two-photon absorption, **(c)** two-step absorption via a mid-gap state, and **(d)** Raman-scattering process in a semiconductor with a valence band (VB) and a conduction band (CB)

appears to be centrosymmetric. In this case, the lowest nonlinear term becomes $\chi^{(3)}EEE$. When $\chi^{(3)}EEE$ can be written as $\chi^{(3)}IE$, where I is the light intensity, we can define the refractive index n as $n = n_0 + n_2 I$, where n_2 is sometimes called the second-order index of refraction [42.2]. Incidentally, in nonlinear optics, the notation poses perplexing problems due to several definitions of parameters. And, the conversion $n_2\,(\mathrm{cm}^2/\mathrm{W}) \approx 0.04\chi^{(3)}(\mathrm{esu})/n_0^2$ is frequently employed [42.2]. On the other hand, for light absorption, which is proportional to $\langle E\mathrm{d}P/\mathrm{d}t\rangle$, where $\langle\cdots\rangle$ represents a time average, we need to take the imaginary parts of $\chi^{(1)}$ and $\chi^{(3)}$, which cause one- and two-photon absorption, into account (Fig. 42.2). In such cases, an effective absorption coefficient can be written as $\alpha\,(\mathrm{cm}^{-1}) + \beta\,(\mathrm{cm/W})I\,(\mathrm{W/cm}^2)$. n_2 and β will be connected through nonlinear Kramers–Kronig relations.

Section 42.2 focuses on noncentrosymmetric systems. From the mid-1980s onward, several kinds of *poling* treatments have been found to add $\chi^{(2)}$ to glasses [42.17]. For instance, *Österberg* and *Margulis* [42.18] demonstrated intense second-harmonic generation in laser-irradiated glass fibers. Such work began with silica, and has been directed toward more complicated glasses. The magnitude of $\chi^{(2)}$ obtained by poling is likely to be smaller than those observed in crystals, due to disordered atomic structures in glasses, but the structural controllability such as spatially selected crystallization may offer some advantages. Section 42.3 introduces glasses incorporating fine semiconductor and metal particles. Such nanostructured glasses are known to exhibit large optical nonlinearities [42.1, 2, 19]. However, as will be described, their features remain to be studied. For ion-doped glass systems, including fiber lasers and amplifiers, readers may refer to Chaps. 40 and 43 and a recent review [42.20]. In Sect. 42.4, we consider photoinduced phenomena. Intense light needed to produce optical nonlinearity is likely to modify the structure of glass. Light that is even more intense may cause damage. While the damaging can be useful for optical engraving, the structural modification may be more important. Actually, commercial fiber Bragg gratings [42.3] have been produced using excimer lasers. Nonlinear optical excitation possibly plays there an important role [42.21]. Also, three-dimensional waveguides are produced through controlled light focusing [42.16, 22]. Section 42.5 provides a summary of the chapter. Parts of this chapter are based on the author's review [42.23].

42.1 Third-Order Nonlinearity in Homogeneous Glass

42.1.1 Experimental

Substantial data are available for n_2 at transparent wavelengths [42.1, 2]. However, to the author's knowledge, almost all experiments have utilized lasers, and spectral dependence has rarely been reported. We should also note that, in comparison to n_0 measurements, n_2 evaluations are much more difficult. The biggest difficulty, which is common to all nonlinear experiments, is the light intensity. Normally, light is pulsed and focused, producing complex temporal and spatial profiles, which in turn means that intensity evaluations are not straightforward. For instance, if the profile is Gaussian, can we simply use the peak value to evaluate the nonlinearity? Because of such evaluation difficulties and also some other characteristics inherent to glasses, including thermodynamical quasi-stability, reported n_2 values vary, even for a reference SiO_2 glass, over the range of 1×10^{-7}–$3\times10^{-7}\,\mathrm{cm}^2/\mathrm{GW}$. In other glasses, values that differ by a factor of ≈ 10 have been reported [42.1, 24–26].

However, we can see a general trend in n_2 in Table 42.1. Halide glasses (BeF_2) have the smallest values, light-metal oxides (BK-7) and SiO_2 have similar values, heavy-metal oxides such as PbO-SiO_2 (SF-59) have larger values [42.27], while the largest belong to the chalcogenides (As_2S_3) [42.1]. The ultimate n_2 value reported so far may be $8\times10^{-3}\,\mathrm{cm}^2/\mathrm{GW}$, seen in $Ag_{20}As_{32}Se_{48}$ at wavelength of 1.05 μm [42.28], which is $\approx 10^5$ times as large as that of SiO_2.

Figure 42.3 shows β spectra for SiO_2 [42.29, 30], As_2S_3, and two PbO-SiO_2 glasses [42.27]. Bi_2O_3-B_2O_3 glasses [42.31, 32] exhibit similar features to those of lead glass. We can see that all the β spectra seem to

Table 42.1 Linear (E_g, n_0, α_0) and nonlinear (n_2, β, β_{max}) optical properties and figures of merit ($n_2/2\beta\lambda_0$, n_2/α_0) in some glasses. E_g is the optical bandgap energy [42.22], n_0 is the refractive index [42.22], α_0 is the attenuation coefficient [42.27], n_2 is the intensity-dependent refractive index [42.1, 2, 22], β is the two-photon absorption coefficient [42.27], and β_{max} is the maximum value. Except β_{max}, the values are evaluated at a wavelength of 1−1.5 μm. BK-7 is a borosilicate glass and SF-59 indicates data for lead-silicate glasses with ≈ 57 mol % PbO

	E_g (eV)	n_0	α_0 (cm^{-1})	n_2 (10^{-7} cm^2/GW)	β (cm/GW)	β_{max} (cm/GW)	$n_2/(2\beta\lambda_0)$	n_2/α_0 (cm^3/GW)
SiO_2	10	1.5	10^{-6}	2	$< 10^{-2}$	1	< 0.1	0.2
BK-7	4	1.5		3				
SF-59	3.8	2.0		30	$< 10^{-1}$	10		
As_2S_3	2.4	2.5	10^{-3}	200	10^{-2}	50	10	0.02
BeF_2	10	1.3		0.8				

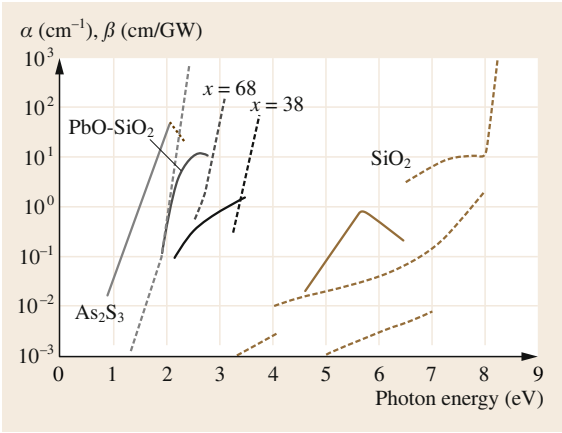

Fig. 42.3 One- (*dashed line*) and two-photon (*solid line*) absorption spectra, α and β, in SiO_2 [42.29, 30], 38PbO-62SiO_2, 68PbO-32SiO_2 [42.27], and As_2S_3 [42.27]. For SiO_2, in transparent regions ($\hbar\omega \leq 8.0$ eV) α should be regarded as an attenuation coefficient; these are not reproducible, probably due to impurities, defects, and light scattering. The *dotted line* for As_2S_3 at $\hbar\omega \geq 2.0$ eV indicates two-step absorption

have maxima at mid-gap regions, $\hbar\omega \approx E_g/2$. However, this is not an absolute rule, since at $\hbar\omega \geq 2.0$ eV As_2S_3 provides two-step absorption (Fig. 42.2c), which tends to mask two-photon absorption signals [42.33]. We also see that the maximal β ($\approx 10^0$ cm/GW) in SiO_2 is markedly smaller than those belonging to the other glasses. Note that such a marked difference does not exist in maximal α, which is $\approx 10^6$ cm^{-1} at the super-bandgap regions of SiO_2 and As_2S_3. It may be worth mentioning here that two-photon excitation produces photocurrents in some glasses [42.34, 35].

42.1.2 Theoretical Treatment

For $\chi^{(3)}$, theoretical treatments of glasses, liquids, and crystals are largely the same. Glasses and liquids can be treated similarly in the sense that both are optically isotropic. Hence, many ideas stemming from types of chemical bonds have been proposed [42.2]. On the other hand, the magnitude of $\chi^{(3)}$ in glass appears to be similar to that in the corresponding crystal, since electronic structures of both glass and crystal governed by short-range atomic structures [42.36], within ≈ 0.5 nm, which are much shorter than the wavelength (≈ 500 nm) of visible light. Specifically, since n_2 is governed by integrated electronic absorption [42.17], the magnitudes of glass and crystal are roughly the same. For instance, in crystalline and glassy SiO_2 at near-infrared wavelengths, the difference in the n_2 values of both seems to be comparable with their experimental accuracy; that is, the values for crystalline and glassy SiO_2 are $\approx 1.14 \times 10^{-13}$ and 0.85×10^{-13} esu, respectively [42.1]. Then, using a formula derived for semiconductor crystals, we can apply a kind of band picture to glasses [42.27], as described below.

Estimation of Nonlinear Refractivity

Several semiempirical relationships have been proposed for $\chi^{(3)}$ or n_2 [42.1]. Such relations are useful, since nonlinear optical constants are much more difficult to evaluate than linear constants. Naturally, since they are simplifications they are also less accurate. The simplest may be the one provided by Wang, $\chi^{(3)} \approx \{\chi^{(1)}\}^4$, which can be regarded as a generalized Miller's rule [42.1]. *Boling* et al. [42.37] have also derived some relations, among which the simplest may be

$$n_2\left(10^{-13}\,\text{esu}\right) \approx 391\frac{(n_d - 1)}{\nu_d^{5/4}}\,, \qquad (42.2)$$

where n_d is the refractive index at the d-line ($\lambda = 588$ nm) and ν_d is the Abbe number, which is defined as $(n_d - 1)/(n_F - n_C)$, where n_F and n_C are the indices at $\lambda = 486$ and 656 nm, respectively. This relation contains only two macroscopic parameters, which can easily be obtained, and so it has often been used to

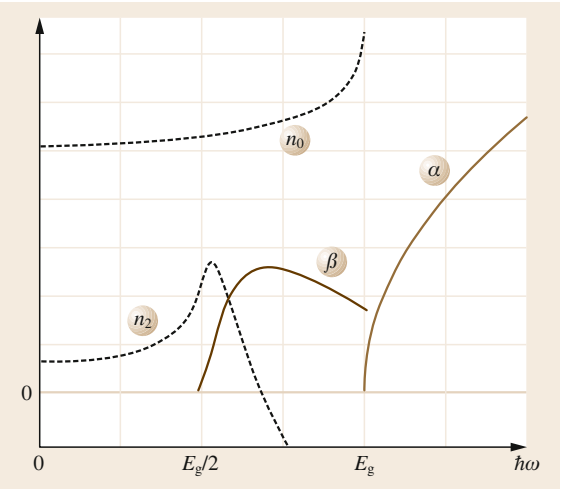

Fig. 42.4 Spectral dependence of linear absorption α, linear refractive index n_0, two-photon absorption β, and intensity-dependent refractive index n_2 in an ideal amorphous semiconductor with energy gap E_g. *Vertical scales* are arbitrary

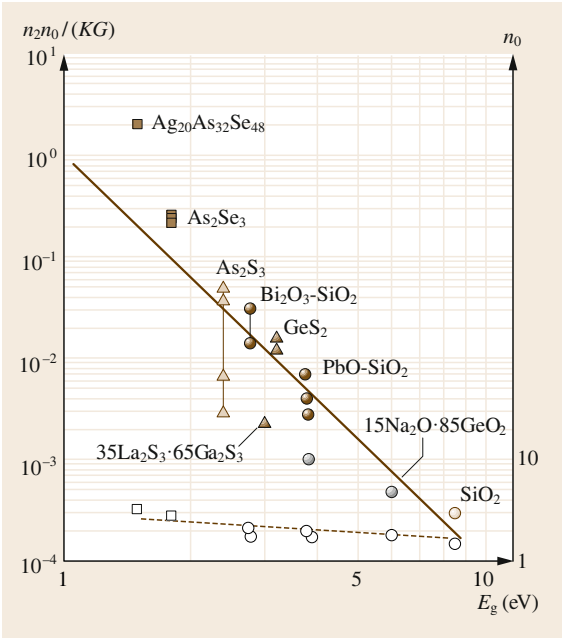

Fig. 42.5 The Sheik-Bahae relation $n_2 n_0 = KG/E_g^4$ (*solid line*), related data (*solid symbols*), the Moss rule $n_0^4 E_g = 77$ (*dashed line*), and related data (*open symbols*) for an oxide (*circles*), sulfide (*triangles*), and selenide (*squares*). The four data for As_2S_3 are obtained from different publications, while those for PbO-SiO_2 with slightly different E_g correspond to different compositions. The illustration is modified from its original form [42.27] due to the additions of $Ag_{20}As_{32}Se_{48}$ [42.28], Bi_2O_3-silica glasses [42.43], $35La_2S_3$-$65Ga_2S_3$ [42.44], and $15Na_2O$-$85GeO_2$ [42.45]

estimate n_2. It actually provides a good approximation for small n_d glasses with $n_d \leq 1.7$ [42.37]. For high n_d glasses, *Lines* [42.24] proposes a relation that contains the atomic distance, and others derive a more complicated formula [42.38, 39]. Ab initio calculations of the nonlinear refractivity in TeO_2-based glasses have also been reported [42.40]. However, these relations cannot predict wavelength dependence (Fig. 42.4), and hence, the estimated n_2 may be regarded as a long-wavelength limit. In addition, the material is regarded as transparent, or an insulator, so that relations between n_2 and β cannot be known.

Nonlinear optical properties of semiconductor crystals have been studied fairly deeply [42.2], and applying the same concepts to glasses appears to be tempting. *Tanaka* [42.27] has adopted a band picture, which was developed by *Sheik-Bahae* et al. [42.41], to glasses. Their formulation gives a universal relationship of

$$n_2 = \frac{KG\left(\hbar\omega/E_g\right)}{n_0 E_g^4}\,, \tag{42.3}$$

for crystals with energy gaps of 1–10 eV, where K is a fixed constant and $G(\hbar\omega/E_g)$ is a spectral function. For the bandgap energy E_g in glasses, we can take the so-called Tauc gap [42.36] if it is known, or otherwise the photon energy $\hbar\omega$ at $\alpha \approx 10^3\,\mathrm{cm}^{-1}$. As shown in Fig. 42.5, the universal line gives reasonable agreement with published data, while the agreement is not so satisfactory as it is for crystals [42.41]. The poorer agreement for glasses may be partly due to experimental difficulties. In addition, band tail states probably cause larger deviations in smaller bandgap glasses such as $Ag_{20}As_{32}Se_{48}$. Incidentally, as shown by the dashed line in the figure, the Moss rule $n_0^4 E_g = 77$ [42.42], which was originally pointed out for crystalline semiconductors, also gives satisfactory fits for glasses.

Nonlinear Kramers–Kronig Relationship

We can take another approach in order to obtain unified insight into optical nonlinearity, β and n_2. In this case, we start with absorption and then obtain the refractive index using Kramers–Kronig relationships (KKR). As illustrated in Fig. 42.6, this approach is able to provide a complete understanding of atomic structure and optical properties, since absorption spectra can be related to electronic structure more directly.

It is well known that, for glasses, and neglecting momentum conservation rules, $\alpha(\hbar\omega)$ and $\beta(\hbar\omega)$ can

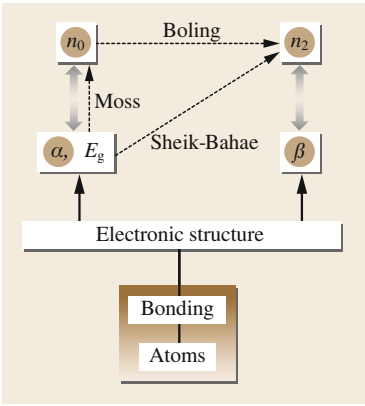

Fig. 42.6 Relationship between atomic structure, electronic structure, linear absorption α including bandgap energy E_g, linear refractive index n_0, two-photon absorption β, and nonlinear refractive index n_2. Absorption and refraction are related by the linear and nonlinear KKR (*double arrows*). The Moss rule may be regarded as a simplified KKR. The Boling and Sheik-Bahae relations connect n_0 and E_g to n_2, respectively

be written as [42.23]

$$\alpha(\hbar\omega) \propto |\langle\phi_f|H|\phi_i\rangle|^2 \int D_f(E+\hbar\omega)\, D_i(E)\, dE\,, \tag{42.4}$$

$$\beta(\hbar\omega) \propto \left|\frac{\Sigma_n \langle\phi_f|H|\phi_n\rangle\langle\phi_n|H|\phi_i\rangle}{E_{ni}-\hbar\omega}\right|^2 \times \int D_f(E+2\hbar\omega)\, D_i(E)\, dE\,, \tag{42.5}$$

where H represents the light–electron interaction, ϕ is a related electron wavefunction, D is the density of states, and the subscripts i, n, and f denote the initial, intermediate, and final states, respectively. α and β are linked to the electronic structure, i. e., the wavefunctions and densities of states, which is determined by the atomic species and bonding structures involved [42.36]. From $\alpha(\hbar\omega)$, $n_0(\omega)$ is expressed using the conventional KKR as [42.2]

$$n_0(\omega) = 1 + \left(\frac{c}{\pi}\right) \wp \int \left(\frac{\alpha(\Omega)}{\Omega^2-\omega^2}\right) d\Omega\,. \tag{42.6}$$

For a nonlinear KKR response Δn, *Hutchings* et al. [42.46] have derived the relation

$$\Delta n(\omega;\zeta) = \left(\frac{c}{\pi}\right) \wp \int \left(\frac{\Delta\alpha(\Omega;\zeta)}{\Omega^2-\omega^2}\right) d\Omega\,, \tag{42.7}$$

where $\Delta\alpha$ is the nonlinear absorption induced by an excitation at ζ and probed at Ω. Note that this relation is derived from the causality principle for nondegenerate cases, for example, two-beam experiments with different photon energies, ζ and Ω. However, this relation may also be applied to degenerate cases ($\zeta = \Omega$) as a rough approximation as [42.47]

$$n_2(\omega) = \left(\frac{c}{\pi}\right) \wp \int \left(\frac{\beta(\Omega)}{\Omega^2-\omega^2}\right) d\Omega\,. \tag{42.8}$$

Using these formulae, we can roughly predict how β and n_2 depend upon E_g. Equation (42.5) suggests that $\beta \propto 1/E_g^2$, provided that the E_g dependence is governed by $|\Sigma_n 1/(E_{ni}-\hbar\omega)|^2$. This relation may be consistent with the material dependence shown in Fig. 42.3, $\beta_{max} \propto 1/E_g^{2\sim3}$, which is comparable to $\beta \propto 1/E_g^3$, the equation theoretically derived and experimentally confirmed for crystalline semiconductors [42.2, 41]. Then, putting $\beta \propto 1/E_g^2$ into (42.8), and assuming $\int[1/(\Omega^2-\omega^2)]d\Omega \propto 1/E_g^2$, we obtain a strong dependence of n_2 on E_g, $n_2 \propto 1/E_g^4$, which is consistent with (42.3). Note that the form is contrastive to $n_0 \propto 1/E_g^{1/4}$ [42.42].

We can also calculate, under some plausible assumptions, the spectral dependence of β and n_2 for an ideal amorphous semiconductor, which contains no gap states [42.48]. Figure 42.4 shows that, at $\hbar\omega = E_g/2$, $\beta = 0$ and n_2 is maximal. This is similar to some degree to the feature at $\hbar\omega = E_g$ for α and n_0. The figure also shows that β becomes maximal at $E_g/2-E_g$. Note, however, that it is not clear whether we can link this photon energy dependence to the experimental results shown in Fig. 42.3, since the observed spectra appear to have fairly sharp peaks.

Figure of Merit

Several figures of merit have been proposed for evaluating the performances of optical devices which utilize n_2. For instance, *Mizrahi* et al. [42.49] emphasized the negative effects of two-photon absorption, and provided a criterion $n_2/(2\beta\lambda_0) > 1$. Then, using the above E_g dependence, we see that $n_2/\beta \propto E_g^{-2}$, so that small E_g materials are preferable. Actually, as listed in Table 42.1, in this figure of merit, As_2S_3 appears to be better than SiO_2. However, this criterion implicitly neglects α. *Lines* [42.24] uses n_2/α instead. Here, α arises from the so-called residual absorption, which is difficult to estimate quantitatively. In addition, it is the attenuation coefficient α_0 instead of the absorption α that could be decisive. Table 42.1 shows that, in this measure, SiO_2 behaves better than As_2S_3. These figures of merit, however, have presumed only nonresonant electronic contributions with sub-ps responses. Then, *Jha* et al. [42.19] utilize $n_2/\tau\alpha$, where τ is a response time. Nevertheless, theoretical predictions of τ remain to be studied.

Naturally, the most appropriate definition of the figure of merit depends on the application of interest. For instance, for an optical fiber device, the maximum length might be $\approx 1\,\mathrm{m}$ [42.50], since the device must be compact and have a fast response. In this case, the light absorption, which arises from $\alpha + \beta I$, should be suppressed to below $10^{-2}\,\mathrm{cm}^{-1}$, or the light propagation loss must be smaller than $\approx 1\,\mathrm{dB/m}$. However, for optical integrated circuits, an effective propagation distance may be $\approx 1\,\mathrm{cm}$, in which the attenuation could be as large as $1\,\mathrm{cm}^{-1}$.

We can suggest another idea by taking the spectral dependence, as shown in Fig. 42.4, into account. That is, the best material that has n_2 at some $\hbar\omega$ is the one which satisfies a bandgap condition of $\hbar\omega = E_g/2$, where α and β are zero and n_2 becomes maximal, provided that there is no gap-state absorption. In practical glass samples, absorption due to impurities, dangling bonds such as E' centers in oxide glasses [42.21, 36], and wrong bonds in chalcogenide glasses [42.36, 48] cannot be neglected. In fact, we can see in Table 42.1 and Fig. 42.3 that residual attenuation exists in nominally transparent regions, parts of which are undoubtedly caused by absorption [42.51]. Note that these mid-gap states also give rise to two-step absorption (Fig. 42.2). We also cannot neglect photoinduced phenomena induced by these photoelectronic excitations (Sect. 42.4). As a matter of fact, selecting an appropriate glass for a specific application is not a straightforward process.

42.1.3 Stimulated Light Scattering, Supercontinuum Generation, and Other Applications

Stimulated Raman scattering has been attracting considerable interest, because it can be utilized for broadband light amplification [42.2, 3, 52]. As illustrated in Fig. 42.2d, Raman scattering can be regarded as a kind of nondegenerate two-photon process. However, in contrast to two-photon absorption, one photon is absorbed by a virtual state at the same time as another photon is emitted through the photon–phonon interaction. And, in the same way with conventional stimulated emission processes, when the incident light is intense, Stokes-shifted light can be amplified. The nonlinear polarization related to this process is given by

$$P^{(3)}(\omega_s) \propto \mathrm{i}\chi_R^{(3)} I(\omega_L) E(\omega_s)\,,$$

or the emitted light intensity is

$$\Delta I(\omega_s) \propto \chi_R^{(3)} I(\omega_L) I(\omega_s)\,,$$

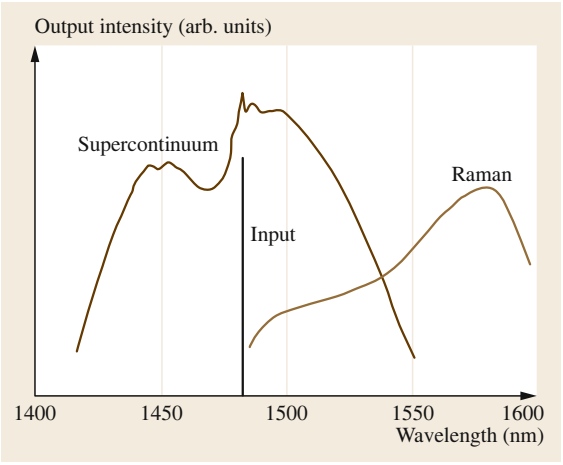

Fig. 42.7 Output spectra from a Raman fiber amplifier [42.54] and from a supercontinuum fiber generator [42.57] excited by 1483 nm light (schematic illustration)

where ω_L and ω_s ($< \omega_L$) are the exciting laser frequency and the Stokes-shifted frequency, respectively.

Most experiments have been performed using optical fibers [42.3, 50, 53] in order to obtain long interaction lengths. For instance, as illustrated in Fig. 42.7, Raman amplifiers comprising 5–10 km lengths of silica fibers can provide broadband gains of $\approx 10\,\mathrm{dB}$ [42.54]. Also interesting are Raman lasers using silica microspheres of diameter $\approx 70\,\mu\mathrm{m}$ [42.11] and amplifiers using submeter As_2Se_3 fibers [42.55]. It should also be mentioned here that stimulated Brillouin scattering in glasses has been explored recently [42.3, 56].

Supercontinuum generation in silica and other glass fibers has been studied intensively [42.1–3]. When pulsed or CW light propagates through a nonlinear medium, it may undergo spectral broadening. For instance, as illustrated in Fig. 42.7, a 350 m single-mode silica fiber excited by a 2.22 W CW laser with a wavelength of $1.483\,\mu\mathrm{m}$ has emitted 2.1 W light over a broad spectrum of 1.43–$1.53\,\mu\mathrm{m}$ [42.57]. The phenomenon appears under strong and prolonged nonlinear interactions, and accordingly, several mechanisms such as intensity-dependent refractive index changes, third-harmonic generation and stimulated Raman scattering could be responsible. Note that, unlike the stimulated light scattering described above, light of shorter wavelengths is also generated in this process. Such spectrum conversion fibers could be utilized as broadband light sources and optical amplifiers. The generation efficiency and bandwidth are becoming much improved using novel fiber structures consisting of, for example, heavy-metal oxide [42.58], tellurite [42.59, 60], chalcogenide [42.61, 62], and fluoride glasses [42.63].

However, in some compositions, atmospheric degradations have to be suppressed [42.64].

Finally, it is mentioned that the nonlinear refractivity in glasses has wider applications to all-optical switching [42.65], third-harmonic generation [42.66], THz-induced Kerr effect in As_2S_3 and As_2Se_3 [42.67], tunable sideband laser [42.68], and so forth. Nevertheless, the nonlinearity is a nuisance in some cases such as phase-modulated telecommunications [42.69]. It may also cause self-focusing damages [42.70].

42.2 Second-Order Nonlinearity in Poled Glass

It has been discovered that several kinds of poling methods can add second-order nonlinearity to glasses [42.17, 71]. At least five kinds have been demonstrated, which are listed in Table 42.2. Note that similar procedures are also employed for polymers. Most experiments utilize second harmonic signals to evaluate $\chi^{(2)}$ and, less commonly, electro-optical effects. Practical applications remain to be studied, while, for second-harmonic generations, the optical phase matching between exciting and nonlinearly generated light is a prerequisite.

The optical poling was demonstrated by *Österberg* and *Margulis* [42.18] using optical fibers. They found that exposing Ge-doped optical fibers of length ≈ 1 m to intense (≈ 70 kW) Nd:YAG laser light for ≈ 1 h could increase the second-harmonic signal to 0.55 kW. *Stolen* and *Tom* [42.72] utilized two light beams ($\times 1$ and $\times 2$, of Nd:YAG laser light) for induction, which reduced the exposure time to ≈ 5 min. However, the method was practical only for optical fibers, since the induced nonlinearity was relatively small, $\chi^{(2)} \approx 10^{-4}$ pm/V. Other glasses may be preferred, and for instance, in Ag-containing glass, laser-fabricated three-dimensional structures with ≈ 2 pm/V have been produced [42.73]. Second, the so-called thermal poling, which was actually electrothermal in nature, was demonstrated [42.74]. Application of high dc fields of 5×10^4 V/cm at $\approx 300\,^\circ$C to *bulk* SiO_2 samples induced a nonlinearity of ≈ 1 pm/V, a similar magnitude to that in quartz, which was evaluated from the second harmonic signals of 1.06 μm laser light. The induced nonlinearity is reasonably large and stable, and this method has been widely applied not only to oxide glasses [42.75–77] but also to chalcogenides [42.78]. Third, *Okada* et al. [42.79] applied corona-discharge poling to 7059 *films* at $\approx 200\,^\circ$C, which were deposited onto Pyrex glass substrates. Such corona-poling procedures, which can efficiently apply high DC fields, have often been also employed for organic polymers. Fourth, electron-beam poling could produce ≈ 1 pm/V in PbO-silica glass [42.80]. An advantage of this method is its high spatial resolution, which may hold promise in the fabrication of optical integrated circuits, despite the fact that a vacuum is needed. This method was applied to chalcogenide glasses as well, Ge-As-S, giving rise to ≈ 1 pm/V [42.81]. Fifth, proton implantation could add $\chi^{(2)}$ of ≈ 1 pm/V in fused silica with exposure times of 10^2 s [42.82]. Finally, *Fujiwara* et al. [42.83] demonstrated UV poling in Ge-doped SiO_2 subjected to electric fields of $\approx 10^5$ V/cm. The $\chi^{(2)}$ induced is reported to be ≈ 3 pm/V, which is comparable to that in $LiNbO_3$.

Two poling mechanisms of note have been proposed [42.17, 77]. One is that space charge produces a built-in electric field of E_{DC} ($\approx 10^6$ V/cm), which induces an effective $\chi^{(2)}$ of $3E_{DC}\chi^{(3)}$ [42.72]. This idea suggests a proportionality, $\chi^{(2)} \approx \chi^{(3)}$, and actually, $\chi^{(2)} \approx 10$ pm/V has been obtained in a high $\chi^{(3)}$ chalcogenide glass, $Ge_{25}Sb_{10}S_{65}$ [42.78]. On the other hand, E_{DC} is governed by the migration of ions such as Na^+ (impurities) under applied or generated electric fields [42.78, 84]. In agreement with this idea, $\chi^{(2)}$ tends to decay with a time constant of 10^1–10^6 days at room temperature, which is connected to the alkali ion mobility. The other idea is that oriented defects such as E' centers [42.21] are responsible for generating $\chi^{(2)}$. We can envisage that UV excitation produces defective dipoles, which are oriented with the static electric field.

It is plausible that the dominant mechanism depends on the poling method. Actually, we can divide the procedures listed in Table 42.2 into two types, depending upon whether or not the glass is heated during the poling process. The heating tends to enhance macroscopic ion migration, while it can relax microscopic defect

Table 42.2 Reported poling methods, applied objects, typical procedures, and induced $\chi^{(2)}$ values in silica. For references, see the main text. The $\chi^{(2)}$ values listed are compared with $\chi^{(2)}_{11} = 1$ pm/V in crystalline SiO_2 and $\chi^{(2)}_{22} = 5$ pm/V in $LiNbO_3$

Method	Object	Procedure	$\chi^{(2)}$ (pm/V)
Optical	Fiber	Nd:YAG laser, 1 h	10^{-4}
Thermal	Bulk	4 kV, 300 °C, 1 h	1
Corona	Film	5 kV, 300 °C, 15 min	1
e-Beam	Bulk	40 kV, 10 mA, 10 min	1
Proton	Bulk	500 kV, 1 mC, 100 s	1
Ultraviolet (UV)	Bulk	ArF laser, 10 kV	3

orientations at the same time [42.21, 36]. Therefore, it seems that the ion migration is responsible in thermal and corona poling, while defect orientation dominates in the other methods. In this context, poling at low temperatures may be a promising way of enhancing defect orientation.

Finally, we note that there exist some glassy materials which can exhibit $\chi^{(2)}$ without poling procedures. The so-called nano-crystallized glass and glass ceramics are well known, in which embedded crystals (or crystallites) are responsible for prominent $\chi^{(2)}$ [42.76, 85–87]. For instance, *Takahashi* et al. [42.86] demonstrated that a heat treatment of a BaO-TiO_2-SiO_2 glass sample at 760 °C for 1 h produced *oriented* $Ba_2TiSi_2O_8$ crystals, and the glass ceramic gives a prominent $\chi^{(2)}$ of $\approx 10\,\mathrm{pm/V}$. The thermal orientated crystallization has been applied not only to oxides [42.88] but also to chalcogenide and chalcohalide glass-ceramics [42.71] such as GeS_2-$CdGa_2S_4$ [42.89] and GeS_2-Ga_2S_3-AgCl [42.90]. Finally, we note that $\chi^{(2)}$ can appear in glasses through different mechanisms. It is known that $\chi^{(2)}$ emerges in TeO_2 glass-ceramics at interfaces [42.91], which probably cause strains. It was recently reported that sputter-deposited Ge-SiO_2 films exhibit $\chi^{(2)}$ amounting to 8 pm/V, which may be ascribed to oriented Ge-related defects [42.92].

42.3 Particle-Embedded Systems

Glasses that contain nanoparticles of semiconductors [42.93] and metals [42.94] have attracted considerable interest due to their unique third-order nonlinearities. Table 42.3 lists typical results [42.95–100]. Such glasses containing dispersed nanoparticles can be prepared by a variety of physical and chemical methods, for example, vacuum deposition and sol–gel techniques [42.1, 101]. For semiconductor systems, a lot of work has been performed using commercial semiconductor-doped color glass filters [42.93].

These nanoparticle systems efficiently function at close to the resonant wavelengths of some electronic excitations. This operating condition gives rise to at least three characteristics. First, the imaginary, not the real, part of $\chi^{(3)}$ may be more prominent, and accordingly, Table 42.3 compares absolute values. Second, the system exhibits a strong spectral dependence [42.1, 102]. For instance, Au–silica and CdSSe–silica are efficient at ≈ 580 and $\approx 800\,\mathrm{nm}$ [42.1], respectively. Third, the response time τ and the linear absorption α tend to become longer and higher. Actually, a trade-off between $\chi^{(3)}$ and τ (and α) seems to exist, for example, CdSSe-dispersed glasses show $\chi^{(3)}$ value of $\approx 10^{-9}$ esu with τ value of $\approx 20\,\mathrm{ps}$, while Au-dispersed glasses give $\approx 10^{-11}$ esu and $\approx 1\,\mathrm{ps}$ [42.1]. Linear absorption can be as large as $10^4\,\mathrm{cm}^{-1}$ [42.94], so these systems can be utilized as small devices, not as fibers. Note that, in pure silica at nonresonant infrared wavelengths, $\chi^{(3)} \approx 10^{-13}$ esu, $\tau \approx 10\,\mathrm{fs}$, and $\alpha \leq 10^{-5}\,\mathrm{cm}^{-1}$ [42.94].

Due to these inherent features, the particle-embedded system should surmount two problems for wide applications. One is the reduction of linear attenuation, including absorption and scattering, and the other is the shift of resonant wavelengths to the optical communication region, 1.3–1.5 μm. Is such a shift possible? What are the mechanisms that give rise to these prominent nonlinearities in particle-embedded systems?

When the particle is a semiconductor such as CuCl and CdSSe, excitons or confined electron–hole pairs are responsible [42.93]. Specifically, the excitons in semiconductor particles behave as two-level systems, and at the resonance frequency, $|\chi^{(3)}|$ is written as

$$|\chi^{(3)}| \approx \mathrm{Im}\{\chi^{(3)}\} \propto |\mu|^4 N T_1 T_2^2 \,, \tag{42.9}$$

where μ is the dipole moment of the exciton, N is the particle number, T_1 ($\approx 100\,\mathrm{ps}$) is the lifetime of the exciton, and T_2 ($\approx$ fs) is the dephasing time. A quan-

Table 42.3 Several particle systems, along with their preparation methods, $|\chi^{(3)}|$ values, and response times τ at the measured wavelength λ, as well as references. PLD and VE depict pulsed laser deposition and vacuum evaporation

System	Preparation	$\lvert\chi^{(3)}\rvert$ (esu)	τ (ps)	λ (nm)	Reference
Au (15 nm)/silica	Shell structure	10^{-9}	2	550	[42.95]
Cu (2 nm)/Al_2O_3	PLD	10^{-7}	5–450	600	[42.96]
Ag (20 nm)/BaO	VE	10^{-10}	0.2	820	[42.97]
Fe (4 nm)/$BaTiO_3$	PLD	10^{-6}		532	[42.98]
SnO_2 (10 nm)/silica	Sol–gel	10^{-12}		1064	[42.99]
CdS (4 nm)/silica	Sol–gel	10^{-11}		500	[42.100]

titative estimation predicts that closely packed CuCl particles of radius 40 nm could provide a $|\chi^{(3)}|$ enhancement of a factor of $\approx 10^3$ when compared with the bulk value [42.103].

When metal particles such as spherical Au particles with diameters of 10–50 nm are used, we can envisage local field enhancement and dynamic responses from conduction electrons, including plasmon effects [42.94, 104]. The result is approximately written as

$$\chi^{(3)} \approx p_\mathrm{m}\chi^{(3)}_\mathrm{m}\left|\frac{3\varepsilon_\mathrm{h}}{\varepsilon_\mathrm{m}+2\varepsilon_\mathrm{h}}\right|^2\left(\frac{3\varepsilon_\mathrm{h}}{\varepsilon_\mathrm{m}+2\varepsilon_\mathrm{h}}\right)^2 , \quad (42.10)$$

where p_m is the volume fraction of the metal particles, $\chi^{(3)}_\mathrm{m}$ is the bulk nonlinearity of the metal, and ε_h and ε_m are the linear dielectric constants of the host (glass) and the metal, respectively. The nonlinearity of the host is neglected here for the sake of simplicity. Also note that ε_h can be real, while ε_m is complex. We then see that the metal's nonlinearity $\chi^{(3)}_\mathrm{m}$ is decreased by the volume factor p_m, while $\chi^{(3)}_\mathrm{m}$ may be enhanced by local fields if $\mathrm{Re}\{\varepsilon_\mathrm{m}+2\varepsilon_\mathrm{h}\}\approx 0$, which determines the resonance wavelength. In agreement with this model, an Au-dispersed glass, for instance, gives a greater $\chi^{(3)}$ than an Au film [42.1].

However, since these systems are complex, consisting of particles and a host glass, a variety of situations arise. For the particle, as well as particle species, we need to consider the size, shape, and concentration. Here, needless to say, a narrow size distribution is preferred for investigating fundamental mechanisms [42.105]. The shape may be spherical, ellipsoidal [42.106], a rod, and so forth. The concentration determines the mean separation distance between particles. As the concentration increases, electrical particle–particle interactions appear [42.95], and then the particles eventually percolate [42.96], which may produce dramatic changes in the nonlinear response. On the other hand, the host material seems to be of secondary importance. Actually, liquids and organic materials as well as glasses have been employed [42.1]. However, some reports suggest that the nonlinearity is greatly affected by the surface states of semiconductor particles [42.107] and by the dielectric constant of a host surrounding metallic particles [42.1].

Finally, a few challenging results may be worth mentioning here. One is that particles can be arrayed to produce photonic structures that exhibit novel nonlinear properties, such as light confinement [42.108]. It is also demonstrated that an arrayed molecular structure, Se-loaded zeolite, gives higher nonlinearity by three orders of magnitude than those of glassy Se [42.109]. The other is the generation of second harmonic signals from oriented ellipsoidal Ag nanoparticles in silica [42.110], which have been produced through a kind of mechanical poling; tensile deformation under simultaneous heating.

42.4 Photoinduced Phenomena

The intense pulsed light, which is employed to produce nonlinear effects, is also likely to produce a variety of transitory and (quasi-)stable optical changes [42.107, 111]. Photochromic effects induced by subgap light are the result of transitory electronic changes [42.112]. The increase in the refractive index of SiO_2 glass induced by fs–ns laser light with $\hbar\omega$ on the range of 1–5 eV is known to occur along with quasi-stable structural changes [42.21]. The optical poling described in Sect. 42.2 can be regarded as a kind of photoinduced anisotropy. When the light is more intense than 1 GW/cm^2–1 TW/cm^2, depending on the duration of the light pulse, permanent damages are likely to occur [42.2]. These photostructural changes can be induced by electronic excitations, which may be triggered by one- and multi-photon processes, depending upon the photon energy and the light intensity. Temperature rises may also add some effects.

However, we should be careful to assert if these photoinduced phenomena are really excited by nonlinear processes. For instance, when a photoinduced phenomenon is induced by exposure to photons with an energy $\hbar\omega \approx E_\mathrm{g}/m$, where m is an integer, it is often asserted that m-photon absorption is responsible. Nevertheless, the phenomenon may be triggered by one-photon absorption by mid-gap states, which give weak absorption tails (Fig. 42.5) arising from defective structures in the glass [42.36, 113]. Otherwise, it may be triggered by m-step absorption processes [42.114], consisting of m one-photon absorptions in succession (Fig. 42.2c). These processes have probably been overlooked when analyzing experimental results.

In addition, as schematically illustrated in Fig. 42.8, the structural changes induced by linear and nonlinear excitation are not necessarily the same. For instance, in As_2S_3 glass, bandgap excitations induced by one-photon and two-photon absorption produce different changes [42.113]; one-photon excitation leads to photodarkening, while two-photon excitation results in an

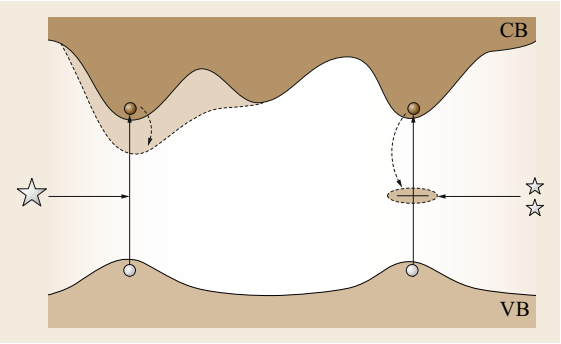

Fig. 42.8 Different relaxation paths from bandgap excitation due to one-photon (*left*) and two-photon (*right*) processes. For instance, the one-photon and two-photon excitations induce bonding strains and defect alterations, respectively

increase in the refractive index with no photodarkening. Such different changes depending upon excitation processes can appear in glasses because the *localized* atomic wavefunction plays an important role, in contrast to the extended Bloch wavefunctions in crystals. For instance, as we can see from (42.4), one-photon excitation occurs between wavefunctions with different parities, such as from s to p orbitals, since H is an odd function. In contrast, (42.5) shows that two-photon excitation tends to occur between states of the same parity, such as from p to p. In addition, $1/(E_{\rm ni}-\hbar\omega)$ in the equation leads to the possibility of *resonant and localized* two-photon excitation if $E_{\rm ni}-\hbar\omega\approx 0$ is satisfied for a mid-gap state. In such cases, the mid-gap state selectively absorbs the excitation energy, leading to an atomic transformation, which is likely to appear as a photoinduced macroscopic change.

42.5 Summary

At present, there is a big gap between the science and the technology of glasses. From a physical point of view, glass science lags far behind crystal science, mainly due to experimental difficulties associated with atomic structure determination and limited applicability of the formulation using spatially extended phonons and electron wavefunctions. On the other hand, it is fully unrealistic to imagine a world without optical glass fibers. And, cutting-edge optical processing needs, in addition to electro-optical devices, novel photo-optical devices, which may utilize the optical nonlinearity. These situations are promoting a deeper understanding of nonlinear photonic glasses and leading to a wider range of photonics applications, the result appearing as the increasing number of publications (Fig. 42.1).

However, the magnitude of optical nonlinearity may still be insufficient for fabricating compact devices. And, we have been exploring newer glass compositions and architectures. For the former, research appears to be gradually shifting from oxides to chalcogenides and more complicated systems, which possess higher nonlinearity with fast responses. However, few studies have been performed to predict the response time τ of nonlinearity in a glass at a particular excitation energy. For device structures, we are developing photonic-structured fibers, nanowires, snaky waveguides, and so forth, which may be assembled as functional bundles and also as plates for two-dimensional signal processing.

Third-order optical nonlinearity in homogeneous glasses has been studied in a fair amount of detail. Substantial experimental data have been obtained for n_2, which have been analyzed using empirical relations such as those from Boling. In contrast, less work has been done on the nonlinear absorption β. In this chapter, therefore, we have tried to present, in a coherent way, the absorption and the refractive index using semiconductor terminology. This approach can be used to connect nonlinear properties to the energy gap.

Two heterogeneous systems have aroused increasing interest. One is poled, crystallized, or ceramic glasses. Enhanced second-order nonlinearity has been reported for such systems, and this can sometimes be added selectively to desired locations. The other is the particle-embedded system, which can give greater third-order nonlinearity, and in some cases enhanced second-order nonlinearity too. However, the mechanism associated with this system remains to be studied. One experimental problem is to find a method that can reproduce particles of a fixed size and shape in arbitrary concentrations. These heterogeneous systems may be fabricated in combination with structured fibers or photonic crystals for improving nonlinear performances.

Finally, nonlinear optical excitations appear to play important roles in a variety of photoinduced phenomena in glasses. However, fundamental studies are still lacking in this area. The phenomenon of interest may be nonlinear in nature, or the linear excitations of gap

states may trigger successive changes. Attempting to understand the nonlinear photo-electro-structural process provides a challenging problem.

Acknowledgments. The author would like to thank his students, K. Sugawara and N. Minamikawa, for preparing illustrations and giving comments.

43. Solar Cells and Photovoltaics

Stuart Irvine

Photovoltaic solar cells are gaining wide acceptance for producing clean, renewable electricity. This has been based on more than 40 years of research that has benefited from the revolution in silicon electronics and compound semiconductors in optoelectronics. This chapter gives an introduction into the basic science of photovoltaic solar cells and the challenge of extracting the maximum amount of electrical energy from the available solar energy. In addition to the constraints of the basic physics of these devices, there are considerable challenges in materials synthesis. The latter has become more prominent with the need to reduce the cost of solar module manufacture as it enters mainstream energy production. The chapter is divided into sections dealing with the fundamentals of solar cells and then considering six very different materials systems, from crystalline silicon through to polycrystalline thin films and perovskites. These materials have been chosen because they are all either in production or have the prospect of being in production over the next few years. Many more materials are being considered in research and some of the more exciting, excitonic cells and nanomaterials are mentioned. However, there is insufficient space to give these very active areas of research the justice they deserve. I hope the reader will feel sufficiently inspired by this topic to read further and explore one of the most exciting areas of semiconductor science. The need for high-volume production at low cost has taken the researcher along paths not normally considered in semiconductor devices and it is this that provides an exciting challenge.

Photovoltaic (PV) devices are a method of converting radiant solar energy into electrical energy. Most of our energy sources, including fossil fuels, hydroelectric and wind power actually come from solar radiation but are indirect conversions into electricity. Another class of solar energy conversion is the heating of water in solar thermal panels. Although the conversion efficiency can be high, they do not generate the thermal energy necessarily where and when it is needed, so storage is required. Direct generation of electric energy is attractive because it is a versatile energy form, rapidly converted into heat, mechanical or light energy. Photovoltaic energy is the main source of energy in the rapidly expanding satellite market with high-efficiency photovoltaic modules producing more than 1 kW of power. Terrestrial applications are also rapidly growing with an estimated total installed capacity worldwide of over 177 GW at the end of 2014 [43.1], and this has been increasing annually by 30%. This, however, is small compared with the total amount of electrical energy consumed each year, but is now supplying more than 1% of primary energy demand. Solar energy is very attractive as it is completely nonpolluting and can help to reduce the amount of fossil fuels that we burn to generate electricity. World CO_2 emissions grew by 4% a year up to 2012. Any contribution from non-fossil-fuel alternatives such as solar energy will help to reduce this annual burden of CO_2 emissions that is now a widely accepted cause of global warming. So how much solar energy is available for conversion to electricity? The total solar energy falling on the Earth's surface each year is huge and 10 000 times the current consumption of energy. We only need to capture a tiny fraction of this to make a major contribution to

our electricity supply but this will mean incorporating solar electric panels into most buildings; to achieve this it will need to be much cheaper to compete with current fossil-fuel electricity generation.

The range of applications outlined here place different demands on the design of the photovoltaic module and hence the materials solutions may well be different. Cost has already been mentioned as paramount for terrestrial power requirements, but for space applications resistance to ionising radiation is important. This section will consider the materials, the implications of competing technologies and how well they meet the criteria for different applications. The first section will deal with how a photovoltaic cell operates and introduces the figures of merit that are used to compare photovoltaic cells and relate performance to theoretical performance. Solar cell technology is promoted as a clean fuel technology that does not introduce CO_2 and pollutants into the atmosphere. However, for this to be a truly environmentally friendly technology, the manufacturing and eventual disposal will also have to be environmentally safe and this depends on the materials used and the fabrication technologies. These factors will be considered for each material system.

43.1 Figures of Merit for Solar Cells

In this section we will consider the operation of a photovoltaic cell and the significant parameters that characterize its performance. The objective of a photovoltaic cell is to capture as much of the solar energy as possible and convert this into electrical energy. The solar energy reaching the Earth's atmosphere fits a black-body distribution for a body at 5800 K. This spectrum becomes highly structured, particularly in the infrared part of the spectrum, by absorption bands due to atmospheric gases. By the time the solar radiation reaches the Earth's surface, it no longer fits a black-body distribution [43.2]. The shift in the spectral distribution will obviously affect the efficiency of absorption of the solar radiation, particularly considering that all semiconductor materials will display a cutoff wavelength dictated by the bandgap of the semiconductor. It is necessary to specify the atmospheric absorption when quoting efficiency, as the depth of atmosphere that the solar radiation has passed through will affect both the spectral distribution and the total amount of energy. The measurement used is air mass (AM) and is defined as 0 for solar radiation outside the atmosphere and 1 for radiation reaching the ground when the Sun is at its zenith. For shallower angles the solar radiation has to penetrate a larger depth of atmosphere and the AM is therefore going to be greater than 1. For space applications AM 0 is the appropriate condition and for terrestrial applications (depending on the position on the Earth) AM 1.5 is a typical value quoted, which corresponds to a solar angle of 48°. All this assumes that there is no cloud cover, which will further reduce the integrated intensity and modify the solar spectrum. Although cloud cover will reduce the amount of solar energy available for conversion, useful amounts of electricity can still be generated.

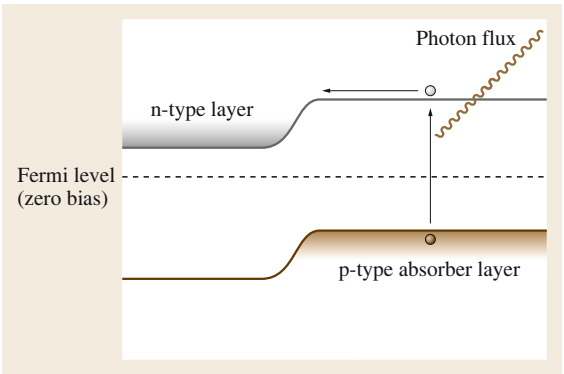

Fig. 43.1 Schematic of an energy-band diagram for a p-n junction solar cell showing photoabsorption to create an electron-hole pair and diffusion of the electron towards the junction

The available solar energy also decreases from $1367\,W/m^2$ outside the atmosphere (AM 0) to $1040\,W/m^2$ for AM 1, when the sun is directly overhead. In practice, for terrestrial applications the available solar energy is considerably less than this where, in general, AM > 1 and is further reduced by cloud cover.

A photovoltaic cell is basically a diode with a photogenerated current. A band diagram is shown schematically in Fig. 43.1. Absorption of radiation can occur on both sides of the junction, creating minority carriers that can diffuse towards the junction. A photocurrent is generated if the minority carriers can drift across the junction without recombination. In practice, the junction is shallow and absorption will occur predominantly on one side where there is a greater depth of absorbing material. There are also heterojunction p-n devices where less absorption will occur in the wider-bandgap layer, as shown in Fig. 43.2. So, one side of the junction is considered to be the absorber layer and it is the spectral absorption characteristics of this layer that will

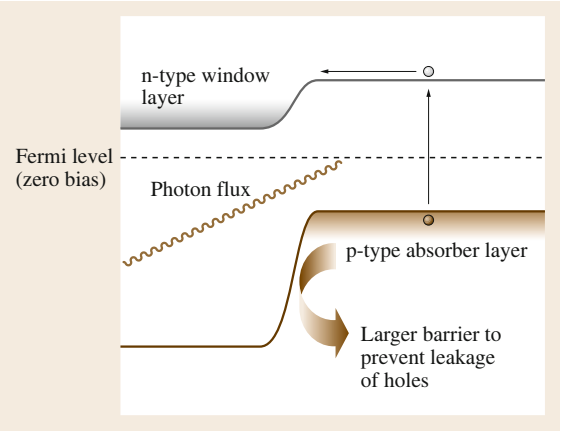

Fig. 43.2 Band diagram for a heterojunction PV cell showing illumination through the wide-bandgap window layer

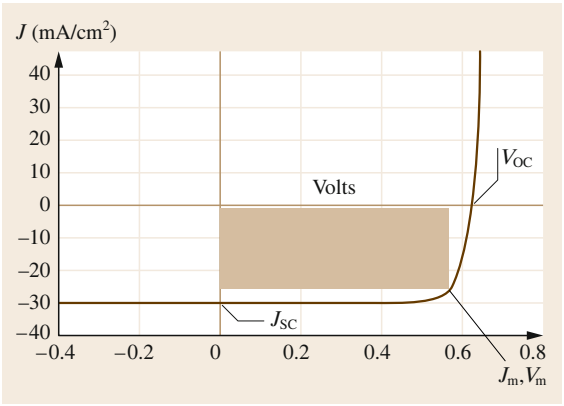

Fig. 43.3 Ideal J–V characteristic for a photovoltaic cell, according to (43.1) with J_s equal to $30\,\mathrm{mA/cm^2}$. The parameters J_{sc} and V_{oc} are indicated on the graph. The maximum extracted power is shown as the *shaded area*

determine the maximum absorption possible from the available solar radiation.

An ideal diode characteristic for an illuminated cell is shown in Fig. 43.3. In the dark the J–V plot would go through the origin and, as the light intensity increases, the short-circuit current becomes increasingly negative, indicating the presence of a photogenerated current. The equation for the J–V characteristic of this ideal device is

$$J = J_s\left(e^{\frac{qV}{k_B T}} - 1\right) - J_L\,, \tag{43.1}$$

where J_s is the saturation current in reverse bias under zero illumination, q is the charge on the carrier, V is the applied voltage, k_B is Boltzmann's constant, T is the temperature of the cell and J_L is the photogenerated current. In the ideal cell this is equal to the short-circuit current, indicated as J_{sc} on the J–V curve in Fig. 43.3. Power can be extracted from the device in the $+V$, $-J$ quadrant of the J–V plot and the load will determine the operating point in this quadrant. The power is determined from the product JV at this operating point, shown graphically in Fig. 43.3. The maximum power will correspond to the operating point that will give the largest JV area on this graph. For the ideal diode characteristics given in (43.1), this maximum power is given by the following (43.2)

$$\begin{aligned} P_m &= J_m V_m \\ &= J_m\left[V_{oc} - \frac{k_B T}{q}\ln\left(1 + \frac{qV_m}{k_B T}\right) - \frac{k_B T}{q}\right] \\ &= J_m\left(\frac{E_m}{q}\right), \end{aligned} \tag{43.2}$$

where E_m is the maximum energy that can be extracted per photon and depends on the band parameters for the semiconductor absorber layer, which determine V_{oc} and V_m. These parameters are marked on the J–V plot in Fig. 43.3. We now have two fundamental parameters which will limit the efficiency of the cell:

- The fraction of solar photons absorbed in the cell
- The electrical energy created per photon.

The first factor can be calculated by integrating over the solar spectrum for the appropriate AM number and including the cutoff wavelength of the semiconductor absorber layer.

$$\eta_{abs} = \frac{\int_{E_g}^{\infty} n_E(E)\mathrm{d}E}{\int_0^{\infty} n_E(E)\mathrm{d}E}\,. \tag{43.3}$$

This is shown graphically in Fig. 43.4 for AM 1.5. Any photons with energy less than the bandgap will not be absorbed and will not contribute to the photocurrent.

The second efficiency factor mentioned above implies that not all the photon energy will be converted into electrical energy, even if one photon absorbed constitutes one minority carrier crossing the junction. The electrical energy per carrier is given by the factor E_m in (43.2), so the maximum power of the device is the product of the absorption rate of photons and the mean electrical energy created per photon. This product is represented by the inner shaded area of the solar spectrum shown in Fig. 43.4. The difference between curve 1 and curve 2 is simply the energy lost per photon because not all the photon energy is converted into electrical energy. Different semiconductor materials will have different efficiencies primarily because of different values for the bandgap. The ideal value for E_m will

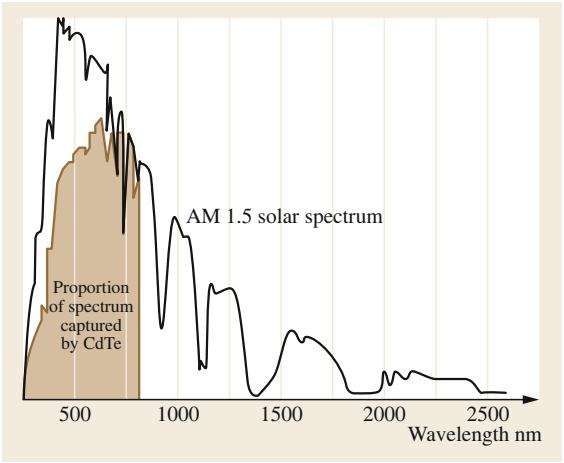

Fig. 43.4 Graphical representation of the maximum energy that can be extracted from a CdTe solar cell with a bandgap energy of 1.45 eV

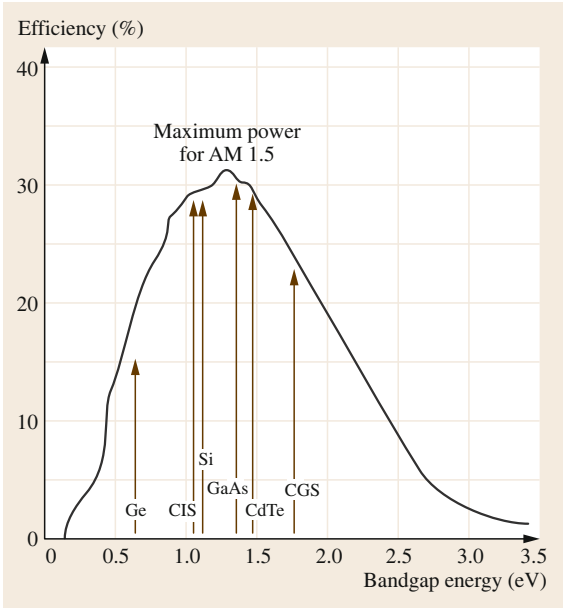

Fig. 43.5 Plot of ideal efficiency against bandgap energy for a single-junction cell for AM 1.5 illumination conditions. (After [43.2])

track the bandgap, so for narrower-bandgap materials there will be a larger proportion of photons absorbed but less electrical energy per photon. The function of efficiency for semiconductors with different bandgaps, taken from curve 2 in Fig. 43.4, is plotted in Fig. 43.5 and shows that the optimum efficiency occurs for semiconductors with a bandgap in the near-infrared region, around 1.5 eV. This represents the best compromise between absorption of solar radiation and transferring the optimum amount of energy per photon into electrical energy.

The maximum efficiency is predicted for Si, InP, GaAs and CdTe, which are in the region of 30% for AM 1.5 irradiation (1 sun illumination) and is called the Shockley–Queisser limit [43.3]. This means that the very best conversion efficiency for a single-junction cell is approximately one third of the available solar energy. In practice, photovoltaic cells have efficiencies considerably less than this due to optical reflections, poor junction characteristics and carrier recombination. These are materials issues that are often traded off against production costs, for example using polycrystalline rather than single-crystal material. Conversely, higher conversion efficiencies can be achieved using multiple junctions, which are more expensive but attractive for space applications and when used in combination with solar concentrators, so less surface area of the expensive multijunction cell is required. Other factors that can influence the choice of photovoltaic materials include the following:

- Absorption coefficient
- Contact resistance
- Abundance of raw materials
- Toxicity of materials
- Stability of materials and junctions
- Radiation resistance.

These factors will be considered in the following examples of different photovoltaic systems to assess the merits of different materials. It is probably true to say that there is not one ideal material but different applications can make one material more attractive than another.

43.2 Crystalline Silicon

Over 85% of the current world production of solar modules are made from either single-crystal or multigrain silicon. This is the most mature of the photovoltaic materials and has benefited considerably from the size of the silicon semiconductor industry. This has ensured a ready supply of material and processing tools suitable for large-scale production. However, crystalline silicon does suffer from a fundamental disadvantage in that the bandgap of silicon is indirect, which means that the absorption coefficient is much lower than

a direct-bandgap semiconductor such as CdTe. In practice this means that a much thicker piece of material is needed to absorb all the solar radiation greater than the bandgap energy. This requires wafers of silicon thicker than 100 μm and means that this material is not suitable for thin-film technology. The highest performance solar electric modules are made from wafers of single-crystal silicon cut from Czochralski-grown crystals, up to 30 cm in diameter. This was originally developed on the back of the silicon electronics industry, but the rapid increase in production volume of PVs is now driving production of silicon crystals. The conversion efficiency for single-crystal PV modules is around 20% with the potential for increases in the near future to 22%.

Multicrystalline silicon involves the relatively cheap path of casting silicon ingots that are not seeded but produce a random grain size of the order of 1 cm across. The ingots are cast in blocks, larger than 100 kg, and then sliced into wafers 300 μm thick and with an area of up to 20 cm^2. The grain boundaries cause these wafers to be mechanically weaker than the single-crystal wafers and they will typically be thicker. This causes some trade off in price. Each cell can be expected to contain grain boundaries, so loss of photogenerated charge at the grain boundary can cause some loss of efficiency. Typical module efficiencies for multicrystalline silicon are currently around 17%.

The junction is formed by phosphorus implantation to form a p-n homojunction and contacted by printing of a metal grid, usually of a Ni-Au alloy. Patterning of the surface prior to implantation and contacting has achieved the highest efficiency cells by improving light collection [43.4]. Another recent innovation that has contributed to higher efficiencies is the *V*-grove or buried junction. This is shown schematically in Fig. 43.6 and entails the grooving of the p-type silicon substrate, implantation of phosphorus to create a buried junction and filling with metal contact alloy. This helps to improve the collection efficiency of the cell, particularly in the blue part of the spectrum. These manufacturing steps have to handle large volumes and be cheap. Cheaper alternatives to ion implantation involve thermal diffusion from a screen-printed paste or spin-on glass [43.5].

The main disadvantage of silicon is that the absorption coefficient is low because it is an indirect-bandgap semiconductor (2×10^3 cm^{-1} for Si compared with 1×10^5 cm^{-1} for CdTe in the green part of the spectrum). This means that the amount of material needed to absorb the solar radiation is greater than for a direct-bandgap semiconductor. The absorption can be improved by having a reflecting back contact that, if it is roughened, will increase the mean path length of

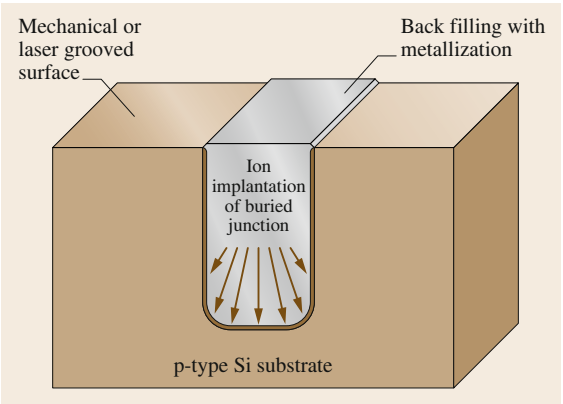

Fig. 43.6 Schematic of buried-contact technology for Si solar cells

the back reflected light in the silicon cell. This is particularly important for thin-film silicon devices where the amount of material is more of an issue, although the thickness of 30–100 μm can be compared with the much thinner layers used for direct-bandgap semiconductors (see CdTe and GaAs).

Thin-film polycrystalline silicon is grown by ribbon casting techniques. The pulling speeds are in the range of 10–1800 cm/min, and this represents a cheap method for the production of solar cell material but the conversion efficiencies are currently low. One way of increasing the absorption coefficient is to deposit a film of amorphous silicon (a-Si), which has a larger bandgap than crystalline silicon but is a direct-bandgap material. Amorphous silicon has led the way in cheap thin-film solar cells but suffers the disadvantages of low efficiency (< 10%) and poor long-term stability. These cells will be discussed in greater detail in the next section.

Crystalline silicon solar cells, over the last ten years, have approximately doubled in efficiency and this has been achieved by a combination of the following:

- Improved material quality, leading to improved minority-carrier diffusion length.
- Improved V_{oc} and fill factor through emitter and base doping and contact optimization.
- Improved J_{sc} through diffusion length improvement using phosphorus gettering, hydrogen passivation and buried contacts.
- Surface passivation and contact grid optimization.

All these aspects involve materials issues, either directly associated with the quality of the silicon or with contacting and passivation. It is also important to avoid degradation of the cell and the final encapsulation must avoid exposure of the cell to water. Multicrystalline silicon can be passivated with silicon nitride deposited by

plasma-assisted CVD (CVD) from SiH_4 and NH_3 to reduce surface recombination [43.6].

Silicon solar modules are becoming cheaper to produce, nontoxic and stability in a nonradiation environment is good. Multicrystalline silicon is not so suitable for space applications because of the combination of thick absorber layers, requiring greater weight per unit area and the sensitivity of the cell to degradation in a high-radiation environment. However, single-crystal silicon has dominated the space market, but it has now been replaced by higher efficiency III-V multijunction cells. Single-crystal modules for terrestrial applications produce the highest available output power with over 300 W (AM1.5) per panel.

43.3 Amorphous Silicon

Amorphous silicon offers the potential for a cheap production technology for terrestrial photovoltaic solar cells. The amorphous state displays different physical properties to the crystalline with a modified band structure. One consequence of this is that the absorption coefficient in the green part of the visible spectrum is a factor of ten higher at $2\times10^4\,\mathrm{cm}^{-1}$, which makes it more suitable for thin-film applications. The amorphous structure leaves dangling bonds, which pin the Fermi level and would normally prevent doping of the material. This is overcome by the inclusion of hydrogen, which passivates these dangling bonds, so the material is referred to as a-Si:H. The Si can also be alloyed with Ge, C, and N in a glow-discharge evaporator. These alloys are particularly useful for multijunction devices used for increasing the solar collection efficiency. In the laboratory single-junction cells have an efficiency around 10% [43.7] with multijunction cells going up to over 13%, where the a-Si junction is combined with nanocrystalline Si junctions [43.8]. In production an a-Si module has an efficiency of 7–10%, considerably less than the crystalline materials.

The most common method for producing a-Si:H for photovoltaics is by plasma-enhanced CVD from SiH_4 mixtures. The films are deposited onto a textured conducting oxide such as indium-tin oxide (ITO), which provides the electrical contact and increases the average light path in the absorber layer to increase absorption. The device structure is a p-i-n with absorption taking place in the middle (insulator) layer, which is only 0.5 μm thick. The p and n layers can be deposited by adding B_2H_6 or PH_3 respectively to the plasma.

One of the major disadvantages of a-Si:H is the instability and long-term deterioration under light illumination. This is caused by the rearrangement of dangling bonds, often associated with rearrangement of hydrogen atoms close to weak or dangling bonds. The energy comes from nonradiative bimolecular reactions and hence depends on the illumination intensity (for further details see the review by *Bloss* et al. [43.9]). In practice, this causes a downward drift in efficiency with time, which can be as much as 2% in 100 h. The cost of a-Si thin-film modules ten years ago was cheaper than crystalline silicon (3 US$/Wp) but has not kept track with falling prices and larger manufacturing volumes of crystalline silicon modules [43.10, 11]. One of the main technical challenges is to maintain stabilized efficiency above 10%. The relatively high cost of PV solar modules compared with more conventional sources of energy can only become attractive if it can operate efficiently over a long period of time. This means that the modules must remain efficient over a period of 20 years. Shorter operating lifetimes would have to be mitigated by much lower production cost.

In conclusion, a-Si:H is a low-cost technology for terrestrial applications and has found its way into low-power and other more bespoke applications such as small-scale standalone systems. The temperatures used in processing these modules is lower than the high temperatures needed to melt silicon for the crystalline silicon modules, which means that the energy payback times and carbon footprint are less. However, longer-term stability will affect the amortized cost of electricity compared with crystalline silicon PV modules.

43.4 GaAs Solar Cells

The III-V semiconductors have advantages over silicon due to their direct-bandgap photon absorption, with an absorption coefficient in the green of $8\times10^4\,\mathrm{cm}^{-1}$. This means that, for example, GaAs can theoretically yield over 30% efficiency (AM 1.5) for an absorber layer thickness of just 1–2 μm, compared with a hundred times this for crystalline silicon. The efficiency, stability and thin-film deposition technology make these cells attractive for space applications. From Fig. 43.5 it is clear that the bandgap of GaAs is well matched to the op-

timum for maximum efficiency. It is also noteworthy that the highest efficiency single-junction solar cell is epitaxial GaAs with 28.8% AM1.5 efficiency [43.12]. The III-V semiconductors also offer the flexibility of alloying to change the bandgap and tune the response of the photovoltaic junction. In addition, heterojunctions can be formed and multijunction solar cells can be produced to convert more of the solar spectrum into electricity and thus exceed the theoretical limits set by the Shockley–Queisser limit. For example, in the laboratory a GaAs/GaSb tandem solar cell was reported with 35.6% efficiency as long ago as 1990 [43.13]. Higher efficiencies are possible with three and even four junctions to capture more of the infrared that would otherwise not be absorbed. The Ge substrate, which is closely lattice matched with GaAs, is commonly used as an infrared absorber to capture the radiation that passes through the $GaInP_2$/GaAs cell [43.14, 15]. The top cell has an absorber of $GaInP_2$, which has a bandgap of 1.9–2 eV, and will capture the visible part of the spectrum without too much voltage loss. The next cell is GaAs, which has a bandgap of 1.42 eV, and will capture the red to infrared part of the spectrum. The bottom junction is formed in the Ge substrate, which has a bandgap of 0.67 eV and will capture the light further into the infrared. The best triple-junction solar cell has achieved 37.9% efficiency under AM1.5 illumination [43.16]. The triple-junction cell, in production for space applications, can yield 29.5% (AM 0) conversion efficiency [43.17].

The layers of these multijunction cells are grown epitaxially onto single-crystal Ge substrates. As with crystalline silicon, high crystalline quality is needed to obtain high efficiency cells; polycrystalline GaAs does not work as well due to grain-boundary conduction that reduces the available photocurrent [43.18]. This restricts the photovoltaic applications to high-quality epitaxial material as GaAs is not suitable for cheap thin-film photovoltaics on glass substrates. The topic of thin-film polycrystalline photovoltaics will be considered in the next section on CdTe solar cells. Epitaxial growth avoids minority-carrier recombination at grain boundaries, by avoiding their formation, but the cost of the substrates is inherently higher than the glass or ceramic substrates used for thin-film devices. However, defects must also be avoided at the junction and interfaces between layers of different composition and this imposes the constraint that the heterostructures should be lattice matched. This restricts the choice of alloys to those that are either lattice matched, or so that the thickness and mismatch are such that the film is strained. The simplest structures use AlGaAs, which has a close lattice match to GaAs over the entire composition range, as a window and passivation

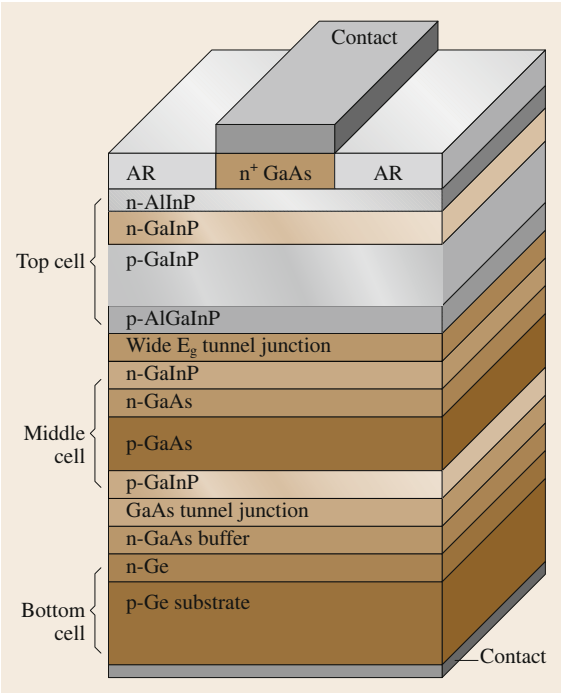

Fig. 43.7 Schematic of a triple-junction GaAs solar cell, showing the positions of three junctions. (After [43.13])

layer. GaAs is also closely matched to Ge, offering a choice of substrates. The GaAs or Ge substrate is the narrowest bandgap part of the structure, so the device has to be front-side illuminated with a grid of metal contacts on the top surface to contact the cells. The design of the cell structure needs to have the wider-bandgap layers further from the substrate (last to be grown) to allow the longer wavelengths to penetrate to the narrow-bandgap absorber layer. This places further constraints on the design of these epitaxial structures.

The Ge and GaAs substrates have a similar lattice parameter to AlGaAs, which is used as a passivation layer for both n-type and p-type GaAs layers. Other III-V compounds that can be used include GaSb, which is sensitive to the near infrared out to 1.8 μm and will therefore absorb the radiation that is transmitted through the GaAs cell, as an alternative to the Ge-bottom cell. The alloy GaInP also lattice matches for the 50% Ga/In mix and is useful as a wider-bandgap junction. GaSb is also attractive for thermo-photovoltaics where the solar radiation is converted into heat, which is then absorbed by the narrow-bandgap GaSb device. The narrow-bandgap quaternary GaInNAs has been investigated [43.19] as a narrow-bandgap absorber layer and can be inserted between the GaAs layer and the Ge substrate to give a small boost in voltage and overcome the

disadvantage of the excess current that would be produced by the Ge bottom cell.

The push to achieving further increases in multijunction solar cell efficiency is driving new approaches to increasing the number of cells without being constrained by lattice mismatch. One of these approaches is the inverted metamorphic structure (IMM) where lattice mismatch is graded out using a buffer layer but to avoid compromising the top GaInP junction with threading dislocations this is grown as an inverted structure onto lattice matched GaAs and then the substrate is removed [43.20]. By this way the highly mismatched bottom junction of $In_{0.27}Ga_{0.73}$ As is grown last but can provide better a bandgap match, giving a boost in efficiency. This is opening the way for better current matching and optimizing the bandgap for increasing the efficiency of multijunction cells and moving towards achieving greater than 50% conversion efficiency.

The III-V photovoltaic structures are grown by metalorganic vapor-phase epitaxy (MOVPE), which gives excellent control over alloy composition and doping concentration. An example of a multijunction cell is shown in Fig. 43.7. The structures tend to be complex because a tunnel junction is needed for current to flow between the two (series) photovoltaic cells, otherwise the connection between the two would be a high-impedance reverse-bias junction. It is also important for the device design to match the currents between the two (or more) junctions so that they can both operate at near-optimum conditions.

GaAs-based solar cells are now dominating the space market to power satellites. Their efficiency is high and stability is good, but the single-crystal Ge substrates and complex epitaxial layer growth leads to high cost. There may be toxicity issues for the disposal of solar modules if GaAs was used widely for terrestrial applications. The most attractive terrestrial application would be in concentrators where the solar radiation is optically concentrated onto the PV cells, so the collection area can be much greater than the area of expensive PV modules. This is looking like an attractive and cost-effective option for regions of the world with a high proportion of direct sunlight [43.21].

43.5 CdTe Thin-Film Solar Cells

The bandgap of CdTe of 1.45 eV at room temperature makes it another semiconductor that is close to the theoretical optimum for efficient conversion of solar radiation (Fig. 43.5) into electrical power. The absorption coefficient is $> 5 \times 10^4\,\mathrm{cm}^{-1}$ for photon energy greater than the bandgap, allowing efficient collection for only 2 μm-thick films, similar to GaAs. CdTe, like GaAs is also a direct-bandgap semiconductor but is from the II-VI family of semiconductor compounds. The theoretical efficiency for the CdS/CdTe photovoltaic cell is ≈ 30% at AM 1.5, the world record efficiency has increased from nearly half this maximum, in 2010 to 21.5% in 2015 [43.22] and for modules in production the efficiency has increased to over 14%. The attraction of CdTe compared with GaAs is that these cells can be made from polycrystalline thin films on glass substrates, thus avoiding the need for expensive single-crystal substrates. A further advantage in using glass substrates is that illumination of the photovoltaic cell occurs through the substrate rather than from the top face, so the substrate becomes the window for the cell. The front contact is made with a transparent conducting oxide (TCO) such as ITO, as shown in Fig. 43.8, and this avoids the need for an opaque grid of metal contacts. This approach of using a TCO on glass substrate as the window is called a superstrate. The TCO has to have high optical transmission as well as a metal-like electrical conductivity. A typical thin-film resistivity would be 10 Ω per square.

The CdTe solar cell is made from a heterojunction between the wider-bandgap CdS and the CdTe absorber layer. CdS is often referred to as the window layer;

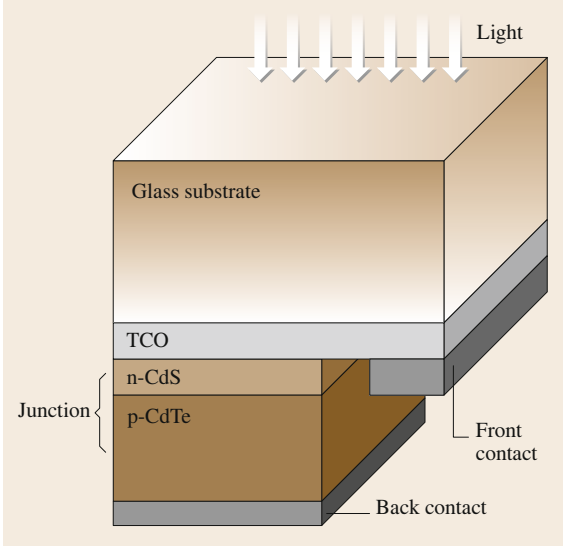

Fig. 43.8 Schematic of a CdTe device structure based on a glass superstrate

it has a bandgap of 2.4 eV allowing most of the visible spectrum to pass with very little absorption. The most common method for depositing CdS is by chemical bath deposition (CBD). The layer is n-type, forming a junction with the p-type CdTe. The thickness is kept to a minimum (around 100–200 nm) in order to minimize absorption at the blue end of the spectrum. A schematic of the CdTe PV structure is shown in Fig. 43.8.

Deposition techniques for CdTe (electrodeposition or close-space sublimation (CSS)) require postdeposition treatment for doping, grain growth and resistivity reduction, at temperatures above 400 °C. The exact processes are not clear but have a role in providing grain boundary passivation, improving efficiency from a few % to > 10% if this anneal is carried out in air in the presence of $CdCl_2$ [43.23]. There are variations in this process in terms of temperature, time and ambient gas but all involve the diffusion of Cl into the CdTe and some interdiffusion of the CdS/CdTe interface. This process improves grain size to $\approx 1\,\mu m$ if the starting material has a much smaller grain size. This is further complicated by the variations in grain size from the CdS interface up to the back surface, where the junction region displays smaller grains. The best efficiency in the laboratory, which stood for ten years since 2001, was 16.5% reported by *Wu* [43.24] and in 2015 rose to 21.5% [43.22].

A typical CdTe module with an area of $0.72\,m^2$ has a peak output power of 110 W; this compares favorably with other thin-film photovoltaics and approaches that of multicrystalline modules [43.25]. The advantage for CdTe thin-film PVs over the maturer crystalline silicon PVs is the smaller temperature coefficient where conversion efficiency decreases with increasing module temperature by −0.5% for crystalline silicon and −0.25% for CdTe modules [43.26]. Future prospects for CdTe can be seen in current research activities with encouraging results for CdTe solar cells on flexible plastic substrates [43.27] and more recently both superstrate on thin polyimide and substrate devices on flexible metal foils [43.28]. Using these substrates places tighter constraints on deposition and annealing temperatures and alternatives to the $CdCl_2$ anneal would be attractive, particularly considering the toxic nature of $CdCl_2$. A nontoxic approach has been proposed by *Major* et al. [43.29] using $MgCl_2$, which achieves the same device improvement as $CdCl_2$ but is nontoxic and costs less than 1% of the cost of $CdCl_2$.

Another area for improvement in CdTe solar cells is in the p-type doping, which has relied on native defects or a controlled Cu diffusion [43.30]. An alternative approach is in situ doping of CdTe with arsenic using metalorganic chemical vapor deposition (MOCVD) [43.31, 32]. Active acceptor doping concentrations as high as $5\times10^{15}\,cm^{-3}$ have been demonstrated and these devices show excellent stability. MOCVD offers greater flexibility over deposition conditions and this has been utilized with CdTe solar cell structures on ultra-thin glass superstrates for ultra-lightweight PV solar cells for space [43.33].

A concern with CdTe is the abundance of tellurium and the volume of available supply to feed a large expansion in the manufacturing of CdTe PV modules. The abundance figures look low but up to 5000 t of Te could be produced each year from copper ore and 20 000 t of Cd is produced each year as a by-product of zinc production. An important environmental and resource issue may be the recycling of these materials. It is important to note that although Cd is a very toxic metal it is relatively benign in the form of CdTe as it is a very stable compound and is not soluble in water. The use of Cd in solar cells has the added benefit of making use of the Cd that is produced as a by-product of zinc production in an environmentally friendly way. *Jager-Waldau* [43.10] states that *Every energy source or product may present some environmental, health and safety hazard, and those of CdTe should by no means be considered barriers to technology scaling*. This technology is less well developed than those in the other case studies but the thin-film technology on glass combined with good stability makes this a very attractive proposition for both terrestrial and space applications.

43.6 $CuInGaSe_2$ ($CIGS_2$) Thin-Film Solar Cells

This is an alternative material system for achieving an optimum bandgap for solar energy conversion and one that has attracted a lot of research effort in the past 20 years with impressive improvements in conversion efficiency. The highest efficiency reported for laboratory solar cells back in 2003 was 19.2%, which then was the best of the thin-film PV technologies [43.34]. This has risen to the current world record in 2015 of 22.3% by the leading CIGS module manufacturer, Solar Frontier [43.35]. In common with other thin-film PV technologies, these films can be deposited onto cheap substrates, at relatively low temperature, and the potential for processing in large volumes. The absorber layer is based on the Chalcopyrite-phase $CuInSe_2$ (CIS). This has a bandgap of 1.04 eV, which is lower than the bandgap for optimum efficiency in

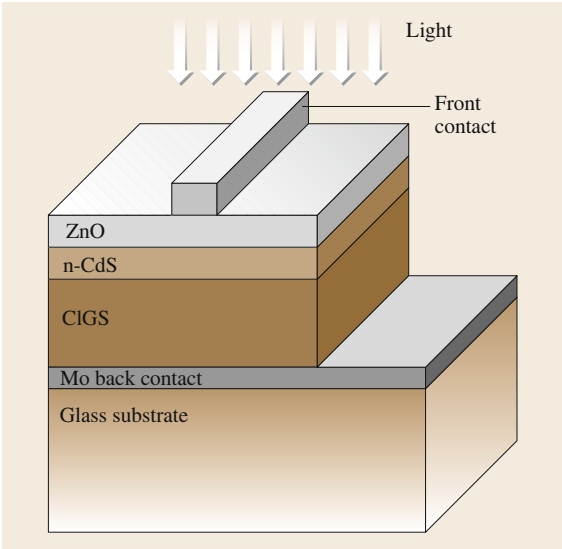

Fig. 43.9 Schematic of CIGS device structure based on a glass substrate

the Shockley–Queisser limit. However, cells made from CIS have achieved > 10% efficiency. Alloying with Ga to form $CuIn_{1-x}Ga_xSe_2$ (CIGS) increases the bandgap to 1.7 eV for $x = 1$. This gives a range of alloy composition across the important optimum range for efficient conversion. An increase in bandgap will increase the voltage of the cell (V_{oc}) but decrease the number of absorbed photons, thus decreasing J_{sc}. In practice the alloy is not uniform and thus a greater proportion of the photon flux is absorbed by the single-junction device than would occur for a single wide-bandgap absorber layer [43.36]. The other benefit of grading of the alloy composition is that the resultant bandgap grading creates a built-in electric field that can drift the electrons towards the junction.

Unlike a-Si and CdTe, the preferred arrangement is the substrate configuration where the cell is illuminated from the top surface as with the crystalline GaAs cells. The typical layer structure is shown in Fig. 43.9. The substrate is soda-lime glass with a sputtered coating of molybdenum, which acts as the back contact. The next layer is the $CuIn_{1-x}Ga_xSe_2$ alloy, which is the p-type absorber layer. The junction is formed with a thin layer of CdS (as with CdTe). The front contact is formed by aluminum-doped ZnO, which is highly conducting but transparent, allowing solar radiation to pass without significant absorption. One disadvantage of the substrate approach is that the top surface is protected with another glass sheet, or other suitable transparent material, when it is fabricated into a solar PV module. This step is not necessary in the superstrate approach. However, the substrate configuration for CIGS has shown much higher maximum efficiency than the superstrate approach (favored by CdTe and a-Si) and provides the opportunity to deposit the CIGS layers onto flexible metal foils. The structure for CIGS on metal foil substrates is similar to those on the Mo/glass substrates except for a barrier layer of SiO_2 between the metal foil and the Mo back contact. This is needed to reduce the diffusion of impurities into the active semiconductor layer. However, one impurity, sodium, is needed to give the desired doping properties for the CIGS absorber layer [43.37]. This impurity occurs naturally when cheap soda-lime substrates are used, as the sodium will diffuse from the glass substrate into the CIGS layer during film deposition and annealing. Using metal foil substrates makes the PV cells flexible and enables their manufacture in a continuous reel-to-reel process.

There are various deposition methods that can be used for the deposition of CIGS and this can lead to low-cost production routes. The early results were obtained by co-evaporation from separate elemental sources. More recently a range of techniques have been used from e-beam evaporation of the metal sources followed by selenisation and annealing to electrodeposition. The characteristic of CIGS synthesis approaches is a separation of the deposition process and alloy formation, allowing cheap and potentially high-throughput techniques to be used. This also enables control of the alloy composition and stoichiometry that will affect the doping [43.38]. The subsequently deposited junction layer, CdS, can be deposited by either chemical bath deposition, sputtering or CVD. The transparent contact layer, ZnO, is typically deposited by sputtering. All these techniques can be operated on a large industrial scale and lend themselves to cheap production methodology.

CIGS solar cells have moved rapidly into production and a number of manufacturers are offering modules with efficiencies in the region of of 14%. For example, Avancis produces a CIGS panel with a peak output power of 140 W for a module area of 1.05 m^2 and Soler Frontier produces modules with a peak power output of 170 W for 1.228 m^2 modules. The potential for further price reduction is similar to other thin-film technologies and competitive with crystalline silicon.

As with CdTe solar cells, the abundance of the elements In and Se appears low, but for a thin-film photovoltaic, where each module only needs a few grams of material, the total amount needed is not huge. However, the current price of In is high as it is not readily produced as a by-product of other mining processes. Price volatility with indium supply could significantly affect the future price of these modules and the cost of the active materials could contribute nearly a half of the

overall module production cost [43.39]. Concerns about materials cost and abundance of materials has stimulated research into alternative chalcogenide absorber materials to replace CIGS in the longer term.

One candidate is the Kesterites copper zinc tin sulfide/selenide (CZTS) with the formula unit Cu_2ZnSnS_4 [43.40]. With a bandgap of 1.45 eV, CZTS has the right characteristics for an efficient single junction absorber material. The synthesis routes are similar to those for CIGS with a preference for formation of the metal precursor through evaporation followed by sulphidisation [43.41]. To achieve the highest conversion efficiencies it has been necessary to alloy with selenium, which reduces the bandgap towards 1.2 eV. The best laboratory efficiency was reported by *Wang* et al. [43.42] with 12.6%, which is well below the CIGS record but shows the potential for high efficiency solar cells using Kesterites. This was achieved through alloying with selenium but it would be advantageous to avoid the less abundance selenium altogether. The best result for selenium-free CZTS is 8.4% reported by *Shin* et al. [43.43] and shows the potential for future development of this material towards low-cost thin-film PV module production.

43.7 Excitonic PV

The drive to find cheaper solutions to the conversion of solar energy has taken research down some interesting and unusual avenues. One of the more successful of the alternative approaches is the dye-sensitized cell, known as the Grätzel cell after its inventor *Michael Grätzel* [43.44]. This uses organic dyes to absorb the solar radiation and transfer electrons to a porous TiO_2 surface, which is effectively the junction. Other approaches have looked at conducting polymers and polymer blends to form photovoltaic junctions. The generic term, excitonic PV, refers to the relatively strong excitonic binding energy of the excited state following photon absorption that binds the electron to the hole. For polymer blend solar cells the dissociation of the exciton is achieved at the interface with a high electron affinity material such as fullerene. The hole is then free to be transported via a hole collector, which is a doped conducting polymer such as PEDOT:PSS [43.45]. The conversion efficiency of this type of solar cell has risen sharply in recent years with the best laboratory efficiency over 10% [43.46]. Organic PV offers the potential for very low-cost production where low temperature processing will also lead to the benefit of a very low carbon footprint.

An exciting recent development with excitonic PV has been the rise of the perovskite absorbers, which were initially used to replace the organic dye in dye-sensitized solar cells [43.14]. A characteristic of excitonic PV is the short excitonic diffusion lengths, so efficient cells require a nanostructured material where an electron collecting interface is never far away. A remarkable property of the methylammonia lead trihalogen perovskites was demonstrated by *Liu* et al. who showed that planar structures could be made, similar to conventional thin-film PV, and achieve high conversion efficiency of over 15% [43.47]. The world record (2015) currently stands at 21%, which was achieved by Michael Grätzel's EPFL team [43.48]. There is still much work to be done on the perovskite solar cells, one of which is to overcome the moisture sensitivity and long term stability. Some of the research is aimed at replacing Pb as the metal center with Sn, which removes any toxicity issues. The potential is for the perovskite solar cells to be used in new applications such as color neutral, partially transparent PV glazing in building-integrated PV [43.49] and many other applications that can take advantage of their unique properties.

43.8 Conclusions

This chapter has introduced some basic concepts about photovoltaic solar cells and examples of some of the more common materials being used for solar-cell production. The area of research is huge with a number of specialist journals dedicated to solar energy and large international conferences held annually. Recent developments with crystalline silicon, III-V heterojunctions, thin-film PV and exciton solar cells have been summarized. These examples show the diversity of materials that can be used for solar PV conversion and different stages of maturity. These approaches will enable very cheap solar PV modules to become a reality in the next five to ten years and also diversify the applications of solar PV.

The largest and most mature production facilities are based on crystalline or multicrystalline silicon.

These modules are also the most efficient for single-junction cells. The most efficient cells are made from multijunction GaAs on Ge substrates and are the most complex and most expensive. Most of the multijunction solar cell production is for the space market but increasingly is showing potential for use with concentrators for terrestrial applications. This is acceptable for standalone solar power generation but the largest challenge for large-scale terrestrial power generation is to integrate photovoltaic modules into buildings. The equivalent of a gigawatt power station would require, at least, of the order of $10^7\,m^2$ of solar modules. In reality it would have to be much larger to account for the average power production being much less than the peak production. A modest installation would have approximately $100\,m^2$ of solar panels so we would need more than 10^5 buildings. So, the goal has to be that every house and building has a PV façade or roof.

Large-scale implementation will require the modules to be architecturally acceptable, in appearance and size, and probably serve multiple functions such as keeping the rain out and heat in, and so on. This need is opening the opportunity for a range of materials and designs and ultimately flexible panels. On top of this the cost per watt of electricity produced needs to come down, probably by a factor of three based on current installed costs. The thin-film technologies are inherently cheaper but much of this cost benefit is not realized at present because the efficiencies and production volumes are lower than crystalline silicon. The current growth in PV solar energy after decades of research has become very rapid and this expansion is set to continue well into the future.

44. Disordered Semiconductors on Mechanically Flexible Substrates for Large-Area Electronics

Peyman Servati, Arokia Nathan

Low-temperature-thin-film semiconductors and dielectrics are critical for large-area flexible electronics, including displays, smart skins and imagers. Despite the presence of structural disorder, these materials show promising electronic transport properties that are vital for devices such as thin-film transistors (TFTs) and sensors. This chapter presents an overview of material and transport properties pertinent to large-area electronics on mechanically flexible substrates. We begin with a summary of process challenges for low-temperature fabrication of a-Si:H TFTs on plastic substrates, followed by a description of transport properties of amorphous semiconducting films, along with their influence on TFT characteristics. The TFTs must maintain electrical integrity under mechanical stress induced by bending of the substrates. Bending-induced changes are not limited to alteration of device dimensions and involve modulation of electronic transport of the active semiconducting layer.

There is significant demand for electronic-grade thin-films for a variety of applications such as organic light-emitting diode (OLED) displays and lighting modules [44.1, 2], solar cells [44.3], digital imagers [44.4, 5], and wearable sensors [44.6]. Interest in these materials is driven by the promise of low-cost roll-to-roll manufacturing [44.7] and amenability to novel flexible and stretchable product designs. They enable high-performance electronic devices including thin-film transistors (TFTs), sensors, diodes and p-i-n photodetectors on large-area flexible plastic, paper and fabric substrates. For example, OLEDs have become highly attractive as thin emissive devices due to their fast response, high conversion efficiency, wide viewing angle, thin profile, and compatibility with plastic substrates [44.8]. In high-information-content displays, the OLED must be integrated with a TFT circuit that provides stable drive currents and allows for fast content switching [44.9]. Here, TFTs based on low-temperature a-Si:H (solution-processed/vacuum-deposited) organic semiconductors or metal-oxides [44.10–12] are needed for building the switches and circuits.

In addition to advances in material deposition and integration technologies, significant research efforts aim to improve the lifetime of TFTs and OLEDs in view of instabilities induced by bias stress and ambient exposure. The instability of TFTs stems from structural and interfacial disorder in the semiconductor and insulator layers, and interfaces. This leads to a shift in the threshold voltage ΔV_T under prolonged bias stress in a-Si:H [44.13] and organic [44.14] TFTs as well as photo-bias instability for metal oxide TFTs [44.10, 11]. To deal with the shift in device parameters, smart pixel circuits and driving schemes have been employed for compensation [44.15]. The lifetime of the OLED, on the other hand, can be enhanced by efficient thin-film encapsulation layers [44.16], which are imperative for active matrix organic light-emitting diode (AMOLED) displays on plastic substrates.

This chapter presents an overview of material and transport properties pertinent to mechanically flexible electronics, in which amorphous-silicon is used as the example. We begin with an overview of low-temperature fabrication of high-performance a-Si:H transistors and associated processing challenges. The transport properties of disordered semiconducting films are then presented, along with their influence on TFT characteristics. We also examine the impact of external mechanical stress, induced by bending of the flexible substrate, on the characteristics of thin-film devices, including strain gauges and TFTs. The shifts are not only limited to changes in device dimensions but also to a modulation of electronic transport of the active semiconducting layer.

44.1 a-Si:H TFTs on Flexible Substrates

Compared to conventional (rigid) glass substrates, mechanically flexible substrates are attractive because of their reduced fragility and weight [44.17]. Polyethylene terephthalate (PET) [44.18] and polyimide [44.19] are examples of such substrates. Most plastic substrates have a low glass-transition temperature T_g ($< 250\,^\circ\mathrm{C}$). Consequently, the device processing temperatures must be reduced without compromising the electronic properties of the deposited materials. Despite the adverse effects of reducing the processing temperature, high-performance low-temperature ($< 150\,^\circ\mathrm{C}$) processes have been developed for fabrication of a-Si:H TFTs on flexible substrates [44.18–20], and even lower temperature processes ($75\,^\circ\mathrm{C}$) are under investigation [44.21].

One of the key challenges in low-temperature fabrication is to achieve a high-quality gate and/or passivation dielectric films, including a-SiO_x [44.21] or a-SiN_x:H [44.20] gate and/or passivation dielectric with low defect density, leakage, and interface state density. Nitrogen rich ($x = 1.6$ to 1.7) a-SiN_x:H films with high resistivity ($\rho > 10^{15}\,\Omega\,\mathrm{cm}$) and breakdown field ($> 5\,\mathrm{MV/cm}$) have been deposited using conventional plasma-enhanced chemical vapor deposition (PECVD) at $120\,^\circ\mathrm{C}$ [44.20].

The fabrication challenges are not limited to the electrical quality of the deposited materials. Most plastic substrates have a large coefficient of thermal expansion (CTE) ($> 50\,\mathrm{ppm/^\circ C}$), which is much higher than that of the TFT layers ($\approx 4\,\mathrm{ppm/^\circ C}$) [44.22]. As the deposited films go through a temperature drop ΔT upon cooling from the process temperature [44.2], thermal stress $\sigma_{th} = Y_f \Delta C \Delta T$ develops in the film [44.23]. Here, ΔC is the difference between CTEs of the substrate and the film, and Y_f denotes the biaxial elastic modulus of the deposited film. The thermal stress bends the composite structure, giving rise to handling problems. Thus, the substrate needs to be held flat in a frame or glued to a rigid substrate [44.2]. In addition, since most layers are patterned during processing, the thermal stress exhibits a local pattern-dependent distribution, which leads to problems in alignment of consecutive masks. Lowering the process temperature and choosing a substrate with a smaller CTE, e.g., polyethylene naphthalate (PEN) with a CTE of $13\,\mathrm{ppm/^\circ C}$ [44.22], will help alleviate the thermal stress, and associated alignment issues. It is important to note that thin rigid (steel, aluminum, or glass) substrates are also mechanically flexible and are being considered for device fabrication [44.24]. Although these substrates can withstand higher temperatures, handling issues still remain and depend on the desired degree of mechanical flexibility.

Research on TFT fabrication on flexible substrates have demonstrated successful handling of material processing issues. For instance, TFTs fabricated on plastic substrate at $150\,^\circ\mathrm{C}$ have been reported to have parameter values very similar to the high-temperature counterparts in terms of low reverse and high on current (with switching ratio of $> 10^8$), reasonable field-effect mobility $> 0.8\,\mathrm{cm^2/(V\,s)}$, threshold voltage of $\approx 1{-}2\,\mathrm{V}$, and low subthreshold slope $< 0.3\,\mathrm{V/dec}$ [44.20].

44.2 Field-Effect Transport in Amorphous Films

The electronic properties of a semiconducting film are primarily determined by its structural disorder and grain size, which strongly depend on deposition conditions and postprocessing treatment [44.25].

The structure of disordered semiconductors such as a-Si:H lacks the long-range periodicity of crystalline silicon. However, the atoms of the materials bond to their neighbors according to the 8-N rule [44.26]

for both amorphous and crystalline silicon, leading to short-range structural order. The extent to which this short-range order is conserved is dependent on processing conditions and leads to different degrees of disorder. This range can be as small as a few nanometers in amorphous semiconductors or as large as a few tens of microns in polycrystalline material. Nanocrystalline (nc) and microcrystalline (μc) materials reside between these extremes depending on grain size and stoichiometry.

The observation of an absorption gap and thermally activated conductivity in amorphous semiconductors stems from the short-range order [44.27] and resembles the band-gap properties of an ideal crystalline semiconductor, which has no states in the gap. The edges of the gap are well defined and represent discontinuities in the density of states (DOS). In contrast, the lack of long-range order in the amorphous semiconductor leads to the presence of states in the gap, and thus, tailing of the band edges.

44.2.1 Localized and Extended States

In the ideal crystalline semiconductor, the band states are all extended with a corresponding band mobility μ_{band}. In the case of an amorphous semiconductor, however, the structural disorder of the material leads to the presence of localized states for which the mobility vanishes at $T = 0$. *Anderson* [44.28] demonstrated that, for a sufficiently large degree of disorder, all states in the band are localized. In his work, the disorder in the material is modeled by a random but uniform distribution U_0 for the energy of the wells at lattice sites. He found that all of the states of the energy band become localized when $U_0/B > 5$, where B is the band width and is given by $B = 2ZI$ [44.26]. Here, Z is the coordination number, and I the overlap energy for the states in neighboring wells, which decreases exponentially with distance based on the tight-binding approximation.

For a small degree of disorder, Anderson's criteria may not hold for states with large overlap energies (i. e., the extended states). *Mott* and *Davis* [44.26] stipulated that, for a given value of U_0, the states can be localized or extended, depending on their overlap energy. Consequently, for some materials there are distinct energies which separate the localized states from the extended ones and can be determined from Anderson's criteria $U_0 \approx 5B$. These energies are referred to as mobility edges (or mobility shoulders) due to the significant change in the mobility expected at these edges. Figure 44.1 illustrates the DOS $g(E)$ for the mobility gap of a-Si:H indicating the extended and localized states. The mobility shoulder E_C of the conduction band separates the localized states from the extended ones. A similar band structure and mobility shoulder is present for the valence band. This graph is compiled from the work of *Cohen* et al. [44.29], who first demonstrated that the change in mobility at these edges can be of the order of 10^3–10^4, signifying the different transport mechanisms on the two sides of the edge.

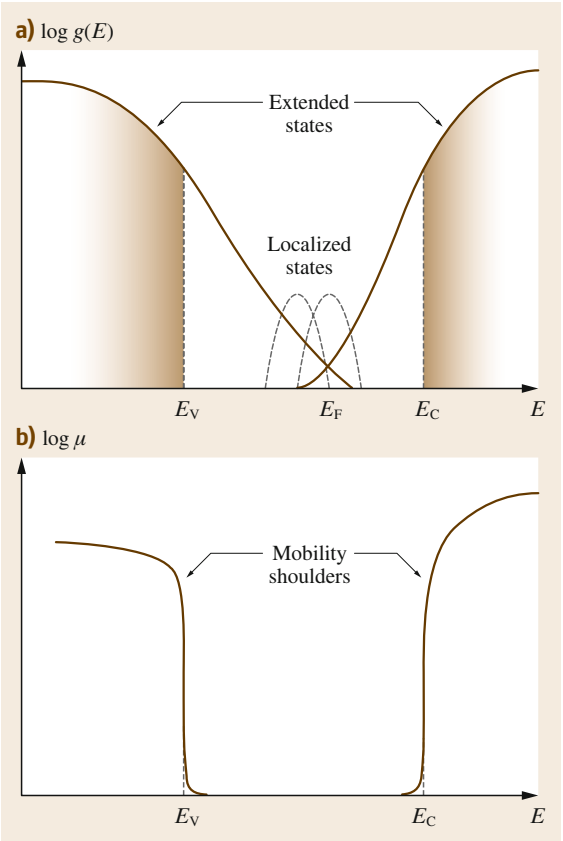

Fig. 44.1 Sketch of (a) DOS in valence and conduction bands, and (b) hole and electron mobilities (After [44.29])

In the extended states, the carriers have a finite mobility, and thus take part in conduction. This prevails at room temperature for a-Si:H and takes the form $\sigma_0 = 0.06q^2/\hbar r(E)$ [44.26], where q is the elementary charge and $r(E)$ the mean distance between the wells that contribute to states with energy E. In the conduction band, $r(E)$ will be close to the lattice constant, which yields $\sigma_0 = 350\,\Omega^{-1}\,\text{cm}^{-1}$. For Fermi energies $E_F < E_C$, the conductivity depends on the Fermi energy and reads

$$\sigma = \sigma_0 \exp\left(\frac{E_F}{k_B T}\right), \tag{44.1}$$

where k_B is Boltzmann's constant and T the temperature, predicting Arrhenius behavior for the conductivity.

Here, E_F is defined as negative for the traps with respect to the conduction band edge E_C. This change in conductivity is due to a change in the concentration of carriers, excited to the extended states n_{band} with a band mobility μ_{band} such that

$$\sigma = q\mu_{band}n_{band}\,, \tag{44.2}$$

where

$$n_{band} = N_b \exp\left(\frac{E_F}{k_B T}\right), \tag{44.3}$$

with $N_b = \sigma_0/q\mu_{band}$. From the given value for σ_0, the band mobility can be found as $\mu_{band} \approx 12\,cm^2/(V\,s)$ for a-Si:H.

In the localized states, the conduction is only possible by hopping of the carriers to the neighboring localized states [44.30]. This method of conduction prevails at low temperatures ($T < 200\,K$) and for highly disordered materials.

The picture of the mobility gap can be completed by adding defect states in the middle of the gap, as indicated by the dashed lines in Fig. 44.1a. These states are attributed to the broken or unsaturated bonds such as dangling bonds in the network structure. The density of dangling bonds is reduced to 10^{15}–$10^{16}\,cm^{-3}$ in a-Si:H by hydrogen atoms, which passivate some of these unsaturated bonds [44.27, 31].

44.2.2 Density of States (DOS)

The density of states (DOS) $g(E)$, including the density of band tail and defect states, as schematically represented in Fig. 44.1a, determines the transport properties of the disordered semiconductor [44.32]. The DOS in a-Si:H has been extensively studied by using different experimental techniques such as field-effect measurements [44.33, 34], photoconductivity measurements [44.35], deep-level transient capacitance spectroscopy (DLTS) [44.36], and capacitance–voltage–frequency (C–V–f) characteristics [44.37, 38]. It is found that an exponential distribution of the deep and tail states [44.39] can efficiently describe the distribution of the localized states and hold for a wide range of materials with rapidly changing DOS. In the case of a-Si:H, the localized states in the upper half of the mobility gap, closer to E_C, behave as acceptor-like states, while the states in the lower part of the gap, closer to E_V, behave as donor-like states. Acceptor-like states are neutral when they are empty, and negatively charged after capturing an electron, whereas the donor-like states are positively charged when they are empty and neutral after capturing an electron.

In a-Si:H, the number of donor-like states closer to the valence band is much higher than the number of acceptor-like states. As a result, following the neutrality condition, the position of the Fermi energy E_F in an intrinsic a-Si:H sample in the dark lies closer to E_C due to the asymmetrical DOS distribution [44.31]. This results in a much stronger electron conduction in a-Si:H, which signifies the role of the conduction band tail in dispersive electron transport. The density of states for the conduction band tail $g(E)$ is written as

$$g(E) = \frac{N_t}{k_B T_t} \exp\left(\frac{E}{k_B T_t}\right), \tag{44.4}$$

where N_t is the total acceptor-like states in the conduction band tail, and T_t the associated slope of the exponential state distribution.

44.2.3 Effective Carrier Mobility

Due to the high density of tail and deep states, only a small number of carriers are thermally excited to the extended states and contribute to conduction as described in (44.2). The total carrier density n is the sum of the excited and trapped carriers such that

$$n = n_{band} + n_t\,. \tag{44.5}$$

To obtain the trapped carrier density n_t as a function of the Fermi energy E_F, we integrate the product of the DOS and the probability of occupation of a state $f(E)$ over the mobility gap

$$n_t = \int_{E_V}^{0} g(E) f(E) \mathrm{d}E\,. \tag{44.6}$$

In equilibrium, the probability of occupation can be described by the Fermi–Dirac function,

$$f(E) = \frac{1}{1 + \exp\left[(E - E_F)/k_B T\right]}\,. \tag{44.7}$$

Equation (44.6) can be numerically solved and approximated along the lines given by *Shaw* and *Hack* [44.40] as

$$n_t(E_F) = N_t \exp\frac{E_F}{k_B T_t} u\left(\frac{T_t}{T}, E_F\right). \tag{44.8}$$

The underlying assumption is that E_F moves no closer than a few $k_B T$ to the mobility edge. This is true because of the high density of tail states, which tends to pin the movement of the Fermi energy. Here,

$u(T_t/T, E_F)$ represents the changes in the trapped-carrier density with normalized ambient temperature T_t/T. For $T \ll T_t$, $u(T_t/T, E_F)$ is often approximated by $[\sin(\pi T/T_t)/\pi T/T_t]$ [44.41] with a value close to 1. The ratio T_t/T, referred to as the dispersion parameter, characterizes the dispersive transport of electrons in the conduction band tail, and can be obtained from the time dependence of the electron drift mobility in time-of-flight experiments [44.42]. The presence of a high trapped-carrier density in amorphous semiconductors leads to an effective trapped-carrier mobility that is lower than the band mobility. *Street* [44.31] has defined the drift mobility μ_D of the carriers as the band mobility reduced by the fraction of time that the carrier is trapped,

$$\mu_D = \mu_{band} \frac{\tau_{band}}{\tau_{band} + \tau_{trap}} , \qquad (44.9)$$

where τ_{band} and τ_{trap} are the times that carriers spend in the extended and localized states, respectively.

Carriers accumulated by the field effect in TFTs also demonstrate similar transport properties. The field-effect mobility μ_{FE} in TFTs is conventionally defined as

$$\mu_{FE} = \frac{g}{qn} , \qquad (44.10)$$

where g is the conductance of the film, and qn is the field-induced charge in the semiconducting film. The terms g and n are averaged over the device active area and are related to the number of band carriers n_{band} and trapped carriers n_t. The μ_{FE} is conventionally retrieved from measurement of the transistor current ($I_{DS,lin}$) in the linear regime ($V_{DS} = 0.1$ V), by using the following

$$\mu_{FE} = \frac{L}{WC_iV_{DS}} \frac{\partial I_{DS,lin}}{\partial V_{GS}} , \qquad (44.11)$$

where W and L are the channel width and length, respectively, C_i the gate capacitance, and V_{GS} and V_{DS} are the gate–source and drain–source biases, respectively.

According to (44.3) and (44.8), the densities of the band and trapped carriers increase differently with increasing E_F. Consequently, when n_{band} and n_t are averaged over the volume of the semiconducting film to obtain the μ_{FE} described by (44.10), the mobility becomes a function of device parameters (e.g., layer thicknesses and bias conditions).

The bias dependence is also evident in temperature-dependence measurements of mobility and conductivity in a-Si:H and organic TFTs. Figure 44.2 illustrates the temperature dependence of μ_{FE} for a-Si:H, pentacene and polythienylene vinylene (PTV) [44.43],

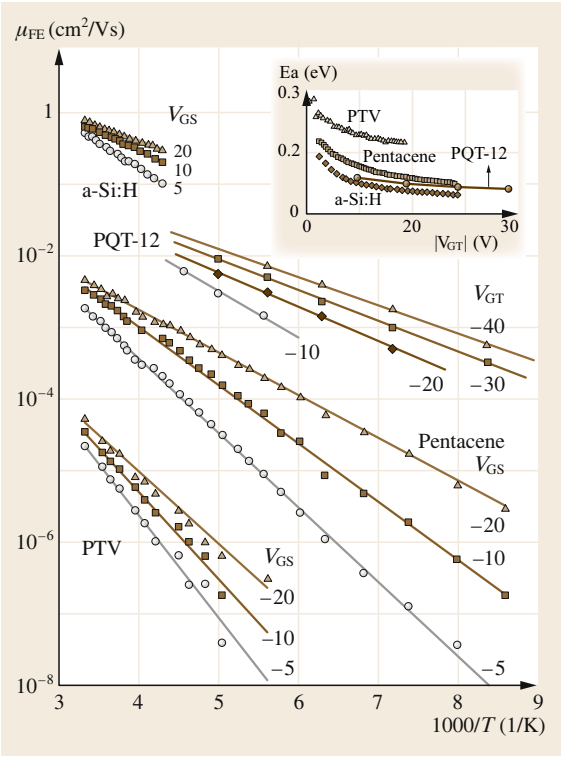

Fig. 44.2 Temperature dependence of μ_{FE} for a-Si:H, PQT-12 [44.44], pentacene and PTV [44.43]. *Inset* shows the bias dependence of the activation energy E_a of μ_{FE} in these materials

and poly[5,5′-bis(3-alkyl-2-thienyl)-2,2′-bithiophene)] (PQT-12) [44.44, 45] TFTs at different gate biases. Here, the activation energy E_a turns out to be bias-dependent (inset of Fig. 44.2). More importantly, an anomaly arises in which the μ_{FE} and E_a become dependent on the gate capacitance C_i, which is solely a geometrical capacitance. A higher C_i implies higher carrier accumulation and consequently higher μ_{FE} for the same bias.

To remove this anomaly, we need to identify the effective carrier mobility such that $\mu_{FE} = \mu_{eff} \times f(\phi)$, where μ_{eff} is the effective physical mobility and $f(\phi)$ describes the device attributes such as bias and geometry.

We reconsider the densities of trapped and free carriers according to (44.3) and (44.8). Since both densities vary exponentially with the Fermi energy, the density of band carriers in terms of trapped carriers can be written as

$$n_{band} = \theta n_t^{T_t/T} , \qquad (44.12)$$

where $\theta = N_b/(N_t u)^{T_t/T}$. Equation (44.12) has been found to hold empirically for a wide range of disor-

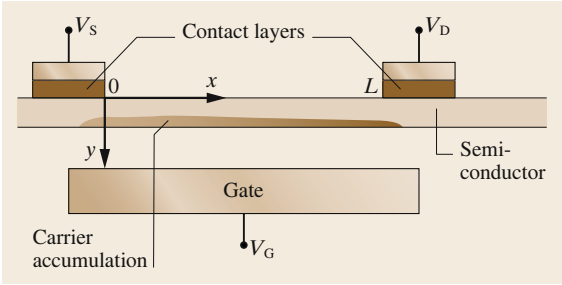

Fig. 44.3 Simplified schematic of a TFT

dered semiconductor systems and operating conditions, including organic semiconductors [44.46, 47].

According to (44.2) and (44.12), the conductivity $\sigma(n)$ as a function of carrier concentration can be written as

$$\sigma(n) = \frac{q}{\mu_{\text{eff}} N_0} \left(\frac{n}{N_0}\right)^{T_t/T} , \tag{44.13}$$

where μ_{eff} is the effective mobility defined at a reference concentration as

$$\mu_{\text{eff}} \equiv \frac{\sigma(n = N_0)}{qN_0} = \mu_{\text{band}} \frac{N_b}{N_0} \left(\frac{N_0}{N_t u}\right)^{T_t/T} . \tag{44.14}$$

Consequently, the conductivity at any carrier concentration is given by μ_{eff} and T_t/T. Here, μ_{eff} represents the effective carrier mobility at concentration N_0 and T_t/T describes the change in conductivity with carrier concentration.

The significance of this representation becomes clear when we use it to obtain the current–voltage characteristics of a TFT (Fig. 44.3). Using the gradual channel approximation, we can write

$$I_{\text{DS,lin}} = \frac{W}{L} V_{\text{DS}} \int_0^{\delta} \sigma(y) \mathrm{d}y , \tag{44.15}$$

where y denotes the location across the channel and δ the channel depth. Using (44.13) for σ and changing the integral parameter from y to n, we find after mathematical manipulation [44.48]

$$I_{\text{DS,lin}} = \mu_{\text{eff}} \zeta \frac{W}{L} (C_i V_{\text{GT}})^{\alpha - 1} V_{\text{DS}} , \tag{44.16}$$

where $V_{\text{GT}} = V_{\text{GS}} - V_{\text{thr}}$, V_{thr} the threshold voltage, $\alpha = 2T_t/T$ the saturation current–voltage characteristics power parameter, and

$$\zeta = \frac{(2\epsilon k_B T_t N_0)^{1-\alpha/2}}{\alpha - 1} . \tag{44.17}$$

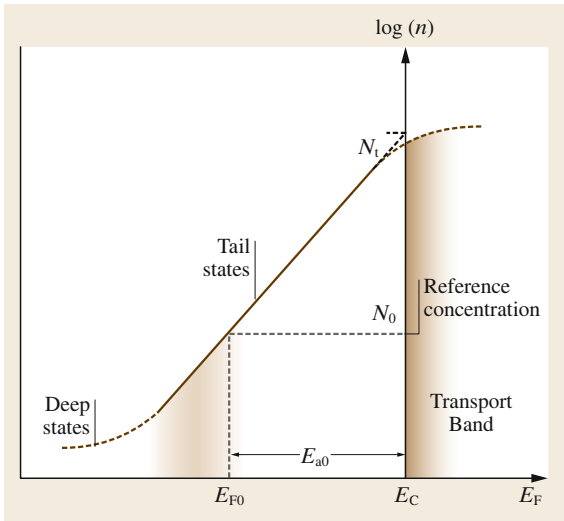

Fig. 44.4 Density of trapped carriers as a function of the Fermi energy, showing the reference concentration N_0 and transport (conduction) band

Here, ζ is just a function of T_t/T and accounts for the carrier distribution across the film. Revisiting the definition of the field-effect mobility as given by (44.11), but this time employing a more meaningful representation of the current, i. e., (44.16), we find

$$f(\phi) \equiv \frac{\mu_{\text{FE}}}{\mu_{\text{eff}}} = \zeta(\alpha - 1)(C_i V_{\text{GT}})^{\alpha - 2} . \tag{44.18}$$

Representation of μ_{eff} according to (44.14) is valid only when there is an exponential relationship between the carrier concentration n and the Fermi energy E_F as given by (44.8). This is true for Fermi energy locations below the transport band edge and above the energies of the deep states (the region shown by the solid slope in Fig. 44.4). Since the deep states mostly contribute to the threshold voltage V_{thr} and are filled before the device turns on, the mobility definition of (44.14) is valid for the above-threshold regime. Consequently, the value of the reference concentration N_0 must be selected such that the Fermi energy E_{F0} associated with N_0 resides well above the deep states. This requires the charge accumulated in the channel Q_{channel} to be higher than the charge $C_i V_{\text{thr}}$ needed to turn on the device. If the carrier concentration at the semiconductor interface is N_0, $Q_{\text{channel}} = C_i V_0$, where $V_0 = (2\epsilon k_B T_t N_0)^{1/2}/C_i$. Thus, for $Q_{\text{channel}} > C_i V_{\text{thr}}$, we conclude $V_0 > V_{\text{thr}}$ or $N_0 > C_i^2 V_{\text{thr}}^2/(2\epsilon k_B T_t)$, indicating the lower limit for N_0. Using typical values, $V_{\text{thr}} = 2\,\text{V}$ and $C_i = 20\,\text{nF/cm}^2$, we have $N_0 > 6 \times 10^{16}\,\text{cm}^{-3}$. For instance, with $N_0 = 10^{17}\,\text{cm}^{-3}$, we have for the bias dependence factor $\zeta = \left(4.1 \times 10^{-16} \alpha\right)^{(1-\alpha/2)}/(\alpha - 1)$.

Table 44.1 Extracted transport parameters (μ_{eff}, T_t, and E_{a0}) for a selection of disordered semiconductors at $N_0 = 10^{17}\,\text{cm}^{-3}$

Semiconductor	μ_{eff} at 300 K ($\text{cm}^2/(\text{V s})$)	T_t (K)	E_{a0} (eV)	Reference
a-Si:H	0.98	350	0.23	Our measurements
PQT-12	3.9×10^{-2}	326	0.24	[44.44]
Pentacene	9.0×10^{-4}	385	0.31	[44.43]
PTV	1.1×10^{-5}	380	0.42	[44.43]

We now revisit the temperature dependence of μ_{eff} by recasting (44.14) in the following manner

$$\mu_{\text{eff}} = \mu_{\text{eff0}} \exp\left(\frac{-E_{a0}}{k_B T}\right), \tag{44.19}$$

where

$$\mu_{\text{eff0}} \equiv \mu_{\text{band}} \frac{N_b}{N_0} \quad \text{and}$$
$$E_{a0} \equiv k_B T_t \ln\left(\frac{N_t u}{N_0}\right) = -E_{F0}\,. \tag{44.20}$$

Equation (44.19) predicts Arrhenius behavior for the effective mobility with an activation energy of $E_{a0} = -E_{F0}$ (Fig. 44.4). The activation energy of μ_{eff} is not bias-dependent and corresponds to the energy needed for carriers to thermalize from E_{F0} to the mobility edge.

We now examine the relation between the two activation energies E_a and E_{a0}. To do so, we look at the temperature dependence of μ_{FE} and μ_{eff}, viz.,

$$\frac{\partial \mu_{\text{FE}}}{\mu_{\text{FE}} \partial T} = \frac{\partial \mu_{\text{eff}}}{\mu_{\text{eff}} \partial T} + \frac{\partial f(\phi)}{f(\phi) \partial T}$$
$$= -\frac{E_{a0}}{k_B T^2} + \frac{2T_t}{T^2} \ln\left|\frac{V_{GT}}{V_0}\right|, \tag{44.21}$$

which yields

$$E_a = E_{a0} - 2k_B T_t \ln\left|\frac{V_{GT}}{V_0}\right|. \tag{44.22}$$

Equation (44.22) describes the bias dependence observed for E_a in the inset of Fig. 44.2.

Amorphous Organic Semiconductors

The concept of effective mobility and transport band may be generalized to accommodate different amorphous organic semiconductors despite differences in the underlying transport mechanism. This generalization follows from the relation $n_{\text{band}} = \theta n^{T_t/T}$ (44.12) for organic semiconductors for a wide range of temperatures and carrier concentrations [44.46]. For this relation to hold, the distribution of trapped and band carriers must be exponential. Although evidence of a Gaussian trap distribution has been reported for organic materials [44.49], the Gaussian distribution is effectively seen as an equivalent exponential distribution due to the small variation in the Fermi energy because of the large tail state distribution. In addition, *Shapiro* and *Adler* [44.50] have demonstrated that a transport band is present in which hopping conduction dominates irrespective of the position of Fermi energy. Similar to the mobility edge, the trapped carriers are thermalized to the hopping band [44.30]. Relative to E_{F0}, the hopping band is located at

$$E_{0\text{hopping}} = k_B T_t \ln\left[\frac{\gamma^3}{N_0}\left(\frac{2T}{3T_t}\right)^3\right], \tag{44.23}$$

where γ is the effective overlap parameter for electronic states in the band tail. *Baranovskii* et al. [44.51] have generalized this concept of transport band beyond the exponential DOS assumption and to a broader range of disordered materials with Gaussian or similar rapidly changing distributions. The generalized band concept can also accommodate the percolation-based hopping transport described by *Vissenberg* and *Matters* [44.43] for amorphous organic semiconductors, which predicts a hopping band that is just $k_B T_t \ln\left(B_C/3\pi^3\right)$ higher than that predicted by *Monroe* [44.30]. Here, $B_C \approx 2.8$ is the critical number for percolation in three-dimensional amorphous systems. Table 44.1 summarizes the values for μ_{eff} at room temperature T_t, and E_{a0} at $N_0 = 10^{17}\,\text{cm}^{-3}$, determined from the results presented for different disordered materials reported in literature.

Amorphous Oxide Semiconductors

Amorphous oxide semiconductors, such as indium zinc oxide (IZO) or the ternary indium gallium zinc oxide (IGZO), have high band gap and strong ionic electronic structure that can exhibit high mobility ($> 5\,\text{cm}^2/(\text{V s})$) even when fabricated at low temperatures. The high mobility and reduced sensitivity to disorder is attributed to the unique role of the spherical 5s orbitals in the conduction of these materials. While chemical bonds in covalent semiconductors such as amorphous silicon are made of sp^3 or p orbitals, strained bonds form deep and high density localized states below the conduction band and above the valence band resulting in formation of tail states [44.52, 53]. On the other hand the electronic structure in oxides benefits from its strong

ionicity. The conduction band minima are made up of spherically extended s orbitals of metal cations and their overlaps with neighboring metal s orbitals are not significantly altered in the disordered oxide. Therefore the electronic levels are not very affected by structural randomness. Carrier transport benefits from the strong ionicity in which charge transfer occurs from metal to oxygen atom. The conduction band minima is almost entirely localized on the metal s orbital and the valence band consists of oxygen 2p states. However, non-bonding state of the metal cation or oxygen defect can be formed in or at conduction band minima in the non-compensated system, allowing vacancies, for example, to act as shallow donors but not as an effective electron trap [44.52]. But these states are not stable; their level relaxes to form either shallow donors or deep occupied states. The presence of oxygen defects leads to persistent conductivity [44.54, 55] behavior, in which the post-stress relaxation of the threshold voltage in an oxide TFT shows an initial rapid recovery followed by a slow-decaying component. This is indicative of a slow- decaying recovery process. The relaxation behavior of the sub-threshold slope is also similar. Here, the slow-decaying component points towards an increased density of shallow states near or above Fermi level. To restore its initial state a positive gate pulse can be applied. This has demonstrated to maintain high frame rates in displays and imagers [44.56].

In multi-component oxides, trap-limited conduction (TLC) and percolation are observed to play a role at low and high gate voltages, respectively [44.57, 58]. The percolation arises from the presence of potential barriers above the conduction band, which lead to spatially distributed perturbations in the minima of conduction band having an average potential barrier of ϕ_{B0} and variance of σ_B. As a result, based on the effective mobility model, the activation energy of TLC conduction for these materials can be written as

$$E_{0TLC} = -E_{F0} - q\phi_{B0} + \frac{(q\sigma_B)^2}{2}\,, \qquad (44.24)$$

At high voltage, as the Fermi energy gets close to the mobility edge, the mobility approaches saturation and percolation dominates the characteristics. A new power law dependence for current voltage characteristics sets in. In contrast, at low temperatures variable range hopping plays a critical role in determining the transport in these materials [44.59].

44.3 Electronic Transport Under Mechanical Stress

Mechanical stress deforms the structure of the thin film leading to modulation in carrier mobility and density of states, and consequently, modulation of resistance. The change in resistance of a solid with elastic strain or stress is commonly referred to as the *elastoresistance* or *piezoresistance* effect, respectively [44.60]. The magnitude of the change is a function of the electronic properties of the material, the dimensions of the solid, and the direction of current flow.

Structural order in the material influences the elastoresistance effect. In the case of crystalline silicon, anisotropic scattering of electrons in the n-type material leads to a strong orientation dependence of the elastoresistive behavior [44.61]. In polycrystalline silicon, the crystallite size and orientation, and material texture play a critical role in determining the magnitude of the effect [44.62, 63]. In amorphous semiconductors, the random network behaves like an isotropic medium, and the anisotropy found in the crystalline material is less visible. However, the elastoresistance coefficients still depend on the relative orientation of the current and applied strain [44.64].

In sputtered amorphous silicon, *Welber* and *Brodsky* [44.65] have reported a decrease in the absorption gap with hydrostatic pressure with a coefficient of about $-1\,\mathrm{meV/kbar}$ ($-1\times10^{-11}\,\mathrm{eV/Pa}$) observed from the shift in the absorption edge. *Weinstein* [44.66] has also reported similar results drawn from photoluminescence experiments. The change in the optical gap is similar in sign and magnitude to that measured for crystalline silicon [44.67]. *Lazarus* [44.68], however, has reported an exponential increase in the resistivity of a-Si:H with increasing hydrostatic pressure at room temperature. The increase in resistivity is ascribed to either a decrease in the number of carriers or a reduction of the mobility with compressive strain [44.64].

In this section, we investigate the impact of mechanical stress on electrical properties of thin-film devices, insight into which is critical for design of mechanically flexible electronics. We begin with metallic and semiconductor thin films for strain-gauge applications and continue with a-Si:H TFTs.

44.3.1 Thin-Film Strain Gauges

Strain gauges are thin-film transducer elements embedded on a substrate Fig. 44.5. The strain in the substrate

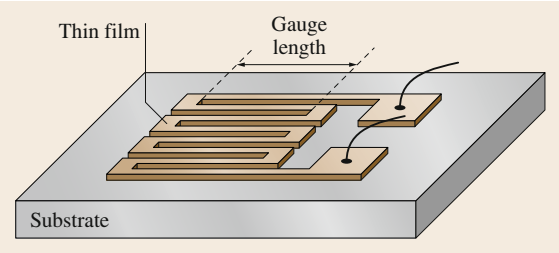

Fig. 44.5 Schematic of a thin-film strain gauge

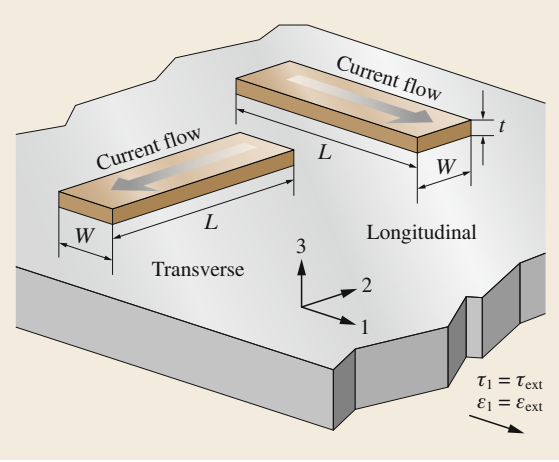

Fig. 44.6 Longitudinal and transverse wires under uniaxial stress and strain components in the 1-direction

leads to a change in the geometry, and therefore, the resistance of the gauge, which is detected and measured by external circuitry. The sensitivity of the resistance R to strain ϵ is referred to as the gauge factor k, which can be written as

$$k \equiv \frac{\Delta R}{\epsilon R} = \frac{\Delta L}{\epsilon L} - \frac{\Delta W}{\epsilon W} - \frac{\Delta t}{\epsilon t} + \frac{\Delta \rho}{\epsilon \rho} , \qquad (44.25)$$

where ρ is the resistivity of the material, and W, L, and t are the width, length, and thickness of the strain gauge, respectively. The last term on the right-hand side of (44.25) reflects the strain-induced change in resistivity of the sample, whereas the first three terms refer to geometrical changes only.

Usually, the gauge length is oriented in a direction where strain is largest to achieve the highest gauge factor. This is referred to as the longitudinal orientation, where the current flows parallel to the strain. Similarly, the transverse orientation is defined when the gauge length is oriented in a direction perpendicular to the maximum strain (Fig. 44.6). The modulation of resistivity in the different orientations with the strain and correspondingly stress can be summarized

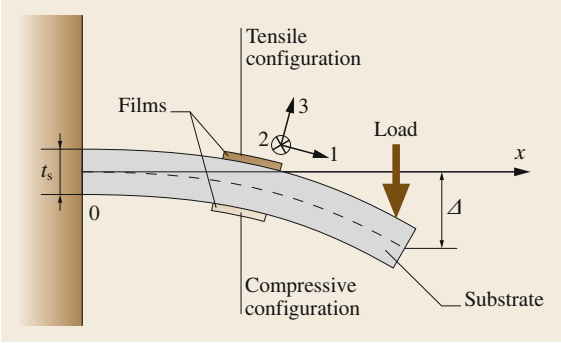

Fig. 44.7 Schematic of a beam-deflection experiment

by the following expression

$$\frac{\Delta \rho_i}{\rho} = \gamma_{ij}\epsilon_j = \pi_{ij}\tau_j$$
$$\text{with } i = 1, 2, 3 \text{ and } j = 1, 2, \ldots, 6 , \qquad (44.26)$$

where γ_{ij} and π_{ij} are the elements of the compact matrix of the elastoresistance and piezoresistance coefficients, respectively, and ϵ_j and τ_j denote the strain and stress components, respectively. (Here, we have used compact notation for these tensors [44.60].)

In metal gauges, the sensitivity of ρ to strain is assumed to be negligible, leading to the well-known longitudinal gauge factor of $k_l = 1 - 2\nu$, where ν is the Poisson's ratio. However, *Arlt* [44.69] has shown that the term $\Delta\rho/\rho$ also includes geometrical attributes. This is due to the change in the volume of the wire and the resulting change in carrier density. According to *Arlt* [44.69], we have for the longitudinal gauge factor

$$k_l = 2 - \frac{\Delta(\gamma\mu)_l}{\epsilon\gamma\mu} , \qquad (44.27)$$

where γ denotes the number of free electrons per atom and μ the electron mobility. Since the last term on the right-hand side of (44.27) is relatively small for metallic gauges, the gauge factor mainly stems from geometrical changes; it is close to 2 and temperature independent [44.70].

These results can be validated using beam-deflection (cantilever) experiments performed on strain gauges integrated on glass and silicon substrates. Figure 44.7 illustrates the schematic of a beam-deflection system. One end of the sample is clamped ($x = 0$) and the free end is deflected by a displacement Δ. *Rajanna* and *Mohan* [44.71] used this method in measurements of both tensile and compressive configurations by simply placing the sample with the films on the top or bottom, respectively (see Fig. 44.7). The strain at lo-

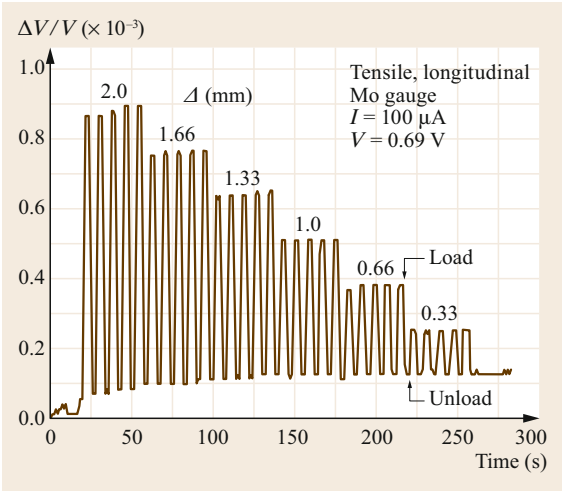

Fig. 44.8 Normalized change in output voltage of a longitudinal Mo strain gauge

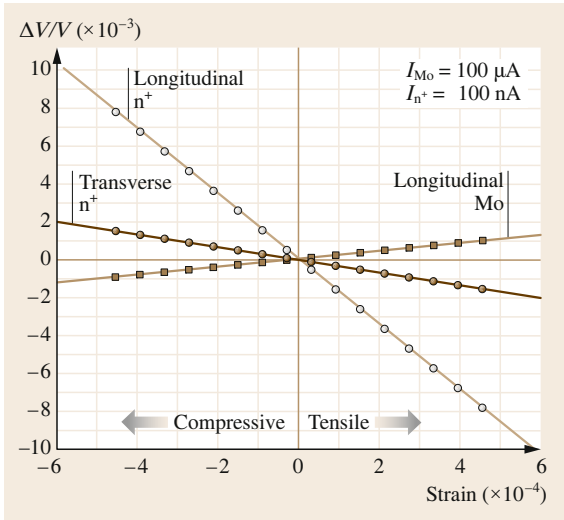

Fig. 44.9 Change in voltage of longitudinal and transverse n^+ μc-Si:H and longitudinal Mo gauges under tensile and compressive strains

cation x along a sample with a length L_0 reads

$$\epsilon(x) = \pm\frac{3t_s\Delta}{2L_0^2}\frac{1-x}{L_0}\,, \tag{44.28}$$

with the positive and negative signs denoting tensile and compressive configurations, respectively.

Figure 44.8 illustrates the result of the beam-deflection experiment on a 150 nm-thick molybdenum strain gauge with 30 turns, line width of 20 μm, and length of 1100 μm. The strain gauges are biased with a constant current of 100 μA and the voltage drop across its terminals is measured. The gauges are subjected to a sequence of loading/unloading steps in tensile configuration to eliminate systematic errors associated with slowly varying transients. By averaging the value of the voltage modulation, we retrieve a gauge factor of approximately $k_l \approx 2.06$ for the longitudinal strain gauges.

The gauge factor for semiconductors is much higher due to the higher elastoresistance coefficients. *Dössel* [44.70] has related the gauge factor to the elastoresistance coefficients as follows

$$k_l = \gamma_1 - (\nu_s + \nu_h)\gamma_2 \quad \text{and}$$
$$k_t = -\nu_s\gamma_1 + (1-\nu_h)\gamma_2\,,$$

where

$$\nu_h = \nu_f\frac{1-\nu_s}{1-\nu_f}\,, \tag{44.29}$$

and $\gamma_1 = 2 - \Delta(\gamma\mu)_l/\gamma\mu\epsilon$ and $\gamma_2 = \Delta(\gamma\mu)_t/\gamma\mu\epsilon$ are the elastoresistance coefficients, and ν_s and ν_f denote the Poisson's ratios for the substrate and the film, respectively.

The same beam-deflection experiment can also be performed on n^+ μc-Si:H strain gauges. Figure 44.9 displays the results of tensile and compressive tests on metal and semiconductor gauges, indicating a higher gauge factor. The values are $k_l = -17.0$ and $k_t = -3.41$ for longitudinal and transverse semiconductor gauges, respectively. Assuming $\nu_s = \nu_f = 0.23$, we find that $\gamma_1 = -22$ and $\gamma_2 = -10.9$ for n^+ μc-Si:H films.

The longitudinal gauge factor obtained for the n^+ μc-Si:H gauges corroborate the results of *Germer* [44.72] for phosphorus-doped microcrystalline thin-film samples with a doping density of $\approx 10^{20}\,\mathrm{cm}^{-3}$. For the transverse gauge factor, Germer has observed a small (negative or positive) gauge factor for doping densities in the range 5×10^{19}–10^{20}. This shows that the transverse gauge factor is highly sensitive to the doping density and other process conditions, which explains the slight difference between our values and that reported by Germer.

44.3.2 Strained Amorphous-Silicon Transistors

Figure 44.10 illustrates measurement results for the transient drain current of a longitudinal TFT subject to a sequence of tensile loading/unloading steps. We see immediate changes in current superimposed on the intrinsic transient response of the TFT. The measured change in current ΔI_D decreases with decreasing dis-

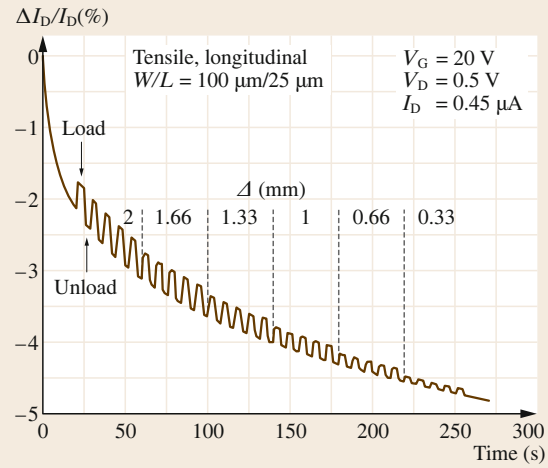

Fig. 44.10 Change in TFT current in deflection experiments

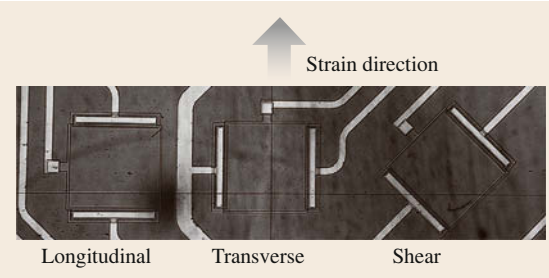

Fig. 44.11 Normalized change in TFT current as a function of tensile and compressive strain

placement. Correspondingly, we define the sensitivity

$$S_\epsilon(I_D) = \frac{1}{I_D}\left.\frac{\partial \Delta I_D}{\partial \epsilon}\right|_{\epsilon=\epsilon_0}, \qquad (44.30)$$

where I_D is the unstrained value of current and ϵ_0 a reference strain value.

Figure 44.11 depicts measurement results for the change in drain current of the longitudinal, shear, and transverse TFTs (Fig. 44.12) under tensile and compressive strains. The TFTs have $W/L = 400\,\mu m/400\,\mu m$ and are biased in the linear regime with constant $V_{GS} = 20\,V$ and $V_{DS} = 0.5\,V$. As seen in the figure, the results for compressive and tensile strain are similar but opposite in sign. For the longitudinal TFT, the current increases with tensile strain with a sensitivity $S_\epsilon(I_{D,l}) = 12.5$. In contrast, for the transverse TFT, this is small and negative $S_\epsilon(I_{D,t}) = -1.1$, clearly signifying an orientation dependence. The value of $S_\epsilon(I_{D,s}) = 4.5$ for the shear TFT can be explained from the linear superposition of

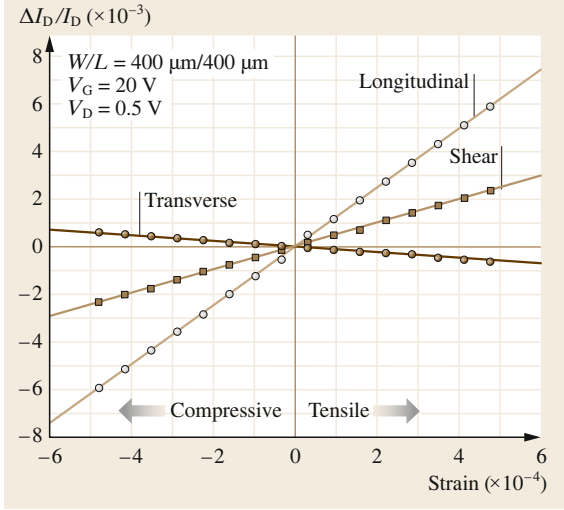

Fig. 44.12 Longitudinal, transverse, and shear TFTs

the effects of longitudinal and transverse strain components.

The measured value for $S_\epsilon(I_{D,l})$ is close to the value of 15 ± 3 reported by *Spear* and *Heintze* [44.64] for intrinsic a-Si:H at room temperature. *Gleskova* et al. [44.73] have found a higher longitudinal sensitivity $S_\epsilon(I_{D,l}) = 26$. For the transverse sensitivity, Spear and Heintze have reported a positive value of $S_\epsilon(I_{D,t}) = 7$ for intrinsic a-Si:H samples.

In addition to TFT orientation, we observe that the gate bias alters the magnitude of strain-induced change in current ΔI_D. To examine the impact of bias, deflection experiments were performed for different values of the gate bias V_{GS} in the range 4–20 V in 1 V steps. Figure 44.13 illustrates the measured $S_\epsilon(I_D)$ as a function of V_{GS} for TFTs of different orientations. Solid symbols denote measurement data for the linear regime ($V_{DS} = 0.5\,V$) while the open symbols are those for the saturation regime where the gate and drain terminals are shorted. Interestingly, the modulation in the current shifts toward positive values as the gate bias decreases. This is true for TFTs of all orientations, and independent of whether the devices were integrated on glass or silicon substrates.

However, the sensitivity $S_\epsilon(I_{D,t})$ for the transverse TFT undergoes a sign change. At high biases, the $S_\epsilon(I_{D,t})$ is generally small and negative (i. e., ΔI_D is positive for tensile strain). As the gate bias decreases, the $S_\epsilon(I_{D,t})$ virtually vanishes at approximately 7 V, and subsequently increases to a sizable positive value (i. e., ΔI_D is negative for tensile strain) at lower voltages ($V_{GS} < 7\,V$).

From the results of Fig. 44.13, we identify two distinct components underlying the strain-induced modu-

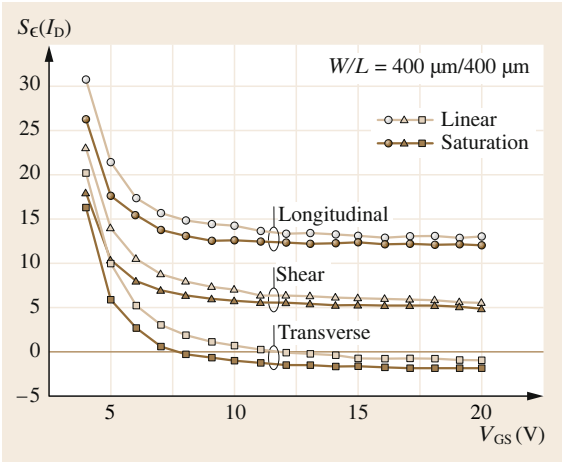

Fig. 44.13 Bias dependence of the TFT current sensitivity

lation of current: the high-bias ($V_{GS} > 7$ V) $S_\epsilon^H(I_D)$ and low-bias ($V_{GS} < 7$ V) $S_\epsilon^L(I_D)$ components such that

$$S_\epsilon(I_D) = S_\epsilon^H(I_D) + S_\epsilon^L(I_D) \,. \tag{44.31}$$

At high biases, $S_\epsilon(I_D)$ of longitudinal, transverse, and shear TFTs gradually approach constant values. As seen from Table 44.2, the extracted values for $S_\epsilon^H(I_D)$ are strongly orientation dependent, suggesting the presence of strain-induced modulation in carrier mobility, whose sensitivity we define as $S_\epsilon(\mu_{eff}) = \Delta\mu_{eff}/\mu_{eff}\epsilon$. The mobility change in the longitudinal orientation is higher than that in the transverse orientation.

Superimposed on the high-bias component is the low-bias component $S_\epsilon^L(I_D)$ which manifests itself as a bias-dependent positive shift in $S_\epsilon(I_D)$. This component can be attributed to the modulation in threshold voltage. Correspondingly, we define the threshold-voltage sensitivity as $S_\epsilon(V_{thr}) = \Delta V_{thr}/V_{thr}\epsilon$. The change in V_{thr} can be attributed to a strain-induced change in the density of deep states, which is orientation independent [44.64]. The modulation in threshold voltage leads to a significant change in current at low biases, and can be quantitatively explained by looking at the current–voltage relation in the linear regime. From (44.16) and using partial differentiation with respect to strain, we can write $S_\epsilon(I_{DS,lin})$ as

$$S_\epsilon(I_{DS,lin}) = S_G + S_\epsilon(\mu_{eff}) - S_\epsilon(V_{thr})\frac{\alpha V_{thr}}{V_{GT}} + S_\epsilon(\alpha)\left(\alpha \ln\left|\frac{V_{GT}}{V_0}\right| - \frac{\alpha}{2} - \frac{1}{\alpha - 1}\right), \tag{44.32}$$

where $V_0 = (2\epsilon k_B T_t N_0)^{1/2}/C_i$, and

$$S_G = S_\epsilon(W) - S_\epsilon(L) + (\alpha - 1)S_\epsilon(C_i) \,.$$

Table 44.2 Values for $S_\epsilon^H(I_D)$, $S_\epsilon(\mu_{eff})$, and $S_\epsilon(V_{thr})$ for different orientations

Parameter	Longitudinal	Transverse	Shear
$S_\epsilon^H(I_D) = \Delta I_D/I_D\epsilon$	12.1	−1.1	4.5
$S_\epsilon(\mu_{eff}) = \Delta\mu_{eff}/\mu_{eff}\epsilon$	11	−1.1	4.0
$S_\epsilon(V_{thr}) = \Delta V_{thr}/V_{thr}\epsilon$	5	4.5	4.7

Here, S_G includes the effect of change in device dimensions. The other terms on the right-hand side of (44.32), in order from the left, describe the dependence of $S_\epsilon(I_{DS,lin})$ on $S_\epsilon(\mu_{eff})$, $S_\epsilon(V_{thr})$, and $S_\epsilon(\alpha)$, respectively, which represent strain-induced modulation of the different TFT parameters (μ_{eff}, V_{thr}, and α).

As seen in (44.32), the modulation in mobility $S_\epsilon(\mu_{eff})$ is directly reflected in the change of current. In contrast, the strain-induced change in threshold voltage $\Delta V_{thr}/V_{thr}\epsilon$ is scaled, and by a factor of $\alpha V_{thr}/V_{GT}$. This is particularly visible at low biases and its effect decreases with increasing gate bias V_{GT}. Thus, at high biases, the impact of threshold-voltage modulation is minimal, which yields

$$S_\epsilon^H(I_D) = S_G + S_\epsilon(\mu_{eff}) \,. \tag{44.33}$$

In contrast, the low-bias component can be written as

$$S_\epsilon^L(I_D) = -S_\epsilon(V_{thr})\frac{\alpha V_{thr}}{V_{GT}} \,. \tag{44.34}$$

It is important to note that the last term on the right-hand side of (44.32) represents the impact of strain-induced modulation of α. This term contains a bias-dependent scaling factor of $\alpha \ln|V_{GT}/V_0|$, which does not correlate with the observed bias dependence of $S_\epsilon(I_D)$ seen in Fig. 44.13. This implies that modulation in V_{thr} and μ_{eff} are the dominant contributors to the observed changes in current.

The activation energy for the temperature dependence of $S_\epsilon^L(I_D)$ and $S_\epsilon^H(I_D)$ is defined as

$$E_i = \frac{\partial S_\epsilon^i(I_D)}{\partial(1/(k_B T))} \quad \text{with } i = \text{H or L} \,. \tag{44.35}$$

The values for E_H and E_L are found to be 140 meV and 0.58 eV, respectively. The much lower activation energy (140 meV) at high biases indicates that the $S_\epsilon^H(I_D)$ stems from the shallow states in the conduction-band tail. Again, this corroborates our previous findings that the sensitivity of the current at high biases is associated with the mobility modulation that is principally determined by the tail states. *Spear* and *Heintze* [44.64] have found an activation energy of 0.52 eV for intrinsic and doped a-Si:H layers. This corroborates with our low-voltage sensitivity data. The high activation energy

for $S_\epsilon^{\mathrm{L}}(I_\mathrm{D})$ identifies the role of deep states in the gap, which is in agreement with our previous finding that $S_\epsilon(I_\mathrm{D}) \propto S_\epsilon(V_\mathrm{thr})$ at low biases. Here, the strain is believed to modify the energy of the deep states [44.64].

From (44.33) and (44.34), the values of $S_\epsilon(\mu_\mathrm{eff})$ and $S_\epsilon(V_\mathrm{thr})$ for different orientations can be determined (Table 44.2). The values can be incorporated in a compact model for the different TFT orientations, which can be used for computer-aided design (CAD) of mechanically flexible TFT circuits [44.74].

45. Photoconductors for X-Ray Image Detectors

M. Zahangir Kabir, Safa Kasap

Modern flat-panel x-ray imaging detectors have played an important role in the transition from analog to digital x-ray imaging. They capture an x-ray image electronically and hence enable a clinical transition to digital radiography. This chapter critically discusses the material, transport and imaging detector properties (e.g., dark current) of several potential x-ray photoconductors and compares them with an ideal photoconductor for use in direct-conversion imaging detectors. The present chapter also considers various metrics of detector performances including sensitivity, detective quantum efficiency, resolution in terms of the modulation transfer function, image lag and ghosting; and examines how these metrics depend on the photoconductor material, and detector structure and design.

The flat-panel x-ray image detector (sensor) concept is illustrated in Fig. 45.1 where x-rays passing through the patient's hand are incident on the sensor. The sensor converts the incident image to a digital image that can be sent to a computer and viewed on a monitor. Research over the past two decades [45.1] has indicated that the most practical flat-panel medical digital radiographic systems (mammography, chest radiography and fluoroscopy) are those based on a large-area integrated circuit or active matrix array (AMA). Flat-panel imagers incorporating active matrix arrays are called active matrix flat-panel imagers or AMFPIs. Active matrix arrays using hydrogenated amorphous silicon (a-Si:H) thin-film transistors (TFTs) have been shown to be practical pixel-addressing systems for displays [45.2]. These a-Si:H arrays can be converted into x-ray-sensitive imaging devices by adding a thick (0.1−1 mm) x-ray-detecting medium, either a phosphor or a photoconductor. The physical form of the x-ray AMFPI is similar to a film/screen cassette and thus it will easily fit into current medical film/screen-based x-ray imaging systems. The x-ray image is stored and displayed on the computer almost immediately after the x-ray exposure. The stored image can be rapidly transmitted to remote locations for consultation and analysis. The dynamic range of recently developed AMFPI systems is much higher than film/screen-based imaging systems [45.3]. AMFPIs are able to read out an entire image in $1/30$ s, sufficiently rapid to perform fluoroscopy (real-time imaging) [45.4].

The active matrix array used for pixel addressing and readout in an AMFPI consists of many single pixels, each of which represents a corresponding pixel of the image. Each pixel collects charge proportional to the x-ray radiation that it receives. To generate this signal charge, either a phosphor converts the x-rays to visible light, which in turn is detected with a pin photodiode at the pixel (indirect) or an x-ray photoconductor converts the incident x-rays to charge (direct) in one step. For both the indirect and direct conversion approaches, the latent image is a charge distribution residing on the array's pixels. The charges are read out by scanning the arrays row by row using peripheral electronics and multiplexing the parallel columns into a serial digital signal. This signal is then transmitted to a computer system for storage and display. Several manufacturers and academic researchers have used the indirect approach [45.5, 6]. However, we believe that

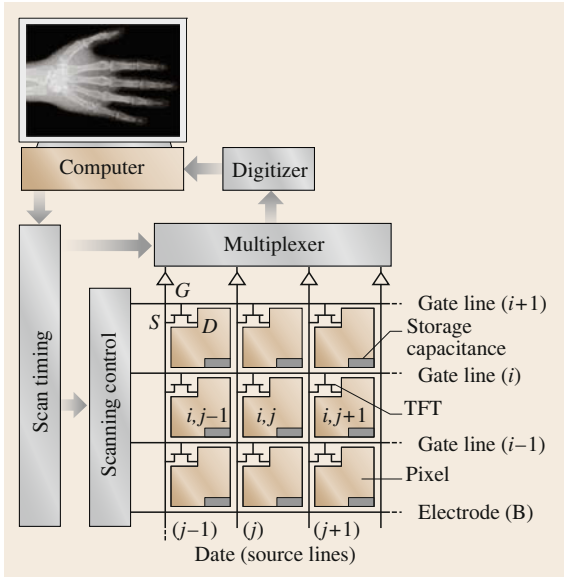

Fig. 45.2 Schematic diagram that shows some pixels of the active matrix array for use in x-ray AMFPI with self-scanned electronic readout. The charge distribution residing on the panel's pixels are read out by scanning the arrays row by row using peripheral electronics and multiplexing the parallel columns into a serial digital signal

the direct approach, due to its higher resolution, has the potential to produce systems superior in image quality to indirect conversion sensors and be both easier and cheaper to manufacture due to their simpler structure. This chapter considers only the direct-conversion x-ray imager and how its dark current, sensitivity, resolution and detective quantum efficiency (DQE) depend on the photoconductor material and detector structure. This chapter also discusses essential photoconductor properties, charge transport and imaging properties of promising photoconductors.

Active matrix arrays allow a monolithic imaging system of large area (e.g., 40×40 cm) to be constructed. As for conventional integrated circuits, planar processing of the array through deposition and doping of lithographically masked individual layers of metals, insulators and semiconductors implement the design of active matrix arrays. In the future, even larger areas should become feasible if required. Millions of individual pixel electrodes in the matrix are connected, as shown in Fig. 45.2. Each pixel has its own thin-film transistor (TFT) switch and storage capacitor to store image charges. The TFT switches control the image charge so that one line of pixels is activated electronically at a time. Normally, all the TFTs are turned off, permitting the latent image charge to accumulate on the array. The readout is achieved by external electronics and software controlling the state of the TFT switches. The active matrix array consists of $M \times N$ (e.g., 2480×3072) storage capacitors C_{ij} whose stored image charge can be read through properly addressing the TFT (i,j) via the gate (i) and source (j) lines. The charges read on each C_{ij} are converted to a digital image. The readout is self-scanning in that no external means such as a laser are used. The scanning is part of the AMFPI electronics and software, thus permitting a truly compact device.

To construct a direct-conversion x-ray AMFPI, a large-bandgap (> 2 eV) high-atomic-number semiconductor or x-ray photoconductor (e.g., stabilized amorphous selenium, a-Se) layer is coated onto the active matrix array. An electrode (A) is subsequently deposited onto the photoconductor layer to facilitate the application of a biasing potential and, hence, an electric field F in the photoconductor layer as shown in Fig. 45.3. The biasing potential applied to the radiation-receiving electrode A (top electrode) may be positive or negative, the selection of which depends on many factors discussed later in this chapter. The applied bias varies from a few hundred to several thousand V. The capacitance C_{pc} of the photoconductor layer over the pixel is in series with, and much smaller than, the pixel capacitance C_{ij} attached to the pixel electrode, so that most of the applied potential is dropped across the photoconductor and not across the pixel capacitance. The electron–hole pairs (EHPs) generated in the photoconductor by the absorption of x-ray photons travel along the field lines and are collected by the electrodes. If the applied bias voltage is positive, then electrons collect at the positive bias electrode and holes accumulate on the storage capacitor C_{ij}. Each pixel electrode car-

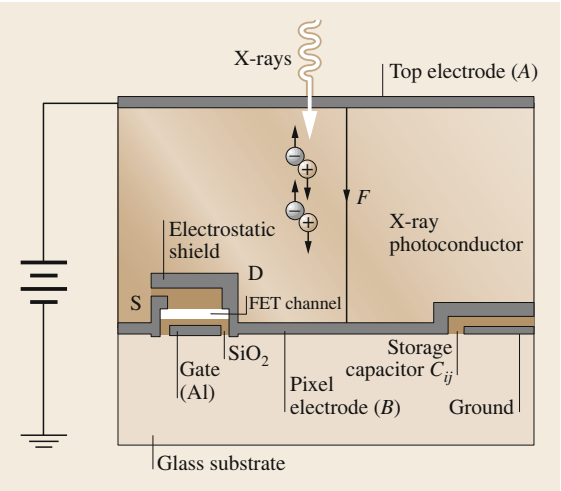

Fig. 45.3 Cross section of a single pixel (i,j) with a TFT switch. The top electrode (A) on the photoconductor is a vacuum-coated metal (e.g., Al). The bottom electrode (B) is the pixel electrode that is one of the plates of the storage capacitance (C_{ij}). (Not to scale – the TFT height is highly exaggerated)

ries an amount of charge Q_{ij} proportional to the amount of incident x-ray radiation in the photoconductor layer over that pixel, which can be read during self-scanning.

For a historical perspective on the development of a-Se based flat panel detectors, the reader is referred to a number of early papers by *Rowlands* and coworkers [45.7–13] and *Lee* et al. [45.14, 15].

The selection of the photoconductor material for use in direct-conversion x-ray image detectors is currently an important research field in electronic materials. There are various competing semiconductors, such as amorphous (a-)Se, HgI_2, CdZnTe, PbI_2, PbO and organic perovskites. Detectors based on a-Se have already been developed and successfully commercialized for mammography [45.16]; the majority of modern direct conversion mammographic detectors now use an a-Se alloy as a photoconductor. This chapter discusses charge-transport and imaging detector properties (e.g., dark current and image lag) of these photoconductors and compares them with an ideal photoconductor for x-ray imaging detectors. The present chapter also examines various imaging characteristics of photoconductor-based x-ray AMFPIs, including dark current, sensitivity (S), detective quantum efficiency (DQE), resolution in terms of the modulation transfer function (MTF), image lag and ghosting. We examine how these characteristics depend not only on the photoconductor's charge-transport properties but also on the detector structure, i. e., the size of the pixel and the thickness of the photoconductor.

45.1 X-Ray Photoconductors

45.1.1 Ideal Photoconductor Properties

The performance of direct-conversion x-ray detectors depends critically on the selection and design of the photoconductor. It is therefore instructive to identify what constitutes a nearly ideal x-ray photoconductor to guide a search for improved performance or a better material. Ideally, the photoconductive layer should possess the following material properties:

1. Most of the incident x-ray radiation should be absorbed within a practical photoconductor thickness to avoid unnecessary patient exposure. This means that, over the energy range of interest, the absorption depth δ of the x-rays must be substantially less than the photoconductor layer thickness L. In other words, the quantum efficiency (η) should be high.
2. The photoconductor should have high intrinsic x-ray sensitivity, i. e., it must be able to generate as many collectable (free) electron–hole pairs (EHPs) as possible per unit of incident radiation. This means the amount of radiation energy required, denoted by $W_{\pm}$, to create a single free electron–hole pair must be as low as possible. Typically, $W_{\pm}$ increases with the bandgap E_g of the photoconductor [45.17] and thus a low E_g is desired for maximum x-ray sensitivity.
3. There should be little bulk recombination of electrons and holes as they drift to the collection electrodes; EHPs are generated in the bulk of the photoconductor. Bulk recombination is proportional to the product of the concentration of holes and electrons, and typically it is negligible for clinical exposure rates (i. e., provided the instantaneous x-ray exposure is not too high) [45.18].
4. There should be negligible deep trapping of electrons and holes, which means that, for both electrons and holes, the schubweg $\mu\tau F$ must be much greater than L, where μ is the drift mobility, τ is the deep-trapping time (lifetime), F is the electric field and L is the photoconductor layer thickness. The schubweg is the mean distance a carrier drifts before it is trapped and unavailable for conduction. The temporal responses of the x-ray image detector, such as lag and ghosting, depend on the rate of carrier trapping.

5. The diffusion of carriers should be negligible compared with their drift. This property ensures less time for lateral carrier diffusion and leads to better spatial resolution.
6. The dark current should be as small as possible, because it is a source of noise. The applied field causes a current to flow through the detector in the absence of irradiation, which is called the dark current. This means the contacts to the photoconductor should be noninjecting and the rate of thermal generation of carriers from various defects or states in the bandgap should be negligibly small (i. e., dark conductivity is practically zero). Small dark conductivity generally requires a wide-bandgap semiconductor, which conflicts with condition (2) above. The dark current should preferably not exceed $10-1000\,\mathrm{pA/cm^2}$, depending on the clinical application [45.19].
7. The longest carrier-transit time, which depends on the smallest drift mobility, must be shorter than the image readout time and interframe time in fluoroscopy.
8. The properties of the photoconductor should not change with time because of repeated exposure to x-rays, i. e., x-ray fatigue and x-ray damage should be negligible.
9. The photoconductor should be easily coated onto the AMA panel (typically $30 \times 30\,\mathrm{cm}$ and larger), for example by conventional vacuum techniques without raising the temperature of the AMA to damaging levels (e.g., $\approx 300\,^{\circ}\mathrm{C}$ for a-Si panels). This eliminates the possibility of using single-crystal materials that would require extended exposure to much higher temperature if they were to be grown directly onto the panel.
10. The photoconductor should have uniform characteristics over its entire area.
11. The temporal artifacts such as image lag and ghosting should be as small as possible. Lag is the carryover of image charge generated by previous x-ray exposures into subsequent image frames. The residual signal fractions following a pulsed x-ray irradiation are referred to as *image lag*. Ghosting is the change of x-ray sensitivity of the x-ray image detector as a result of previous exposure to radiation. In the presence of ghosting, a shadow impression of a previously acquired image is visible in subsequent uniform exposures.

The large-area-coating requirement in (9) rules out the use of crystalline semiconductors, whose only practical production process is to grow large boules, which are subsequently sliced. Thus, only amorphous or polycrystalline (poly)photoconductors are currently practical for use in large-area x-ray imaging detectors. Amorphous selenium (a-Se) is one of the most highly developed photoconductors for large-area detectors due to its commercial use in photocopiers and laser printers as an electrophotographic photoreceptor [45.20]. In fact, the direct-conversion flat-panel imaging technology has been made possible by the use of two key elemental amorphous semiconductors: a-Si:H (used for TFTs) and a-Se (used for photoconductor layers). Although their properties are different, both can be readily prepared in large areas, which is essential for an x-ray imaging detector. Stabilized a-Se (a-Se alloyed with 0.2−0.5% As and doped with 5−20 ppm Cl) is currently the preferred photoconductor for clinical x-ray image sensors, because it can be quickly and easily deposited as a uniform film over large areas and it has an acceptable x-ray absorption coefficient, good charge-transport properties for both holes and electrons, and lower dark current than many competing polycrystalline layers [45.17, 19]. Flat-panel x-ray image detectors with an a-Se photoconductor have been shown to provide excellent images.

There has been active research to find potential x-ray photoconductors to replace a-Se in flat-panel image detectors because of the substantially higher $W_{\pm}$ and operating electric field of a-Se compared to other potential x-ray photoconductors [45.19, 21]. For example, the typical value of the electric field used in a-Se devices is $10\,\mathrm{V/\mu m}$ where the value of $W_{\pm}$ is about 45 eV; the value of $W_{\pm}$ is 5−6 eV for polycrystalline mercuric iodide (poly-HgI_2) and poly-CdZnTe. The main drawback of polycrystalline materials is the adverse effects of grain boundaries in limiting charge transport and the nonuniform response of the sensor due to large grain sizes. Grain boundaries in the polycrystalline material are expected to create trapping levels within the bandgap and introduce potential barriers between neighboring grains [45.22, 23]. Another disadvantage of these polycrystalline detectors is the higher dark current compared to a-Se detectors. However, there have been efforts to improve the material properties and reduce the dark currents of poly-HgI_2 and poly-CdZnTe-based image detectors [45.24, 25]. Indeed, experiments on large-area HgI_2, PbI_2, CdZnTe (< 10% Zn), and PbO polycrystalline x-ray photoconductive layers deposited on active matrix arrays have shown encouraging results [45.26–28]. A more detailed description of these three potential photoconductors for direct-conversion AMFPIs is presented below.

45.1.2 Potential Photoconductors

The properties of an ideal photoconductor for x-ray image detectors have been discussed in the section above.

In this section, important properties of potential photoconductors for x-ray image detectors are discussed and compared with the ideal case.

Amorphous Selenium (a-Se)

Stabilized a-Se can be easily coated as thick films (e.g., 100−1000 μm) onto suitable substrates by conventional vacuum deposition techniques and without the need to raise the substrate temperature beyond 60–70 °C (much below the damage threshold of the AMA, e.g., ≈ 300 °C for a-Si:H panels). Its amorphous state maintains uniform characteristics to a very fine scale over large areas. Stabilized a-Se, not pure a-Se, is used in x-ray sensors, because pure a-Se is thermally unstable and crystallizes over several weeks or months following manufacture. Crystalline Se is unsuitable as an x-ray photoconductor because it has a much lower dark resistivity and hence orders of magnitude larger dark current than a-Se. Alloying pure a-Se with As (0.2−0.5% As) greatly improves the stability of the composite film and helps to prevent crystallization. However, it has been found that the addition of As has an adverse effect on the hole lifetime because the arsenic introduces deep hole traps. If the alloy is doped with 5−20 parts per million (ppm) of a halogen (such as Cl), the hole lifetime is restored to its initial value. Thus, an a-Se film that has been alloyed with 0.2−0.5% As (nominal 0.3% As) and doped with ppm-levels of Cl is called stabilized a-Se. The density of a-Se is 4.3 g/cm^3 with a bandgap (usually called the mobility gap in amorphous semiconductors) of $E_g \approx 2.1-2.2$ eV.

There are localized states within the mobility gap of a-Se. Some of these are located near the band edges (*shallow traps*), while some are located deep in the energy band (*deep traps*). Localized states are simply traps and are not extended throughout the material, but are localized in space (both shallow and deep) due to various structural defects that are stable at room temperature. Drift of both electrons and holes involves interactions with shallow and deep traps, as shown in Fig. 45.4. Shallow traps reduce the drift mobility; deep traps prevent the carriers from crossing the photoconductor. The effective drift mobility μ of carriers is the mobility μ_0 in the extended states reduced by the trapping and release events due to the presence of shallow traps,

$$\mu = \frac{\tau_c}{\tau_c + \tau_r}\mu_0 \,, \tag{45.1}$$

where τ_c and τ_r are the average capture and release times in the shallow-trap centers. The capture time represents the mean time that a mobile carrier drifts in the extended states before becoming trapped in a shallow-trap center. The release time is the mean time that

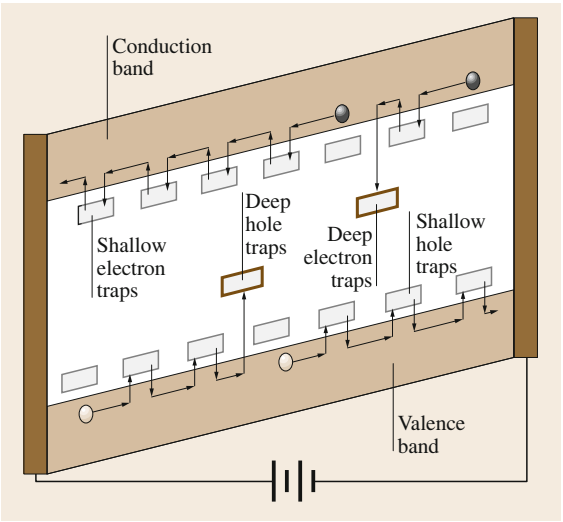

Fig. 45.4 Diagram illustrating the bandgap of a photoconductor with an applied electric field that tilts the bands, encouraging drift of holes in the direction of the field and electrons counter to the field. Drift of both electrons and holes involves interactions with *shallow* and *deep traps*. *Shallow traps* reduce the drift mobility and *deep traps* prevent the carriers from crossing the photoconductor

a carrier remains in a trap before being released back into the extended states. Re-emission from a shallow trap is mostly dominated by thermally activated processes. The shallow-trap release time is relatively short and a typical carrier may experience many shallow capture and release events while traversing the detector thickness (100−1000 μm).

Although the nature of the shallow traps in a-Se has not been fully established, the drift mobilities of both holes and electrons are quite reproducible. The room-temperature effective hole mobility μ_h up to moderate fields ($F \leq 10\,\mathrm{V/\mu m}$) is independent of the preparation of the sample and has a value of $\approx 0.12\,\mathrm{cm^2/Vs}$, whereas the effective electron mobility μ_e is in the range $0.003-0.006\,\mathrm{cm^2/Vs}$ [45.21]. The hole drift mobility does not change with the addition of As or Cl. The value of μ_e decreases with the addition of As to a-Se (e.g., in stabilized a-Se) but Cl doping does not affect it.

Once a carrier is caught in a deep trap, it will remain immobile until a lattice vibration gives it enough energy to be excited back into the extended states, where it can drift once again. The deep-trap release time is very long (minutes to hours), and a deeply trapped carrier is essentially permanently removed from conduction. Therefore, the carrier lifetime depends on the concentration of deep rather than shallow traps. The charge-carrier lifetimes vary substantially between

different samples and depend on factors such as the source of a-Se material, impurities, and the preparation method. The electron lifetime τ_e is particularly sensitive to impurities in the a-Se source material. The hole lifetime τ_h drops rapidly with decreasing substrate temperature (temperature of the a-Se substrate during the evaporation process) whereas τ_e is unaffected. Increasing the As concentration in a-Se decreases τ_h and increases τ_e [45.29]. On the other hand, Cl doping increases τ_h and decreases τ_e. The typical lifetimes in stabilized a-Se are in the range 10–500 μs for holes and 100–1500 μs for electrons [45.21].

The fractional increase in the τ_e with As addition is greater than the drop in μ_e. Thus the electron range ($\mu_e\tau_e$) increases with As content. The effect of Cl doping on the carrier ranges ($\mu\tau$ products) is more pronounced than that of As doping. Thus, we can control both electron and hole ranges by appropriately choosing the relative amounts of As and Cl in a-Se.

The electron–hole-pair creation energy $W_\pm$ in a-Se has a strong dependence on electric field F but only a weak dependence on the x-ray photon energy E [45.30, 31]. The quantity $W_\pm$ is decreased by increasing either F or E. $W_\pm$ at a given E in a-Se follows an empirical relation given by

$$W_\pm \approx W_\pm^0 + \frac{B(E)}{F^n} , \qquad (45.2)$$

where $B(E)$ is a constant that depends on E, $W_\pm^0$ is the saturated EHP creation energy (at infinite F), and n is typically in the range 0.7–1 [45.32]. The value of $W_\pm^0$ should be $2.2E_g + E_{phonon}$ [45.33], where E_{phonon} is a phonon energy term. With $E_g \approx 2.1$ eV and $E_{phonon} < 0.5$ eV, we would expect that $W_\pm^0 \approx 5$ eV. The energetic primary electron generates many EHPs but only a certain fraction of these are free to drift and the rest recombine before they can contribute to the photocurrent. There are various possible explanations for the F dependence of the EHP creation energy. First, the simultaneously generated electron and its hole twin are attracted to each other by their mutual Coulombic force and may eventually recombine. This type of recombination is called geminate recombination (from Gemini – the twins). Another possible mechanism is columnar recombination that involves the recombination of nongeminate electrons and holes generated close to each other in the columnar track of the single high-energy electron (primary) created by the absorption of an x-ray. In both the geminate and columnar cases, the number of carriers escaping recombination should increase with increasing F, which acts to separate the oppositely charged carriers. The question of whether the F dependence of $W_\pm$ in a-Se is dominated by geminate or columnar recombination has not been fully resolved and is currently an area of active research [45.33, 34]. However, the energy dependence of $W_\pm$ is better understood. It decreases slowly with increasing photon energy in the diagnostic [45.30] and megavolt range [45.35]. The total change in $W_\pm$ from 20 keV to 6 MeV is of the factor of 3. This appears to be due to a reduction of recombination with increase in energy. The rate of deposition of energy per unit distance traveled by a primary electron decreases as a function of energy, decreasing the density of EHPs in the column around it. This is expected to reduce columnar recombination – as is seen. Thus, it appears that at low energies the contribution from columnar recombination is approximately twice that from geminate, but at high enough energy the columnar effect is reduced to zero. The typical field value used in a-Se devices is 10 V/μm where the value $W_\pm$ is 35–55 eV over the diagnostic beam energy (12–120 keV) and ≈ 15 eV at megavolt energies.

The dark resistivity of a-Se is often quoted roughly as 10^{14} Ωcm. However, experimental results in the literature have shown that the main source of the dark current is the injection of holes from the metal contacts and the bulk thermal generation current is negligible [45.36, 37]. It was the development of multilayer p-i-n type device structures that eventually reduced the dark current to very low levels (< 0.1 nA/cm^2 at F as high as 20 V/μm [45.38]) and made an a-Se commercially viable detector [45.39]. A pin (p-like-intrinsic-n-like) a-Se structure is shown in Fig. 45.5, where the thickness of both the p-like and n-like blocking contact layers is a few microns. These p- and n-like-layers are appropriately doped to serve as unipolar conducting layers that easily trap electrons and holes respectively, but allow the transport of oppositely charged carriers. The rate of emission of these deeply trapped carriers is so small that there is no significant current injection into the bulk a-Se layer. The commercial a-Se detector (in this example, the Analogic detector) is n-i-p or p-i-n type where the p-like layer is usually a-As_2Se_3 and the n-like layer is alkali metal doped a-Se [45.36]. Recent work has

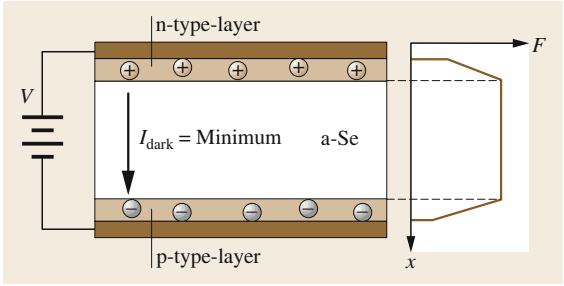

Fig. 45.5 A multilayer pin-type a-Se device structure for blocking the dark current

shown that an n-i structure with a cold deposited n-like layer also has a very low dark current [45.39]. With these n- and p-like layers, the field at the metal electrodes is sufficiently small to minimize charge injection from the contacts, which substantially reduces the dark current.

The image lag in a-Se detectors is under 2% after 33 ms and $< 1\%$ after 0.5 s in the fluoroscopic mode of operation [45.40]. Therefore, image lag in a-Se detectors is considered to be negligible. The pixel-to-pixel sensitivity variation is also negligible in a-Se detectors. The presampling MTF of these detectors is almost equal to the theoretical MTF (sinc function) determined by the pixel aperture [45.40].

Avalanche Gain a-Se

Amorphous selenium is one of the exceptional amorphous semiconductors, which exhibits usable impact ionization, i. e., at a very high field F (above $\approx 70\,\mathrm{V/\mu m}$) holes in a-Se can gain enough energy to create additional EHPs through impact ionization with a useful avalanche gain of 1000 or more [45.41]. Based on this hole impact ionization, a practical vacuum device, the high-gain avalanche rushing photoconductor (HARP) optical image sensor, has been developed [45.42]. Recently, there has been an intense interest to replace the electron beam of HARP by a two-dimensional array of pixel electrodes utilizing avalanche selenium detectors for low-dose medical x-ray imaging [45.43]. The avalanche multiplication may increase the signal strength and improve the signal to noise ratio in low dose x-ray imaging applications. However, the dark current in avalanche detectors can be high and very critical because of extremely high fields and the avalanche nature of the dark current. Electrons start impact ionization at a field of $\approx 100\,\mathrm{V/\mu m}$ in a 30 μm thick a-Se detector structure (it is $110\,\mathrm{V/\mu m}$ for the thickness of 10 μm) [45.44]. Once electron impact ionization starts, a self-sustaining avalanche breakdown process is initiated and the large number of multiplied charge carriers act to screen the external bias. Therefore, $110\,\mathrm{V/\mu m}$ field and 30 μm thickness are considered as the practical limit for an avalanche a-Se detector for x-ray imaging applications.

The potential avalanche selenium detector structures for solid state flat-panel digital x-ray imaging are shown in Fig. 45.6. The prospective detector structures are classified as; (a) type 1: cerium dioxide (CeO_2) hole blocking and resistive interface layer (RIL) electron blocking layers, and Au bottom electrode, and (b) type 2: indium gallium zinc oxide (IGZO) hole blocking layer and Au bottom electrode. The top electrode for all the structures is positively biased indium-tin-oxide (ITO). The thicknesses of the CeO_2 and IGZO layers are ≈ 10–30 and 375 nm respectively. Both CeO_2 and IGZO are n-type wide bandgap (bandgap $E_g = 3.3$ and 3.7 eV for CeO_2 and IGZO respectively) materials [45.42, 45]. Their bandgaps and electron affinities are such that they both block hole injection from electrodes but don't block the flow of photogenerated electrons from the a-Se layer to the positive electrode [45.45, 46]. The RIL layer is 1 μm thick and it is a semi-insulating polymer, namely cellulose acetate. RIL blocks electron injection and prevents gold diffusion into the a-Se structure [45.47]. Among the reported avalanche detector structures, the type 2 structure has shown the minimum steady-state dark current ($1\,\mathrm{pA/mm^2}$ at $F = 60\,\mathrm{V/\mu m}$). Another advantage of the type 2 structure is that it doesn't block the flow of photogenerated electrons from the a-Se layer to the positive electrode.

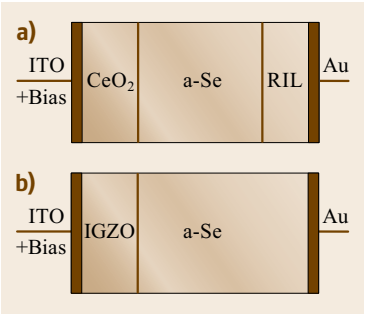

Fig. 45.6a,b Schematic diagrams of a-Se avalanche detector structures with ITO and Au top and bottom electrodes respectively. **(a)** Type 1: Cerium dioxide (CeO_2) hole blocking layer and resistive interface layer (RIL) as electron blocking layer. **(b)** Type 2: Indium gallium zinc oxide (IGZO) hole blocking layer. (After [45.48])

The avalanche multiplication gain g depends on the photoconductor layer thickness L and the impact ionization coefficient of the carrier. If only holes undergo impact ionization, the carrier multiplication is $\exp(\alpha_h L)$, where α_h is the impact ionization coefficient for holes. The field dependence of the α_h, at least over the limited fields where avalanche is observed, can be modeled by the following empirical relation

$$\alpha_h = \alpha_0 \exp\left(-\frac{F_0}{F}\right), \tag{45.3}$$

where α_0 and F_0 are the fitting parameters. *Reznik* et al. [45.41] carefully measured α_h for holes in various samples at room temperature and plotted as α_h versus $1/F$. The experimental results for different samples are surprisingly quite close as shown in Fig. 45.7. The symbols represent the experimental results and the solid line represents (45.3) with $\alpha_0 = 1.1 \times 10^4\,\mu\mathrm{m}^{-1}$ and $F_0 = 1.09 \times 10^3\,\mathrm{V/\mu m}$.

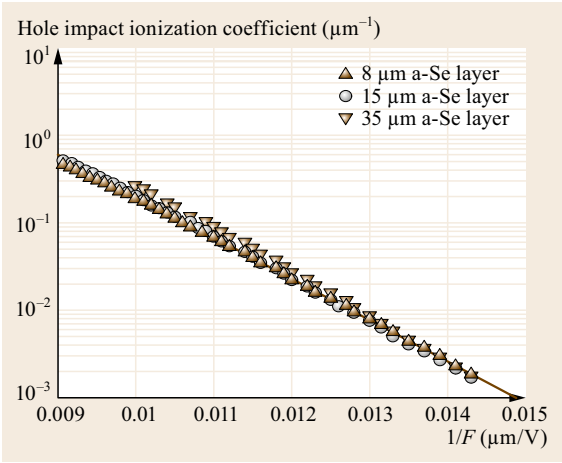

Fig. 45.7 The hole impact ionization coefficient as a function of electric field. *Symbols*: experimental data. (After [45.41]). *Solid line*: empirical equation (45.3)

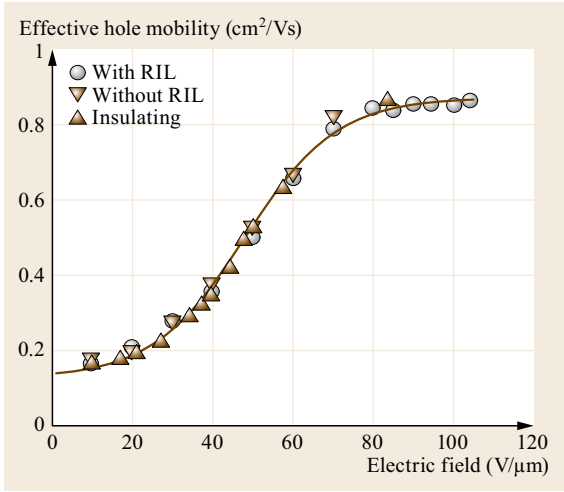

Fig. 45.8 The effective hole drift mobility as a function of the applied electric field at room temperature. *Symbols*: experimental data. (After [45.47]). *Solid line*: empirical equation (45.4)

The effective mobility of holes at extremely high fields increases with increasing field. The effective hole mobility at room temperature T_r is well defined and almost independent of the preparation conditions of the sample [45.47, 49]. An empirical relation for the effective hole mobility in a-Se at T_r can be expressed by fitting the experimental results, which is [45.50]

$$\mu_h\,(F, T_r) \approx 0.127 + \frac{0.745}{1 + \exp\left[-\frac{(F-48)}{11.5}\right]}\,, \qquad (45.4)$$

where F is the electric field in V/μm and μ_h is in cm^2/Vs. Figure 45.8 shows the effective hole drift mobility as a function of applied electric field at room temperature. The symbols and solid line represent the experimental results and the empirical relation (45.4) respectively. The experimental field-dependent effective mobility data have been extracted from Fig. 3 of [45.47]. The drift mobility was measured in ITO/CeO_2/a-Se/Sb_2S_3/Au and ITO/CeO_2/a-Se/Sb_2S_3/RIL/Au detector structures. As evident from Fig. 45.8, the above empirical expression gives a close fit to the experimental results. The physical models for the field-dependent mobility and impact ionization coefficients are also described in the literature [45.50].

Mercuric Iodide (HgI_2)

Polycrystalline HgI_2 (poly-HgI_2) has been used as a photoconductor layer in x-ray image detectors. It has been prepared by either physical vapor deposition (PVD) or screen printing (SP) from a slurry of HgI_2 crystals using a wet particle-in-binder process [45.26]. There appears to be no technological barrier to preparing large-area layers, and direct-conversion x-ray AMFPI of $20 \times 25\,cm^2$ (1536×1920 pixels) and $5 \times 5\,cm^2$ (512×512 pixels) size have been demonstrated using PVD [45.26] and SP poly-HgI_2 layers. The prototype HgI_2 sensors can potentially be used for radiation therapy [45.51], mammographic [45.52], fluoroscopic or radiographic imaging. There has been active research to improve the material properties of poly-HgI_2-based image detectors including improving the nonuniformity by reducing the grain size [45.53]. The bandgap energy $E_g = 2.1\,eV$, the ionization energy $W_\pm \approx 5\,eV$ and the density of poly-HgI_2 is $6.3\,g/cm^3$. The resistivity of this material is $\approx 4 \times 10^{13}\,\Omega cm$ [45.54].

The HgI_2 layer is deposited onto either conductive (indium-tin-oxide-(ITO) or gold-coated) glass plates or a-Si TFT arrays. HgI_2 tends to react chemically with most metals; hence a thin blocking layer (typically, $\approx 1\,\mu m$ layer of insulating polymer) is used between the HgI_2 layer and the pixel electrodes to prevent the reaction and also to reduce the dark current. The HgI_2 layer thickness varies in the range 100–500 μm and the grain size is 20–60 μm. Several hundred Å of palladium (Pd) or Au are deposited (by direct evaporation) on top of the HgI_2 layer followed by a polymer encapsulation layer to form a bias electrode.

The dark current of HgI_2 imagers increases superlinearly with the applied bias voltage [45.55]. For PVD HgI_2 detectors the dark current depends strongly on the operating temperature. It increases by a factor of about two for each 6 °C of temperature rise. It is reported that the dark current varies from $\approx 2\,pA/mm^2$ at 10 °C to $\approx 180\,pA/mm^2$ at 35 °C at $F = 0.95\,V/\mu m$, which is not desirable for medical imagers (the maximum dark

current for medical imaging should be $< 10\,\mathrm{pA/mm^2}$). Therefore, PVD HgI_2 imagers should be operated at relatively low bias (preferably less than $\approx 0.5\,\mathrm{V/\mu m}$) and relatively low temperature ($< 25\,^\circ\mathrm{C}$). The dark current in the SP sample is an order of magnitude smaller than in the PVD sample and more stable against temperature variation. It is possible to keep the dark current below $10\,\mathrm{pA/mm^2}$ at temperatures up to $35\,^\circ\mathrm{C}$ and $F = 1\,\mathrm{V/\mu m}$ [45.55]. A major disadvantage of SP detectors is that they show 2–4 times less sensitivity compared to PVD detectors.

Electrons have much longer range than holes in HgI_2 and thus the radiation-receiving electrode is negatively biased to obtain a higher sensitivity. The $\mu_e\tau_e$ for electrons in the SP HgI_2 is in the range 10^{-6}–$10^{-5}\,\mathrm{cm^2/V}$ [45.26, 56], and $\mu_e\tau_e$ in the PVD sample is about an order of magnitude larger. Recently it was reported that $\mu_e\tau_e$ in PVD HgI_2 is in the range 10^{-5}–$10^{-4}\,\mathrm{cm^2/V}$, which is almost equal to that of single-crystal HgI_2 [45.24, 57]. The reason is that the PVD HgI_2 layer grows in a columnar structure perpendicular to the substrate. Thus, a charge carrier may drift along a column without having to pass through grain boundaries, where it would encounter excess trapping and/or recombination. Samples with larger grain sizes may have fewer grain-boundary defects. Hence there is a trend of increasing $\mu_e\tau_e$ with grain size in the PVD samples. However, this trend is not observed in the SP sample, which indicates another mechanism is responsible for its low $\mu_e\tau_e$. Larger grain sizes may cause nonuniform sensor response. The grain sizes must be much smaller than the pixel size to get a uniform response. $\mu_h\tau_h$ in poly-HgI_2 is of the order $\approx 10^{-7}\,\mathrm{cm^2/V}$ [45.56].

Two important drawbacks of polycrystalline sensors are the image lag and the pixel-to-pixel sensitivity variation or nonuniform response. The lowest image-lag characteristics reported are $\approx 7\%$ first-frame lag, $\approx 0.8\%$ after 1 s and $\approx 0.1\%$ at 3 s in fluoroscopic mode (15 frames/s). The pixel-to-pixel sensitivity variation reduces the dynamic range of the imagers. The relative standard deviation of the sensitivity (standard deviation/average value) in the latest HgI_2 AMFPI is $\approx 10\%$. It is reported that HgI_2 image detectors with smaller grain sizes show good sensitivity and also an acceptably uniform response. The presampling MTF of these detectors is almost equal to the theoretical MTF (sinc function) determined by the pixel aperture.

Cadmium Zinc Telluride (CdZnTe)

CdZnTe ($< 10\%$ Zn) polycrystalline film has been used as a photoconductor layer in x-ray AMFPI. CdZnTe is commonly called CZT. Although CZT can be deposited on large areas, direct-conversion AMFPI of only $7.7 \times 7.7\,\mathrm{cm^2}$ (512×512 pixels) have been demonstrated using polycrystalline CZT (poly-CZT). The CZT layer thickness varies in the range $200-500\,\mu\mathrm{m}$ [45.58]. Temporal lag and nonuniform response were noticeable in early CZT sensors. Large and nonuniform grain sizes are believed to be responsible for the temporal lag and nonuniform response of the sensor. Recent studies show that Cl doping makes a finer and more uniform grain structure [45.25]. The ionization energy $W_\pm \approx 5\,\mathrm{eV}$, and the density of $Cd_{0.95}Zn_{0.05}Te$ is $5.8\,\mathrm{g/cm^3}$. The bandgap energy E_g of $Cd_{0.95}Zn_{0.05}Te$ is 1.7 eV and the resistivity of this material is $\approx 10^{11}\,\Omega\mathrm{cm}$ [45.59].

Typically CZT is first coated onto an inert substrate and then attached to the active matrix array. The advantage of this technique is that the electrical properties and hence imaging performances of the detector can be optimized without causing any thermal or chemical damage to the TFT array. The CZT film is deposited by the close-spaced sublimation method [45.60] onto an alumina (Al_2O_3) substrate coated with ITO, which forms the bias (top) electrode. A cross section of the poly-CZT detector is shown in Fig. 45.9. The several-microns-thick ZnTe layer acts as a barrier to electron injection and hence suppresses dark current under the negative bias. This ZnTe layer is omitted for the positive bias. Conducting resin bumps on the pixel electrodes connect each pixel to the CZT layer.

Introduction of Zn into the CdTe lattice increases the bandgap, decreases the conductivity and hence reduces the dark current. In CZT μ_h decreases with increasing Zn concentration whereas μ_e remains nearly constant. Again, addition of Zn to CdTe increases lattice defects and hence reduces carrier lifetimes. The poly-CZT has a lower density, which results in a lower quantum efficiency η than its single-crystal counterpart. Although (for a detector of given thickness) x-ray sensitivity in CZT detectors is lower than in CdTe detectors, the CZT detectors show a better signal-to-noise ratio and hence give a better DQE. The measured sensitivities are higher than a-Se.

The dark current of $Cd_{0.95}Zn_{0.05}Te$ imagers increases almost linearly with F and is $\approx 70\,\mathrm{pA/mm^2}$ at

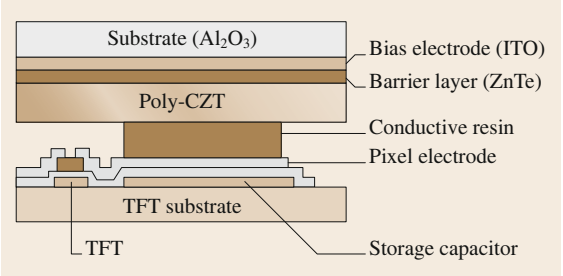

Fig. 45.9 Cross section of the polycristalline CZT detector structure. (After [45.25])

$F = 0.25\,\mathrm{V/\mu m}$ [45.27], which makes it unsuitable for applications requiring long exposure times. The dark current would be expected to decrease with increasing Zn concentration due to the increased E_g. This has in fact been demonstrated [45.25], i. e., the dark current in $Cd_{0.92}Zn_{0.08}Te$ sensors is $40\,\mathrm{pA/mm^2}$ at $F = 0.4\,\mathrm{V/\mu m}$.

The mobility lifetime products of both electrons and holes in poly-CZT are less than that in single-crystal CZT. The values of $\mu\tau$ in single-crystal $Cd_{0.9}Zn_{0.1}Te$ are in the range 10^{-4}–$10^{-3}\,\mathrm{cm^2/V}$ (electrons) and 10^{-6}–$10^{-5}\,\mathrm{cm^2/V}$ (holes) [45.61]. But the values of $\mu\tau$ in poly-$Cd_{0.95}Zn_{0.05}Te$ are $\approx 2\times10^{-4}\,\mathrm{cm^2/V}$ (electrons), and $\approx 3\times10^{-6}\,\mathrm{cm^2/V}$ (holes) [45.62, 63]. Since $\mu_e\tau_e \gg \mu_h\tau_h$ in CZT, negative bias to the radiation-receiving electrode is the preferred choice for better sensitivity and temporal response.

The relative standard deviation of the sensitivity (standard deviation/average value) in the latest CZT AMFPI is $\approx 20\%$ [45.25]. The image-lag characteristics reported are $\approx 70\%$ first-frame lag, $\approx 20\%$ after three frames and 10% at 1 s in fluoroscopic mode (30 frames/s). In single-pulse radiographic mode the first-frame lag is less than 10% [45.25]. The longer image-lag characteristics of CZT sensors in fluoroscopic mode imply that it is not yet suitable for fluoroscopic applications. The presampling MTF of CZT detector is ≈ 0.3(150 µm pixel size) at the Nyquist frequency f_N (theoretical MTF, sinc function, is ≈ 0.64 at $f_N = 3.3$ line pairs per mm), where the MTF of CsI imagers is less than 0.2 [45.27].

Lead Iodide (PbI_2)

Polycrystalline PbI_2 photoconductive layers have been prepared using PVD at a substrate temperature of 200–230 °C. A deposition of several hundred Å of palladium (Pd) is used to form the top electrode. Grains are described as hexagonal platelets with the longest dimensions being 10 µm or less. The platelets grow perpendicular to the substrate, producing films that are less dense (3–5 $\mathrm{g/cm^3}$) than bulk crystalline material (6.2 $\mathrm{g/cm^3}$). There appears to be no technological barrier to preparing large-area layers, and direct-conversion AMFPI of $20\times25\,\mathrm{cm^2}$ size (1536×1920 pixels) have been demonstrated [45.64]. Coating thickness varies in the range 60–250 µm and prototype PbI_2 imagers have been used for radiographic imaging [45.64]. The bandgap energy $E_g = 2.3$ eV, and the ionization energy $W_\pm \approx 5$ eV. The resistivity of this material is in the range 10^{11}–$10^{12}\,\Omega$cm.

Lead iodide detectors have a very long image-lag decay time. The image lag depends on the exposure history. The image-lag characteristics reported are $\approx$ 75% first-frame lag, $\approx 15\%$ after 3 s in fluoroscopic mode (15 frames/s), whereas in single-pulse radiographic mode the first-frame lag is less than 50% and drops below 1% within 1 s [45.64]. The long image-lag characteristics of PbI_2 in fluoroscopic mode imply that it is unsuitable for fluoroscopic applications.

The dark current of PbI_2 imagers increases sublinearly with the applied bias voltage. The dark current is in the range 10–50 $\mathrm{pA/mm^2}$ at $F = 0.5\,\mathrm{V/\mu m}$ [45.64] and 0.1–0.45 $\mathrm{nA/mm^2}$ at $F = 1.0\,\mathrm{V/\mu m}$ [45.65], much higher than PVD HgI_2 detectors, making it unsuitable for long-exposure-time applications. The presampling MTF is ≈ 0.35 (127 µm pixel size) at f_N (theoretical MTF, sinc function, is ≈ 0.64 at $f_N = 3.93$ lp/mm), where the MTF of CsI imagers is less than 0.2 [45.64]. The resolution of PbI_2 imagers is acceptable but slightly worse than that of HgI_2 imagers. Also, the x-ray sensitivity of PbI_2 imagers is lower than that of HgI_2 imagers. The pixel-to-pixel sensitivity variation in PbI_2 imagers is substantially lower.

The $\mu\tau$ product of holes and electrons in PVD PbI_2 are $1.8\times10^{-6}\,\mathrm{cm^2/V}$ and $7\times10^{-8}\,\mathrm{cm^2/V}$ respectively [45.64]. μ_h in poly-PbI_2 is in the range 0.02–0.15 $\mathrm{cm^2/Vs}$ whereas μ_h in single-crystal PbI_2 is 2 $\mathrm{cm^2/Vs}$ [45.66]. This indicates that μ_h in poly-PbI_2 is controlled by shallow traps, probably introduced at the grain boundaries.

Lead Oxide (PbO)

The large-area deposition requirement is compatible with the use of polycrystalline PbO (poly-PbO) film as a photoconductor layer in AMFPI. Direct-conversion flat-panel x-ray imagers of $18\times20\,\mathrm{cm^2}$ (1080×960 pixels) from a poly-PbO with film thicknesses of $\approx$ 300 µm have been demonstrated [45.28]. One advantage of PbO over other x-ray photoconductors is the absence of heavy-element K-edges for the entire diagnostic energy range up to 88 keV, which suppresses additional noise and blurring due to the K-fluorescence. The ionization energy $W_\pm \approx 8$ eV and the density of crystalline PbO is 9.6 $\mathrm{g/cm^3}$ whereas its density is reduced by almost 50% in poly-PbO. The bandgap energy E_g of PbO is 1.9 eV and the resistivity of this material is in the range $(7-10)\times10^{12}\,\Omega$cm [45.28].

Lead oxide photoconductive polycrystalline layers have been prepared by thermal evaporation in a vacuum chamber at a substrate temperature of ≈ 100 °C. An evaporated layer of Al, Au or Pd was used to form a top electrode of thickness 100–200 nm [45.67]. The PbO layer consists of very thin platelets of a few microns thickness and has a density of $\approx 50\%$ of the single-crystal density. PbO slowly degrades if it is exposed to air under normal ambient temperature but a few hours exposure is acceptable. However, in the long term PbO reacts with water and CO_2 causing

an increase in dark current and a decrease in x-ray sensitivity. Therefore, a polymer or a semiconductor (e.g., doped a-Se) passivation layer is used to prevent exposure to the atmosphere. This is usually placed between the photoconductor layer and the top metal electrode. The passivation layer avoids degradation of the PbO layer and reduces the dark current [45.67]. The dark current in PbO sensors is $\approx 40\,\mathrm{pA/mm^2}$ at $F = 3\,\mathrm{V/\mu m}$ [45.28]. The $\mu_e\tau_e$ and $\mu_h\tau_h$ in poly-PbO are 3.5×10^{-7} and $\approx 10^{-8}\,\mathrm{cm^2/V}$ respectively [45.68]. The lag signal in fluoroscopic mode is in the range 3–8% after 1 s. The presampling MTF of a PbO detector is ≈ 0.5 (184 µm pixel size) at f_N (theoretical MTF, sinc function, is ≈ 0.64 at $f_N = 2.72\,\mathrm{lp/mm}$) [45.28].

Thallium Bromide (TlBr)

Polycrystalline thallium bromide (poly-TlBr) has not yet been used in an AMFPI but has been used in a large-area (9 in-diameter) direct-conversion detector called an x-ray-sensitive electron-beam image tube (XEBIT). The operational principle of the XEBIT is similar to the standard light-sensitive vidicon that was utilized extensively in the commercial television industry. The XEBIT can replace an x-ray image intensifier coupled to a video camera using relay lenses with a single direct-conversion device [45.69]. The typical TlBr layer thickness is 300 µm.

The ionization energy $W_\pm \approx 6.5$ eV and the relative dielectric constant of TlBr is 31 [45.70]. The bandgap energy E_g of TlBr is 2.7 eV and its resistivity is $\approx 5\times10^9\,\Omega$cm under ambient conditions. At room temperature the dominant contribution to the dark current is ionic conductivity [45.69]. The ionic conductivity has an exponential dependence on temperature; the conductivity decreases by an order of magnitude for every 19 °C temperature decrease. Therefore, the dark current can be greatly decreased by Peltier cooling. $\mu_h\tau_h$ and $\mu_e\tau_e$ in TlBr are $\approx 1.5\times10^{-6}$ and $\approx 4\times10^{-7}\,\mathrm{cm^2/V}$ respectively [45.69, 70].

Organic Perovskites

Yakunin et al. [45.71] reported that a thick layer ($\approx$ 100 µm) of polycrystalline methylammonium lead iodide (poly-$MAPbI_3$ where MA is CH_3NH_3) perovskite (grain size is larger than 0.25 µm) can be uniformly deposited over large areas using a solution-based synthesis technique without affecting the underlying AMA electronics. This material also shows a reasonable x-ray absorption coefficient and its x-ray sensitivity is comparable to a-Se [45.71]. Therefore, $MAPbI_3$ can be a potential candidate for large-area AMFPI and thus opens the door to a new class of perovskite large-area x-ray sensors. $MAPbI_3$ is a direct bandgap semiconductors of bandgap energy of 1.6 eV and the relative dielectric constant of 28. Its density is $4.3\,\mathrm{g/cm^3}$ [45.72]. The electron and hole mobilities in polycrystalline films are ≈ 8 and $\approx 15\,\mathrm{cm^2/Vs}$ respectively [45.71]. The dark resistivity is $\approx 10^9\,\Omega$cm. The effective masses of electrons and holes are 0.23 m_0 and 0.29 m_0 respectively [45.73], where m_0 is the free electron mass.

Although the reported 60 µm-thick detector structure [45.71] shows a reasonable level of photocurrent for the x-ray fluence of $1.4\times10^7\,\mathrm{photons/mm^2s}$, the dark current is almost half of the photocurrent. Moreover, the dark current increases linearly with the applied field and the detectors shows a photoconductive gain, which indicates that the contacts are ohmic-type. As a result, the dark current could be unacceptably large at high applied field (the high field is needed to achieve acceptable charge collection efficiency and x-ray sensitivity). Though the ohmic contact is required for the photovoltaics, the x-ray detectors need blocking contacts in order to minimize the noise and enhance the DQE. Therefore, the optimization of the structure (for example, the appropriate metal contacts and the blocking layers) is essential for their use in practical AMFPIs.

45.1.3 Summary and the Future

The material and imaging properties of potential photoconductors for x-ray image detectors are summarized in Tables 45.1 and 45.2. Stabilized a-Se is currently the best choice of photoconductor for mammographic x-ray image detectors. The next closest competitor for both mammography and general radiology is the poly-HgI_2 imagers, which show excellent sensitivity, good resolution, and acceptable dark current, homogeneity and lag characteristics. However, the long-term stability of HgI_2 imagers has not been as thoroughly studied as stabilized a-Se detectors. Both the dark current and the image-lag characteristics of CZT, PbI_2 and PbO detectors are worse than those of HgI_2 detectors. However, the x-ray detectors made with CZT photoconductive layers should be mechanically and chemically more stable than HgI_2-based detectors. The main drawback of a-Se detectors are their low conversion gain, which particularly affects the imaging sensor performance at low exposure. This can be overcome by utilizing the avalanche multiplication technique in the a-Se layer [45.74] and/or using on-pixel amplification [45.2]. However, further research is necessary to demonstrate basic operation as well as to examine the long-term stability of detectors utilizing these techniques. The main drawbacks of polycrystalline sensors are the image lag and the nonuniform response. Making smaller, finer and more uniform grain size in polycrystalline sensors may overcome these drawbacks.

Table 45.1 Material properties

Photoconductor, state and preparation	E_g (eV)	$W_{\pm}$ (eV)	Density (g/cm^3)	Resistivity (Ωcm)	Electrons μ_e(cm^2/Vs), $\mu_e\tau_e$(cm^2/V)	Holes μ_h(cm^2/Vs) $\mu_h\tau_h$(cm^2/V)
Stabilized a-Se, vacuum deposition	2.1–2.2	≈ 45 at 10 V/μm	4.3	10^{14}–10^{15}	$\mu_e =$ 0.003–0.006 $\mu_e\tau_e =$ 0.3×10^{-6}–10^{-5}	$\mu_h = 0.12$ $\mu_h\tau_h =$ 10^{-6}–6×10^{-5}
HgI_2, polycrystalline, PVD	2.1	5	6.3	$\approx 4\times10^{13}$	$\mu_e = 88$ $\mu_e\tau_e \approx$ 10^{-5}–10^{-4}	$\mu_h = 3$–4 $\mu_h\tau_h \approx 10^{-6}$
HgI_2, polycrystalline, SP	2.1	5	6.3	$\approx 4\times10^{13}$	$\mu_e\tau_e \approx$ 10^{-6}–10^{-5}	$\mu_h\tau_h \approx 10^{-7}$
$Cd_{0.95}Zn_{0.05}Te$, polycrystalline, vacuum deposition	1.7	5	5.8	$\approx 10^{11}$	$\mu_e\tau_e \approx 2\times10^{-4}$	$\mu_h\tau_h \approx 3\times10^{-6}$
PbI_2, polycrystalline, PVD	2.3	5	3–5	10^{11}–10^{12}	$\mu_e\tau_e = 7\times10^{-8}$	$\mu_h = 0.02$–0.15, $\mu_h\tau_h \approx 2\times10^{-6}$
PbO, polycrystalline, vacuum deposition	1.9	8–20	4.8	7–10×10^{12}	$\mu_e\tau_e \approx 3.5\times10^{-7}$	$\mu_h\tau_h \approx 10^{-8}$
TlBr, polycrystalline	2.7	6.5	7.5	$\approx 5\times10^{9}$ at 20 °C	$\mu_e\tau_e \approx 4\times10^{-7}$	$\mu_h\tau_h \approx 1.5\times10^{-6}$
$MAPbI_3$, polycrystalline	1.6	5	4.3	$\approx 10^{9}$	$\mu_e = 8$	$\mu_h = 15$

Table 45.2 Imaging properties

Photoconductor, state and preparation	Typical operating F (V/μm)	Dark current (pA/mm^2)	Lag (fluoroscopic mode of operation)	Uniformity/ sensitivity variation (standard deviation/ average value)
Stabilized a-Se, single layer	≈ 10	< 10 up to $F = 20$ V/μm	$< 2\%$ after 33 ms	Negligible
Stabilized a-Se, multilayer (pin or nip)	≈ 10	< 1 up to $F = 20$ V/μm	$< 2\%$ after 33 ms	Negligible
HgI_2, polycrystalline, PVD	≈ 0.5	≈ 6 at $F = 0.5$ V/μm	$\approx 7\%$ after 66 ms	$\approx 10\%$
HgI_2, polycrystalline, SP	≈ 1.0	≈ 8 at $F = 1.0$ V/μm	$\approx 7\%$ after 66 ms	$\approx 10\%$
$Cd_{0.95}Zn_{0.05}Te$, polycrystalline	≈ 0.25	≈ 25 at $F = 0.25$ V/μm	$\approx 70\%$ after 33 ms	$\approx 20\%$
PbI_2, polycrystalline, PVD	≈ 0.5	10–50 at $F = 0.5$ V/μm	$\approx 75\%$ after 66 ms	?
PbO, polycrystalline	≈ 1.0	40 at $F = 3$ V/μm field	3–8% after 1 s	?
TlBr, polycrystalline	≈ 0.5	?	?	?

45.2 Dark Current Limitations

As mentioned earlier, a large electric field (e.g., ≈ 10 V/μm in conventional a-Se detectors) is applied across the x-ray detectors in order to collect photogenerated EHPs [45.43]. One of the most important attributes of a photoconductor is the dark current, which should be negligibly small, since it is a source of noise and thus reduces the detectivity and dynamic range of the detector. The dark current in detectors is usually very high right after applying the bias voltage and decays with time. In most of the cases, it reaches a plateau within the time range of 100–10 000 s [45.36, 37, 47].

The dark current in x-ray detectors may have three origins:

1. The depletion of carriers from the defect states within the bandgap after applying the bias
2. Steady-state thermal generation of carriers in the bulk

3. Carrier injections from the metal contacts towards the photoconductor layer.

45.2.1 Charge Carrier Depletion

The depletion of the majority carrier from the bulk and interface defect states within the mobility gap can constitute a transient dark current decay behavior. After applying the bias, majority carriers are depleted and the steady-state quasi-Fermi level E_{FD} becomes slightly different from the Fermi level E_F. Let us consider a-Se as an example. a-Se is slightly p-type and E_F in a-Se at zero bias is slightly below the midgap. After applying the bias, holes are depleted and the steady-state quasi-Fermi level E_{FD} lies above E_F as shown in Fig. 45.10. The temporal behavior of the carrier depletion process is determined by the detrapping time constants. The time-dependent hole depletion rate due to carrier detrapping from the bulk a-Se is [45.48, 75]

$$g_d(t) = \int_{E_v}^{E_c} \frac{N(E)}{\tau_r(E)} [f_{FD}(E) - f_F(E)] \exp\left[-\frac{t}{\tau_r(E)}\right] dE \,, \tag{45.5}$$

where

$$f_F(E) = \frac{1}{1 + \exp\left[\frac{(E-E_F)}{k_B T}\right]}, \tag{45.6}$$

$$f_{FD}(E) = \frac{1}{1 + \exp\left[\frac{(E-E_{FD})}{k_B T}\right]}. \tag{45.7}$$

The mean detrapping or mean release time constant is

$$\tau_r(E) = \nu^{-1} \exp\left[\frac{\left(E - E_V - \beta_{pf}\sqrt{F}\right)}{k_B T}\right], \tag{45.8}$$

where $N(E)$ is the density of states (DOS) of the photoconductor at energy E in the midgap, ν is the attempt-to-escape frequency, k_B is the Boltzmann constant, T is the absolute temperature, t is the instantaneous time (in seconds), $\beta_{pf} = \sqrt{e^3/\pi\varepsilon_s}$ is the Poole–Frenkel coefficient, e is the elementary charge, ε_s is the permittivity of the photoconductor, and E_C and E_V are the conduction and valence band edges respectively. Equation (45.5) represents the rate of hole depletion per unit volume, which decays with time.

The depleted holes drift under the influence of the electric field and induce a current in the detector. Currents resulting from the drifting of carriers in the photoconductive detectors are due entirely to induction, which can conveniently be calculated by using the Shockley–Ramo theorem [45.76]. The transient current density due to the hole depletion from the bulk is [45.77],

$$J_{dpb}(t) = \frac{eL}{2} g_d(t) \,. \tag{45.9}$$

Similarly, the time-dependent hole depletion current density due to carrier detrapping from the interface (e.g., the top interface at positive bias to the top electrode) is [45.48],

$$J_{dpi}(t) = e \int_{E_v}^{E_c} \frac{D_i(E)}{\tau_r(E)} [f_{FD}(E) - f_F(E)] \exp\left[-\frac{t}{\tau_r(E)}\right] dE \,, \tag{45.10}$$

where $D_i(E)$ is the density of interface states ($cm^{-2}\,eV^{-1}$). Note that (45.5)–(45.10) can also applied to slightly n-type photoconductors (e.g., HgI_2) by interchanging f_F and f_{FD} [45.78].

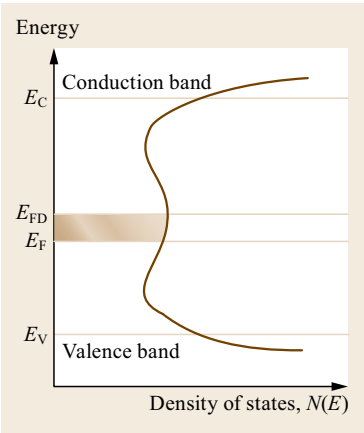

Fig. 45.10 A schematic representing the carrier depletion from the mobility gap in slightly p-type amorphous/polycrystalline materials after applying the bias. The *shaded area* represents the approximate amount of depleted carriers. The figure shows an arbitrary DOS for an amorphous material. (After [45.48])

45.2.2 Steady-State Thermal Generation

The defect states close to the middle of the bandgap of the x-ray photoconductor have a significant probability for thermal excitation of both types of carriers. The bandgap/mobility gap of x-ray photoconductors is quite large and thus the band-to-band thermal carrier generation is expected to be negligible. Therefore, the steady-state thermal generation rate is dominated by the emission from traps within $k_B T$ of E_{FD} as shown in Fig. 45.11. If the excitation rates for electrons and holes are equal, E_{FD} is very close to the middle of the bandgap. The generation rate for a fully depleted sample is determined by the average carrier release time and

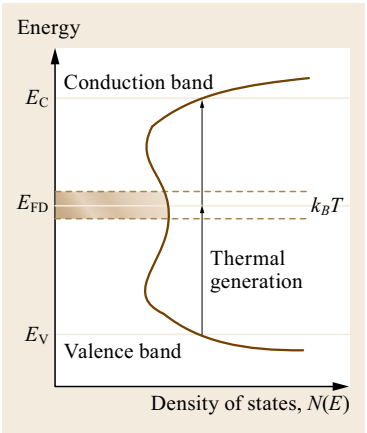

Fig. 45.11 A Schematic representing the thermal generation of carriers from the mobility gap of amorphous/polycrystalline materials near the quasi-Fermi level E_{FD}. (After [45.48])

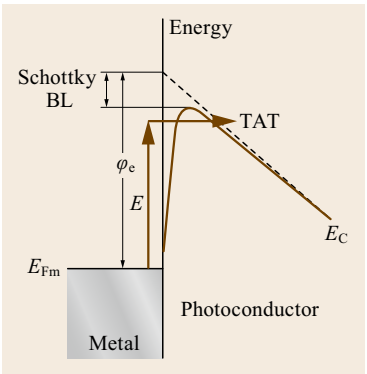

Fig. 45.12 A schematic representing the electron injection process from the metal towards the photoconductor layer. TAT and BL stand for the thermally assisted tunneling and barrier lowering respectively. (After [45.48])

can be written as [45.48],

$$g = N(E_{FD}) k_B T \nu \exp\left[-\frac{\left(E_C - E_{FD} - \beta_{pf}\sqrt{F}\right)}{k_B T}\right], \tag{45.11}$$

where $N(E_{FD})$ is the density of states at energy E_{FD} in the midgap. It is assumed in (45.11) that the density of states is constant over $k_B T$ near E_{FD}. Assuming that the liberated carriers are not lost by trapping or recombination (any loss of carriers can be reflected in the effective value of g), the steady-state thermal generation current is

$$J_{th}(t) = egL\,. \tag{45.12}$$

45.2.3 Carrier Injection

The metal/photoconductor contacts in detectors are generally blocking in nature and the carrier injection is mainly controlled by the Schottky emission. Once the carriers are injected into the photoconductive layer, they move by the drift mechanisms (the diffusion component of current is negligible compared to its drift component because of the very high applied bias) [45.79]. Therefore, the injected current densities through the metal/photoconductor contacts are [45.79],

$$J_e(t) = eN_C v_{de}(t)\left(\frac{v_r}{v_{de}+v_r}\right) \times \exp\left[-\frac{\phi_e - \Delta\phi_e(F)}{k_B T}\right] \tag{45.13}$$

and

$$J_h(t) = eN_V v_{dh}(t)\left(\frac{v_r}{v_{dh}+v_r}\right) \times \exp\left[-\frac{\phi_h - \Delta\phi_h(F)}{k_B T}\right], \tag{45.14}$$

where $v_r = A^* T^2/eN_C$ is the thermal velocity, A^* is the effective Richardson constant, $N_{V(C)}$ is the effective density of states in the valence (conduction) band, $v_d(t) \approx \mu F$ is the instantaneous drift velocity of the injected carriers, μ is the effective mobility of carriers, and ϕ is the effective barrier height for injecting carriers from the metal into the photoconductor layer, considering the effect of surface states. The subscripts e and h stand for electrons and holes respectively. For the potential x-ray photoconductors, $v_r \gg v_{dh}$ or v_{de}, the term inside the square bracket of (45.13) and (45.14) becomes unity, and the injection current is dominated by v_{dh} or v_{de} depending on the particular photoconductor (e.g., $v_{dh} \gg v_{de}$ in a-Se) [45.79].

The quantity $\Delta\phi(F)$ within the exponential in (45.13) and (45.14) is the field-dependent barrier lowering due to other effects such as charge rearrangement in the interfacial layer, the image force barrier lowering, and/or thermally assisted tunneling as shown in Fig. 45.12. For the metal-to-semiconductor carrier injection, the term $\Delta\phi(F)$ can be written as

$$\Delta\phi(F) = \sqrt{\frac{e^3 F}{4\pi\varepsilon_s}} + e\alpha F^2\,. \tag{45.15}$$

The first term in (45.15) is the image force barrier lowering (Schottky barrier lowering), and the second term is the optimum barrier lowering due to the thermally assisted tunneling. The potential barrier for the injecting carriers from the metal contact under a strong applied field is essentially a triangular barrier. Note that the thermally activated tunneling is much more probable than the direct tunneling. In thermally activated tunneling process, as the vibration energy E_p increases, the tunneling barrier decreases and hence the probability increases. On the other hand the population of

the energy level E_p decreases with increasing E_p proportionally to $\exp(-E_p/k_BT)$. Thus, there exists an optimum energy level from where the resultant escape probability is the maximum, which is proportional to $\exp(\alpha F^2/k_BT)$ [45.80]. The expression of α is determined by considering the tunneling probability through a triangular barrier together with Boltzmann occupation probability and given by [45.80]

$$\alpha = \frac{e\hbar^2}{24m^*\,(k_BT)^2}\,, \tag{45.16}$$

where h is the modified Plank constant and m^* is the effective mass of the photoconductor.

Concluding Remarks on Dark Current

One of the advantages of a-Se over competing large-area x-ray photoconductors is the comparatively smaller dark current under typical operating fields [45.36, 81]. The operating field refers to the applied field that ensures the x-ray generated charges are collected; i. e., the sensitivity is not limited by the charge collection efficiency [45.82]. For example, the dark current that has been recently reported for PbI_2 [45.81] is in the range 0.1–0.45 nA/mm^2 at a field of 1 V/μm. Under normal operation, the field needs to be greater than 1 V/μm to ensure good charge collection but this would also mean a dark current that is greater than 1 nA/mm^2, which is much higher than the dark current in typical a-Se detectors even at the operating field of 10 V/μm [45.36].

As mentioned earlier, the conventional a-Se detector can be either n-i-p or n-i type. The experimental results in the literature show that the main source of the dark current is the injection of holes from the metal contacts and the bulk thermal generation current is negligible [45.36, 37]. The above results are consistent with the facts that the bulk thermal generation and electron injection currents are negligible compared to the hole injection current because of a large bandgap and a very low electron mobility in a-Se respectively. *Frey* et al. [45.36] have also shown that the dark current has a strong dependence on the n-like layer thickness; it decreases abruptly with increasing the n-like layer thickness (≈ 4 to 8 μm). The carrier injection, from the metal to the semiconductor, depends on the internal electric field at the metal/a-Se interface. It is believed that the electric field right after applying the bias is almost uniform but quickly decreases at the interface due to high initial current and high carrier trapping in the blocking layers, which reduces carrier injection and hence reduces the dark current. The typical electric field profiles, after applying the bias on the n-i-p and n-i structures, are illustrated in Fig. 45.5. To reduce the contact electric field and dark current, the n-like layer must have a sufficient amount of trap centers and the energy depths of these trap centers should be ≈ 0.75–0.8 eV or more from the valence band mobility edge. The shallower trap levels are unable to retain a sufficient amount of trapped charge and the deeper trap centers create longer transient times to reach a steady state dark current. The detailed descriptions of the dark current mechanisms are given in [45.48].

At the normal operating fields (less than 10 V/μm) of conventional a-Se or poly-HgI_2 x-ray detectors, the thermal generation current is negligible as compared to the injection currents from the metallic electrodes [45.48, 78]. However, the thermal generation rate can be increased exponentially with field because of Poole–Frenkel or thermally assisted tunneling effects [45.83]. Therefore, both the injection and thermal generation currents should be considered to determine the dark current in a-Se avalanche detectors. The excessive dark current has been one of the factors that limits the highest operating field. An acceptable level of dark current up to an electric field as high as 60 V/μm in some a-Se detector structures has recently been reported [45.45]. The injection current is minimized and the dark is slightly higher than the thermal generation current in the type 2 structure in Fig. 45.6.

45.3 Metrics of Detector Performance

X-ray sensitivity, resolution in terms of modulation transfer function (MTF), detective quantum efficiency (DQE), image lag and ghosting are often considered as the metrics of imaging performance. For most practical applications, the spatial-frequency-dependent (f-dependent) detective quantum efficiency, DQE(f), is the appropriate metric of overall system performance and is unity at all f for an ideal detector. The detector performance depends critically on the photoconductor material properties such as the mobility, carrier trapping (both shallow and deep), EHP creation energy, x-ray attenuation and absorption coefficients. The material properties such as carrier mobility, EHP creation energy, x-ray attenuation and absorption coefficients in a well-defined photoconductor are almost constant, but the carrier lifetimes may vary from sample to sample. Shallow and deep trapping are particularly responsible for image lag and ghosting respectively. The effects of charge-transport properties ($\mu\tau$) and the attenuation coefficient of the photoconductor material on the detector

performance depends on L and F through the following normalized parameters

$$\Delta = \text{normalized attenuation depth (attenuation depth/thickness)} = \frac{1}{(\alpha L)},$$

$$x_e = \text{normalized electron schubweg (electron schubweg per unit thickness)} = \frac{\mu_e \tau_e F}{L}, \text{ and },$$

$$x_h = \text{normalized hole schubweg (hole schubweg per unit thickness)} = \frac{\mu_h \tau_h F}{L},$$

where α is the linear attenuation coefficient of the photoconductor, $\mu_{e(h)}$ is the mobility and $\tau_{e(h)}$ is the deep-trapping time (lifetime) of electrons (holes). Equivalently, x_e and x_h are the normalized carrier lifetimes (carrier lifetimes per unit transit time) for electrons and holes respectively. The ranges of these normalized parameters for the three most promising photoconductors (a-Se, poly-HgI_2 and poly-CZT) for use in x-ray image detectors are given in Table 45.3. The combined effects of charge-transport properties (mobility and carrier lifetime), operating conditions (F and E), photoconductor thickness, and the attenuation coefficient of the photoconductor material on the imaging characteristics (x-ray sensitivity, DQE, MTF and ghosting) are examined in the following sections. It must be emphasized that the photoconductor thickness L and the operating field F are as important to the overall performance of the detector as the material properties of the photoconductor itself, a point that will become apparent in the results presented in this chapter.

45.3.1 X-Ray Sensitivity

The x-ray sensitivity (S) of a photoconductive detector is defined as the collected charge per unit area per unit exposure of radiation and is considered an important performance measure for a superior image. High S permits the use of low detector radiation-exposure levels, which also increases the dynamic range of the AMPFI. The selection of the x-ray photoconductor is highly influenced by the value of S.

The value of S can be considered to arise in terms of three controlling factors:

1. The amount of radiation actually attenuated from the incident radiation that is useful for the generation of electron–hole pairs (EHPs), which is characterized by the quantum efficiency η of the detector and depends on the value of α (the linear attenuation coefficient) of the photoconductor and L through $\eta = 1 - e^{-\alpha L}$, where the value of α is x-ray photon-energy-dependent.
2. The generation of EHPs by x-ray interactions, which is characterized by the value of $W_{\pm}$ of the photoconductor and the average absorbed energy E_{ab} per attenuated x-ray photon of energy E, where $W_{\pm}$ depends on the material properties of the photoconductor, and E_{ab} depends on the incident x-ray photon energy [45.84] and the material properties. Note that $E_{ab} = E(\alpha_{en}/\alpha)$, where α_{en} is the energy absorption coefficient of the photoconductor, which depends on the x-ray photon energy E.
3. How much of the x-ray generated charge is actually collected in the external circuit. This is characterized by the charge-carrier drift mobilities (μ) and lifetimes (τ), of the applied F and L.

The S of an x-ray image detector can be normalized with respect to the maximum sensitivity (S_0) that would arise if all the incident radiation were absorbed and all the liberated carriers were collected. Neglecting secondary photon interactions, the expression for S_0 is [45.32]

$$S_0 = \left(\frac{5.45 \times 10^{13}\, e}{\left(\frac{\alpha_{air}}{\rho_{air}}\right) W_{\pm}} \right) \left(\frac{\alpha_{en}}{\alpha}\right), \qquad (45.17)$$

where e is the elementary charge, while α_{air} and ρ_{air} are the energy absorption coefficients of air and its density. If $W_{\pm}$ is expressed in eV, α_{air}/ρ_{air} is in cm^2/g and exposure in (45.17) is in R, then S_0 is in units of C/cm^2R. Thus S_0 is a constant that depends on the x-ray photon

Table 45.3 The values of Δ, x_e and x_h for a-Se, poly-HgI_2 and poly-CZT detectors

Photoconductor	$\mu_e\tau_e$ (cm^2/V) $\mu_h\tau_h$ (cm^2/V)	F (V/μm)	E (keV)	L (mm)	x_e	x_h	Δ
Stabilized a-Se	$\mu_e\tau_e = 0.3\times10^{-6}$–$10^{-5}$ $\mu_h\tau_h = 10^{-6}$–6×10^{-5}	≈ 10	20 60	0.2 1.0	1.5–50 0.3–10	5–300 1–60	0.24 0.98

Poly-$Cd_{0.95}Zn_{0.05}Te$	$\mu_e\tau_e \approx 2\times10^{-4}$ $\mu_h\tau_h \approx 3\times10^{-6}$	≈ 0.25	20 60	0.3 0.3	≈ 17 ≈ 17	≈ 0.25 ≈ 0.25	0.26 0.89

energy E and the material properties of the photoconductor, since $W_{\pm}$ is a material property that can usually be taken as constant for a given material. For those materials (e.g., a-Se) that have a significant F- and/or E-dependent $W_{\pm}$, then S_0 depends on F and/or E.

The quantity $s = S/S_0$ takes into account the x-ray absorption and charge-transport effects and is called the charge-collection and absorption-limited normalized sensitivity. It should be emphasized that s is a quantity that is determined by the x-ray absorption profile, photoconductor thickness and the charge-collection efficiency. The s of an x-ray detector considering small signal operation, a constant μ and a single deep-trapping time (lifetime) τ for each type of carrier (holes and electrons) and neglecting carrier diffusion is given by [45.82],

$$\begin{aligned}\frac{S}{S_0} &= x_h\left[\left(1-e^{-\frac{1}{\Delta}}\right)+\frac{1}{\frac{\Delta}{x_h}-1}\left(e^{-\frac{1}{x_h}}-e^{-\frac{1}{\Delta}}\right)\right]\\ &\quad + x_e\left[\left(1-e^{-\frac{1}{\Delta}}\right)-\frac{1}{\frac{\Delta}{x_e+1}}\left(1-e^{-\frac{1}{\Delta}-\frac{1}{x_e}}\right)\right]\\ &= s_h(x_h,\Delta)+s_e(x_e,\Delta)=s(x_h,x_e,\Delta)\,,\end{aligned} \tag{45.18}$$

where subscripts h and e refer to holes and electrons respectively.

The two square brackets on the right-hand side of the normalized sensitivity s expression (45.18) represent the relative contributions of hole and electron transport to the overall sensitivity for a given Δ. It is assumed in (45.18) that the radiation-receiving side of the detector is biased positively. If the bias polarity is reversed, then x_e and x_h must be interchanged. The expression in (45.18) applies for incident radiation that is monoenergetic and has to be appropriately integrated over the radiation spectrum of a practical polyenergic x-ray source by considering the x-ray photon-energy-dependent terms $W_{\pm}$, α and α_{en}. Equation (45.18) applies to an isolated photoconductor sandwiched between two large-area parallel-plate electrodes (small pixel effects are excluded) [45.85] and operating under a constant F (small signal case). An excellent fit of (45.18) to experimental data on poly-HgI_2 is given in [45.56].

The value of s is always less than unity since S for a photoconductor of finite thickness in which carrier collection is not perfect is always less than S_0. Note that $s(x_h, x_e, \Delta) = s_h + s_e = 1$ when all the incident radiation is absorbed and all the charges are collected, i. e., $x_h, x_e \gg 1$ and $\Delta \ll 1$. The sensitivity is then simply S_0 and is controlled by $W_{\pm}$.

The sensitivity is mainly controlled by the charges that have the same polarity as the bias on the radiation-receiving electrode: holes for positive bias and electrons for negative bias [45.55, 81]. The extent of the disparity between s_h and s_e depends on Δ. The disparity is stronger for lower Δ, which can be understood by noting that electron and hole generation do not occur uniformly throughout the thickness of the sample but rather it is more effective closer to the radiation-receiving electrode. An advantage of a-Se detectors is that both x_e and x_h are much greater than one, which is not the case for other photoconductors, as shown in Table 45.3. Therefore, charge collection in a-Se detectors is close to unity and the normalized sensitivity is controlled by the quantum efficiency of the detector. The S and s of different photoconductive detectors using the normalized parameters from Table 45.3 are given in Table 45.4. The values of $W_{\pm}$ for a-Se were taken from the work of *Blevis* et al. [45.30]. At $F = 10\,V/\mu m$, $W_{\pm} = 42.5$ and 46 eV for x-ray photon energies of 60 and 20 keV respectively. The maximum x-ray sensitivity S_0 of chest radiographic detectors ($E = 60$ eV) is much higher than of mammographic detectors ($E = 20$ eV) because of the lower α_{air}/ρ_{air} values in (45.17) at higher x-ray photon energies [45.84]. The value of S_0 in a-Se detectors is much lower than in poly-HgI_2 and poly-CZT detectors because of the higher value of $W_{\pm}$ in a-Se.

45.3.2 Detective Quantum Efficiency

DQE measures the ability of the detector to transfer signal relative to noise from its input to its output. The random nature of image quanta gives rise to random

Table 45.4 X-ray sensitivity of a-Se, poly-HgI_2 and poly-CZT detectors using the normalized parameters from Table 45.3 (E is the x-ray photon energy)

Photoconductor	E (keV)	S_0 ($\mu C/cm^2R$)	$s = S/S_0$		$S(\mu C/cm^2R)$	
			Positive bias	Negative bias	Positive bias	Negative bias
Stabilized a-Se	20	0.244	0.9–0.98	0.8–0.98	0.22–0.24	0.2–0.24
	60	5.37	0.39–0.64	0.35–0.62	2.1–3.38	1.88–3.35

	60	38.54	0.15–0.3	0.21–0.4	6.76–11.21	8.18–15.6
Poly-$Cd_{0.95}Zn_{0.05}Te$	20	3	≈ 0.456	≈ 0.85	≈ 1.37	≈ 2.55
	60	35.87	≈ 0.41	≈ 0.51	≈ 14.69	≈ 18.12

fluctuations in image signals, which contributes to image formation and hence creates random noises. The scattering of image quanta gives rise to image blurring, which is quantified by the MTF(f). Images are partially degraded by various sources of statistical fluctuations that arise along the imaging chain. The relative increase in image noise due to an imaging system as a function of spatial frequency f is expressed quantitatively by DQE(f) which represents the signal-to-noise transfer efficiency for different frequencies of information in an image. DQE(f) is defined as

$$\mathrm{DQE}(f) = \frac{\mathrm{SNR}^2_{\mathrm{out}}(f)}{\mathrm{SNR}^2_{\mathrm{in}}(f)}\,, \tag{45.19}$$

where $\mathrm{SNR}_{\mathrm{in}}$ and $\mathrm{SNR}_{\mathrm{out}}$ are the signal-to-noise ratios (SNR) at the input and output stages of the image detector respectively. DQE(f) is unity for an ideal detector. For simplicity, we are often interested in measuring DQE($f = 0$) of an imaging detector since it represents the signal quality degradation due to the signal and noise transfer characteristics of the system without considering signal spreading.

The random nature of charge-carrier trapping (i. e., incomplete charge collection) in the photoconductor layer creates fluctuations in the collected charge and hence creates additional noise. Thus carrier trapping degrades signal-to-noise performance of the image and reduces the DQE. *Kabir* and *Kasap* [45.86] have examined the effects of charge-carrier trapping on the DQE(0) of an a-Se detector by considering depth-dependent conversion gain and depth-dependent charge-collection efficiency in the cascaded-linear-system model [45.87, 88]. Below we apply the DQE(0) model in [45.86] to potential photoconductive detectors such as a-Se, poly-HgI_2 and poly-$Cd_{0.95}Zn_{0.05}Te$ detectors for fluoroscopic applications to study and compare their DQE(0) performance.

Figure 45.13 shows DQE(0) as a function of x-ray exposure for a-Se, HgI_2, and CZT detectors for a 60 keV x-ray beam. The x-ray exposure (X) is varied from 0.1 μR to 10 μR, which is the range of x-ray exposure for fluoroscopic applications. We assume that the pixel area, $A = 200 \times 200\,\mu\mathrm{m}$, and the effective fill factor is 1.0 for all the photoconductors. The average E is 60 keV and the additive electronic noise (N_e) is assumed to be 2000 electrons per pixel. The following transport and operating parameters are used in Fig. 45.13: for a-Se detectors, $L = 1000\,\mu\mathrm{m}$, $F = 10\,\mathrm{V/\mu m}$, $W_{\pm} \approx 43\,\mathrm{eV}$, $\mu_e\tau_e = 10^{-6}\,\mathrm{cm^2/V}$ and $\mu_h\tau_h = 10^{-5}\,\mathrm{cm^2/V}$; for HgI_2 detectors, $L = 260\,\mu\mathrm{m}$, $F = 0.5\,\mathrm{V/\mu m}$, $W_{\pm} = 5\,\mathrm{eV}$, $\mu_e\tau_e = 6\times10^{-6}\,\mathrm{cm^2/V}$ and $\mu_h\tau_h = 10^{-7}\,\mathrm{cm^2/V}$; and for CZT detectors, $L = 270\,\mu\mathrm{m}$, $F = 0.25\,\mathrm{V/\mu m}$, $W_{\pm} = 5\,\mathrm{eV}$,

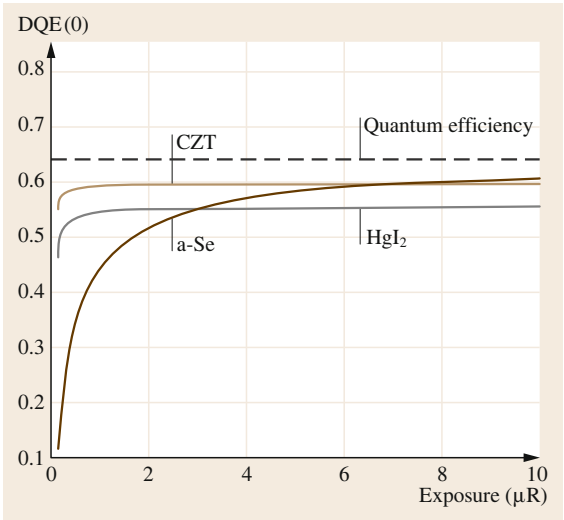

Fig. 45.13 DQE(0) versus x-ray exposure for a-Se, poly-HgI_2, and poly-CZT detectors and for a 60 keV monoenergetic x-ray beam. The electronic noise is 2000 e/pixel. It is assumed that $F = 10\,\mathrm{V/\mu m}$ for a-Se, $0.5\,\mathrm{V/\mu m}$ for HgI_2 and $0.25\,\mathrm{V/\mu m}$ for CZT

$\mu_e\tau_e = 2\times10^{-4}\,\mathrm{cm^2/V}$ and $\mu_h\tau_h = 3\times10^{-6}\,\mathrm{cm^2/V}$. The radiation-receiving electrode is biased positively for a-Se detectors and negatively for HgI_2 and CZT detectors. $\Delta \approx 0.98$ is for all photoconductors. $\eta = 1 - \exp(-1/\Delta) \approx 0.64$ is the maximum achievable DQE(0) if all the liberated charges are collected.

The DQE for the CZT detector is relatively unchanged over the whole exposure range due to a large conversion gain (low $W_{\pm}$) and high charge-collection efficiency (good transport properties). The DQE for a-Se detectors is small at low exposures because of its relatively low conversion gain and is controlled by the added electronic noise. As the x-ray exposure increases, each pixel receives more photons. The relative contribution of electronic noise to the total noise becomes less important and the DQE increases. The DQE for HgI_2 detectors is relatively small even at higher exposures because of its low charge-collection efficiency, which gives rise to considerable gain-fluctuation noise. Therefore, both high conversion gain and high charge-collection efficiency are required to improve the DQE performance of an x-ray image detector [45.89]. The conversion gain depends on $W_{\pm}$, which is a material property of the photoconductor. The charge-collection efficiency can be improved by increasing F and improving the $\mu\tau$ products of the carriers. However, increasing F also increases the dark current dramatically in both HgI_2 and CdZnTe detectors. Thus, there is a practical limitation on F. An F as high as $20\,\mathrm{V/\mu m}$ is achievable in a-Se detectors while keeping the dark current

within an acceptable level for x-ray imaging [45.38]. The charge-collection efficiency of a-Se detectors is relatively high because of the high F that is used (10–20 V/μm) in operating the detector for a reasonable $W_{\pm}$.

45.3.3 Modulation Transfer Function (MTF)

Resolution or resolving power is the ability to record separate images of small objects that are placed very closely together. The overall resolution of a system can be expressed as a convolution of the component resolutions. However, the spatial resolution of an imaging device or a system can also be described in terms of the MTF, which is the relative response of the system as a function of spatial frequency. The MTF of an imaging system can be described as a cascade of several stages where the overall MTF is simply the product of the MTFs of all the individual stages. The MTF(f) is a much more convenient descriptor of spatial response since the resolving power from multiplication is much more easily comprehended than convolution. The overall MTF (or presampling MTF) of an image detector can be expressed as

$$\mathrm{MTF}(f) = \mathrm{MTF_m}(f)\,\mathrm{MTF_a}(f)\,, \qquad (45.20)$$

where $\mathrm{MTF_m}(f)$ is the modulation transfer function of the detector material and $\mathrm{MTF_a}(f)$ is the modulation transfer function associated with the aperture function of the pixel electrodes. $\mathrm{MTF_a}(f)$ arises due to averaging of the signal over a pixel area. If the aperture is square with dimension a, then $\mathrm{MTF_a}(f)$ will be of the form sinc (af). The aperture MTF describes how spatial frequencies are passed through the detector elements.

The spatial resolution in direct-conversion AMFPI is high and closer to the aperture function, as compared to phosphor-based AMFPI. Based on current understanding, charge-carrier trapping and reabsorption of K-fluorescent x-ray photons are the two dominant mechanisms responsible for the loss of resolution [45.89] in direct-conversion AMFPI. Some of the K-fluorescent x-ray photons may be reabsorbed at different points within the detector volume from the primary x-ray-photon interaction point. This creates a lateral spreading of signal and a loss of resolution. The loss of resolution due to fluorescence reabsorption is maximum (although not very substantial [45.89]) just above the K-edge of the photoconductor. This effect can be ignored when: (i) the incident x-ray photon energy is lower than the K-edge of the photoconductor, or (ii) the mean energy of the x-ray beam and the K-edge occur at widely different energies [45.90]. The charge-carrier trapping has a significant effect on the resolution of these direct-conversion x-ray image detectors [45.63], which will be discussed below.

The direct-conversion AMFPI geometry consists of a photoconductor layer sandwiched between two electrodes; the electrode at one side is a continuous metal plate and the electrode on the other side of the photoconductor is segmented into an array of individual square pixels of size $a \times a$, as shown in Fig. 45.14a. The geometric pixel aperture width in a flat-panel detector is smaller than the pixel pitch (center-to-center spacing between two pixels). However, it has been shown that the effective fill factor (the effective fraction of pixel area used for image-charge collection) of a photoconductive flat-panel detector is close to unity [45.91, 92]. Therefore, the effective pixel aperture width a is virtually identical to the pixel pitch. Some of the x-ray-generated carriers are captured by deep traps in the bulk of the photoconductor during their drift across the photoconductor layer. Suppose that a carrier is trapped in the photoconductor above a particular (central) pixel electrode of a pixelated image sensor. This trapped carrier induces charges not only on the central pixel electrode but also on neighboring pixel electrodes, as shown in Fig. 45.14b, and consequently there is a lateral spread of information and hence a loss of image resolution.

An analytical expression for the MTF due to distributed carrier trapping in the bulk of the photoconductor has been developed in [45.63], which examines the effect of charge-carrier trapping on the resolution of direct-conversion AMFPI. The effect of trapping on MTF increases with decreasing normalized carrier lifetime (i. e., normalized schubweg). Trapping of the carriers that move towards the pixel electrodes degrades the MTF performance, whereas trapping of the other type of carriers, which move away from the pixels, improves the sharpness of the x-ray image.

Figure 45.15 shows the experimental MTF and theoretical fit of a 300 μm-thick positively biased CZT detector exposed to an 80 kVp x-ray beam with 26 mm Al filtration. The experimental data have been extracted from [45.93]. The operating $F = 0.25\,\mathrm{V/\mu m}$ and pixel pitch is 150 μm. The Nyquist frequency is 3.3 lp/mm. The dotted line shows the MTF due to the bulk carrier trapping only. The bulk carrier trapping has a significant effect on the MTF of the detector. As is apparent from Fig. 45.15, there is very good agreement between the model and the experimental data. The best-fit $\mu\tau$ products of electrons and holes are $\mu_e\tau_e = 2.4 \times 10^{-4}\,\mathrm{cm^2/V}$ and $\mu_h\tau_h = 3.2 \times 10^{-6}\,\mathrm{cm^2/V}$, which are very close to the $\mu\tau$ values reported previously [45.58, 61]. Although the charge-carrier-trapping-limited MTF model has been applied to the CZT sensors, the model can also be applied to other photoconductive (e.g., a-

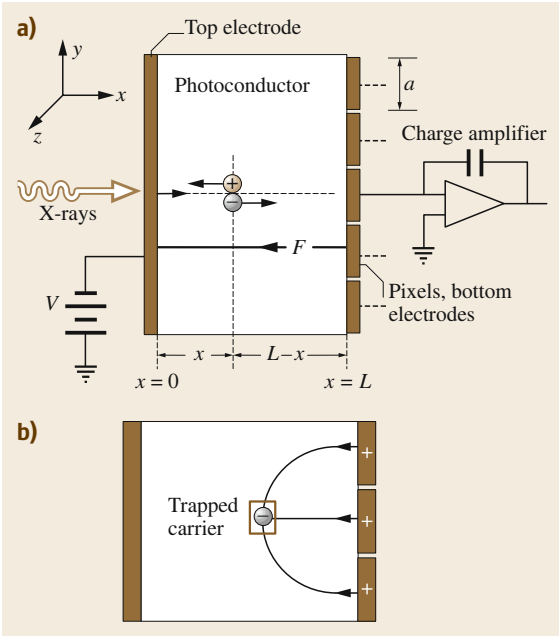

Fig. 45.14 **(a)** A cross section of a direct-conversion pixelated x-ray image detector. **(b)** Trapped carriers in the photoconductor induce charges not only on the central pixel electrode but also on neighboring pixel electrodes, spreading the information and hence reducing spatial resolution

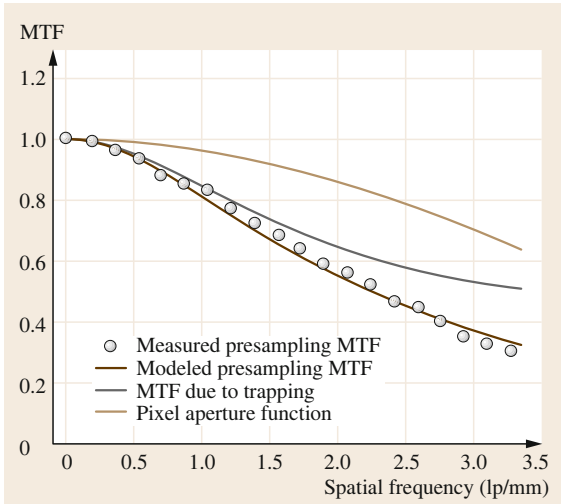

Fig. 45.15 Measured presampling MTF of a polycrystalline CdZnTe detector in comparison with modeled results that included blurring due to charge-carrier trapping in the bulk of the photoconductor. The detector thickness is 300 μm and the pixel pitch is 150 μm. (Experimental data extracted from [45.93, Fig. 12]. Theoretical model from [45.63])

Se, PbO and HgI_2) panel x-ray image detectors. The same model has been also applied to PbO detectors in [45.68].

45.3.4 Image Lag and Ghosting

The detectors should be free of image lag and ghosting effects. When the photoconductor is exposed to x-rays, a transient photocurrent starts to flow that reaches almost a steady value at the carrier transit time [45.94]. Ideally, the current should be present as long as the detector is subjected to x-ray exposure and, once the radiation is stopped, it should diminish to zero. In reality, some of the drifting carriers are trapped in the energy distributed defect states within the bandgap/mobility gap of the photoconductor layer and these trapped carriers are released later. The release time depends on their energy depths from the band/mobility edges [45.95]. As a result, a transient decaying current can be detected for several hundreds/thousands of seconds in some detectors even after the excitation is removed. This is known as the residual current or the lag signal, and has been modeled for a-Se detectors in [45.94]. For most applications, this is an undesirable phenomenon because when part of the current from a previous exposure combines with the next one, the resulting image can be inaccurate. As mentioned in Sect. 45.1.2, the image lag signal was measured in most of the photoconductive detectors. The amount of image lag signal in a-Se detectors has been found to be negligible, whereas it is quite significant in some of other polycrystalline detectors (Sect. 45.1.2).

The x-ray exposure can change the x-ray sensitivity of the exposed area and thus a shadow impression of a previously acquired image is visible in subsequent uniform exposure, which leads to what is called *ghosting* [45.96]. Ghosting can affect the diagnostic value of x-ray images in particular when images are acquired in a fast sequence, for example in fluoroscopy. The causes of change in x-ray sensitivity and resolution, and their recovery mechanisms in a-Se detectors have been systematically investigated in the last decade [45.97, 98]. Though the relative amounts of the sensitivity and resolution changes owing to repeated exposure in a-Se are under an acceptable level, they are due to several mechanisms such as:

1. Recombination of drifting carriers with oppositely charged trapped carriers
2. Creation of x-ray-induced metastable trap centers, and/or
3. Reduction of the free carrier generation due to space charge (i. e., due to a nonuniform electric field) [45.95, 98].

It is expected that the ghosting phenomenon may also be present in other photoconductive (e.g., HgI_2, CZT, PbO and PbI_2) detectors, although it has not yet been systematically measured.

45.4 Summary

The principles of operation of a direct-conversion AMFPI for medical applications have been briefly discussed. The charge-transport and imaging properties of some of the potential photoconductors have been critically discussed and compared with the properties of an ideal photoconductor for x-ray image detectors. The various imaging characteristics of photoconductor-based AMFPIs such as the dark current, sensitivity (S), detective quantum efficiency (DQE), and resolution in terms of the modulation transfer function (MTF) have also been examined. These characteristics depend critically not only on the photoconductor's charge-transport properties but also on the detector structure, i. e., the size of the pixel and the thickness of the photoconductor. It has been shown that the detector structure in terms of the photoconductor thickness and the pixel size is just as important to the overall performance of the detector as the material properties of the photoconductor itself. Long-term stability, and x-ray-induced effects and phenomena should also be examined in the future to obtain more comprehensive detector models.

Acknowledgments. The authors would like to thank Dr. John Rowlands for many fruitful discussions and suggestions during the first edition of this article. The authors acknowledge financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC) through its discovery grants program.

46. Phase-Change Memory Materials

Alexander V. Kolobov, Junji Tominaga, Paul Fons

Phase-change materials are Te-containing alloys, typically lying along the $GeTe$-Sb_2Te_3 quasibinary tie line. Their ability to switch, reversibly and extremely quickly, between the crystalline and amorphous phases, combined with the high stability of both phases, makes them ideally suitable for memory applications. They have been long used in optical data storage in the form of DVD and Blu-Ray disks and recently have also emerged as a leading candidate for electronic nonvolatile memory devices. In this chapter, a detailed description of these materials is provided starting with the global and local structures of the two phases, which were extensively studied both experimentally and using ab initio computer simulations, and followed by the discussion of possible atomistic mechanisms of the phase-change process, with special accent on the role of electronic excitation. The chapter is concluded by a brief description of the present and emerging applications of this class of chalcogenide materials.

Nonvolatile memory devices are key elements of a wide variety of electronic and portable systems such as digital cameras, solid-state disks, smartphones, computers, e-books, tablets, etc., and their market has been increasing exponentially over the last decade. Even though flash memory represents today the leading technology, to allow its scalability down to the 16 nm technology node and beyond, new architectures are necessary. Therefore, new emerging nonvolatile memory concepts are under investigation and one of the leading candidates is phase-change memory (PCM). PCM has been successfully used in optical memory devices such as DVD-RAM since the 1990s and recently commercial production of electronic nonvolatile phase-change random access memory (PRAM) has been launched by two of the world's leading memory makers Samsung and Micron. PCM is considered to be a storage class memory in which unlike flash its elements are individually addressable, have a demonstrated cyclability of over 10^{11} cycles, and have access times on the tens to hundreds of nanoseconds scale.

The basic idea of PCM of utilizing the property contrast between the amorphous and crystalline phases (the SET and RESET states) of some materials belongs to *Ovshinsky* and dates back to the 1960s [46.1] and is based on the following. When a liquid is cooled, it can solidify either discontinuously to form a crystal or in a continuous way to form a glass. The process is schematically illustrated in Fig. 46.1.

A very simplified picture of the phase-change process is based on the idea that as the temperature of the melt decreases, the viscosity becomes larger, and at a certain point the structure can no longer follow the change in temperature. As a result, if the melt is cooled slowly, the equilibrium crystalline phase is formed. If, on the other hand, the melt is cooled fast enough so that the structure cannot follow the change in temperature, the disordered phase is frozen; one obtains a supercooled liquid and subsequently a glass. When the obtained glass is annealed at temperatures between the glass-transition temperature and the melting point, it gradually transforms into the crystalline

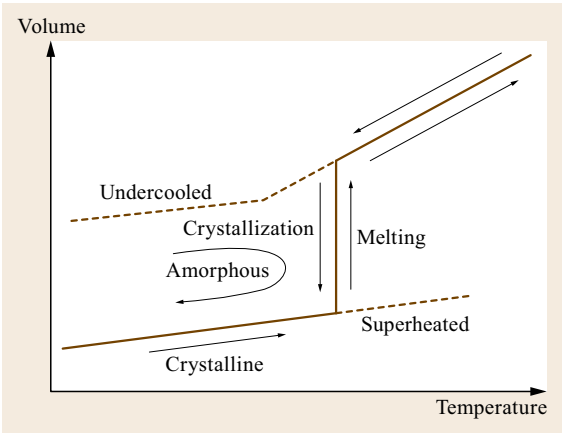

Fig. 46.1 A volume–temperature phase diagram demonstrating the formation of either a crystalline or amorphous phase from the melt

state. One can thus cycle a material between the ordered crystalline and disordered amorphous phases. In the device-relevant phase-change process, a short intense laser or current pulse melts the material that is subsequently quenched into the amorphous phase. A longer pulse of lower intensity reverts the material to the crystalline phase.

The research and development of phase-change optical storage has a long history starting with the discovery of the switching effect in some chalcogenide alloys [46.1–3]. In particular, in amorphous $Si_{12}Te_{48}As_{30}Ge_{10}$ it was found that when a voltage that exceeded a critical value, called the threshold voltage, was applied, the chalcogenide alloy switched from the low-conductivity state to the high-conductivity state [46.1]. As the current in the high-conductivity state was reduced below the characteristic value termed the holding current, the system switched back to the original low-conductivity state. The observed switching process was reversible and could be repeated many times. The observed increase in the conductivity was attributed to the formation of a current filament, growing in diameter with increasing current flow. In the same paper [46.1], it was reported that by tuning the composition a memory effect was observed that was attributed to a change in the structure of the material, namely:

> *[. . .] after switching from a highly resistive state, structural changes result in the preservation of a conductive state even when the current is totally removed. The material can be reversibly switched back to the highly resistive state by application of a current pulse of either polarity exceeding a threshold value.*

This finding marked the beginning of intensive – and extensive – research on phase-change materials. In order for a material to become commercially relevant, it has to satisfy simultaneously several requirements such as sufficiently large property contrast between the two states and high stability of both phases at operating temperatures alongside high switching speed in both directions. Less obvious but equally important are the need for low thermal conductivity of the crystalline phase (to ensure low-energy switching), the relative softness of the material needed to withstand stresses generated at the amorphous-crystalline boundaries allowing for high cyclability, and good scalability. While there are many materials that satisfy some of these requirements, very few satisfy them all.

Years of research have singled out GeTe-based PCM alloys. In practical applications, GeTe is usually alloyed with Sb or other additives such as C or N to tune desirable properties, such as thermal stability, switching speed, or optical contrast (e.g., $Ge_2Sb_2Te_5$ is used in DVDs but $Ge_8Sb_2Te_{11}$ is used in Blu-ray disks). What makes the GeTe alloys special? Since the properties of a material are determined by its structure, we start by discussing the structure of GeTe-based alloys.

46.1 Structure of Ge-Sb-Te Phase-Change Alloys

46.1.1 Crystalline Phase

Binary GeTe

It is natural to start the description with the binary compound GeTe, which is the simplest material in the Ge-Sb-Te (GST) system. In the low-temperature ferroelectric phase, GeTe possesses a rhombohedral structure with the space group $R3m$. This structure can be viewed as a rock-salt structure slightly distorted along the ⟨111⟩ direction with a subsequent shear relaxation. The driving force for the formation of the rhombohedral phase has been a subject of several studies in the past [46.4]. In this phase, Ge and Te atoms are sixfold coordinated to each other with subsets of three shorter (2.83 Å) and three longer (3.15 Å) bonds often described as a Peierls distortion [46.5] due to the reduced coupling between the orthogonal p-type orbitals that constitute the basis for bonding in GeTe.

Based on diffraction studies, mainly neutron diffraction [46.6], it was concluded from a Bragg peaks analysis that GeTe undergoes a displacive ferroelectric-to-paraelectric transition at the Curie temperature, T_c,

around 705 K whereupon the structure changes to the rock-salt structure (space group ($Fm\bar{3}m$) with a concomitant disappearance of the Peierls distortion). Subsequent use of local probes such as extended x-ray absorption fine structure (EXAFS) or pair-distribution function analysis of total scattering unambiguously demonstrated that the structure *locally* remains distorted above T_c in essentially the same manner as it is distorted at lower temperatures but the distribution of shorter and longer bonds becomes random, which manifests itself as a rock-salt average structure from the perspective on long-range averaging probes such as Bragg diffraction [46.7, 8].

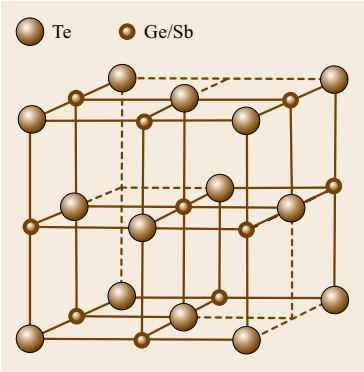

Fig. 46.2 Metastable cubic structure of $Ge_2Sb_2Te_5$

$Ge_2Sb_2Te_5$ and Related Materials

The first report on the structure of Ge-Sb-Te dates back to the late 1960s when *Petrov* et al. [46.9] investigated the structures of $Ge_2Sb_2Te_5$ and $GeSb_4Te_7$. Analysis of electron-diffraction results led the authors to conclude that the studied crystals possessed a hexagonal cell with space group $P\bar{3}m1$ and the lattice constants $a = 4.20 \pm 0.02$ and $c = 16.96 \pm 0.06$ Å and $a = 4.21 \pm 0.02$ and $c = 23.65 \pm 0.08$ Å for $Ge_2Sb_2Te_5$ and $GeSb_4Te_7$, respectively. The structure of $Ge_2Sb_2Te_5$ was described as a layered structure with the stacking sequence along the *c*-axis of Te-Sb-Te-Ge-Te-Te-Ge-Te-Sb-Te. This sequence is sometimes referred to as the Petrov sequence. The stable phase of $Ge_2Sb_2Te_5$ was subsequently reexamined by *Kooi* et al. [46.10]. Very similar lattice parameters were obtained ($a = 4.2$ Å and $c = 17.2$ Å) but the stacking sequence was found to be different, namely, Te-Ge-Te-Sb-Te-Te-Sb-Te-Ge-Te, that is, with the Ge and Sb positions exchanged. A later study using synchrotron radiation found that the Ge/Sb layers were randomly occupied by these two elements [46.11].

Yamada [46.12] was the first to study the structure of a thin layer, crystallized from the amorphous phase. It was found that it possesses a structure that was different from that of the stable trigonal phase. This issue was further explored using x-ray diffraction (XRD) by *Nonaka* et al. [46.13] and by *Yamada* and *Matsunaga* [46.14].

Based on these results, the crystal structure of $Ge_2Sb_2Te_5$ was identified as the rock-salt (NaCl) structure ($Fm\bar{3}m$). From Rietveld refinement, it was concluded that the anion face-centered cubic (fcc) sublattice was fully occupied by Te atoms with Ge and Sb atoms randomly located on the cation sublattice. The stoichiometry of the structure requires that there are vacancies on the Ge/Sb sites and their presence has been confirmed by structure refinement. The proposed structure is shown in Fig. 46.2. It was subsequently shown that the rock-salt structure is characteristic of a wide range of GST alloys [46.15–18].

EXAFS studies performed by various groups [46.19, 20] demonstrated that the Ge-Te bond length in metastable $Ge_2Sb_2Te_5$ is 2.83 ± 0.01 Å, that is, significantly shorter than might be expected based on the rock-salt structure as determined by XRD and the experimental lattice parameter of slightly over 6.00 Å. Based on these results, it was argued [46.20] that the structure of metastable $Ge_2Sb_2Te_5$ does not possess rock-salt symmetry but is locally distorted. The local structure around the Ge species is very similar to that of the binary GeTe, which possesses a rhombohedral structure with subsets of three shorter and three longer bonds. The distortion of the Ge atom location was subsequently confirmed experimentally using scattering measurements [46.21, 22]. The Sb-Te bond length was also found to be shorter than half the lattice parameter (2.94 Å [46.20]). The distortion present in GST alloys is usually referred to as Peierls distortion [46.5].

While the obtained bond lengths are significantly shorter than those expected from the experimental lattice parameters and the rock-salt symmetry, they are at the same time significantly longer that the sum of the corresponding covalent radii, which suggests that the bonds are not purely covalent.

The rock-salt like arrangement of atoms in the crystalline phase requires the formation of six bonds by each participating atom while at the same time, the number of valence electrons located on Ge and Sb atoms is lower. A way to ensure six bonds is by virtue of sharing the valence electrons among several bonds with less than two electrons per bond on average through resonance bonding, a concept that is described as follows. *Lucovsky* and *White* [46.23] were the first to discuss this possibility and its consequences for IV-VI crystals such as GeTe.

In particular, in the cited work [46.23] resonance bonding in IV-VI and chalcogen (Se and Te) crystals was considered and it was suggested that *we might expect materials that exhibit resonance bonding in the*

crystalline phase to have different properties in the amorphous phase. It was also stated that long-range order is crucial for resonance bonding to exist. If long-range order is lost, the system will be unable to achieve resonant bonding [46.23]. This approach has been subsequently elaborated in [46.24–26] to describe the unusually large property contrast in GST alloys and the fast switching rate.

How does the bond length asymmetry effect the electron density distribution? A plot of the charge density difference (CDD) between a simulated relaxed GeTe model at 0 K and isolated pseudo-atoms shown in Fig. 46.3 demonstrates that the electron density is only significant along the short bonds. In contrast, the electron density pile-up along the long bonds is *significantly* lower demonstrating that there is a pronounced bonding energy hierarchy between short and long bonds [46.27]. The existing bonding energy hierarchy should manifest itself in the different response of the short and long bonds to thermal and/or electronic excitations. The fact that long-range order is associated with weak secondary bonds suggests that the crystalline phase is intrinsically fragile.

Vacancies present in the structure deserve a dedicated paragraph. *Kolobov* et al. [46.20] suggested that vacancies serve to stabilize the structure by ensuring the appropriate charge balance. The role of vacancies was a subject of several consequent studies, where it was also concluded that vacancies, whose concentration varies as $x/(1+2x)$ for the $GeTe_{1-x}$-$(Sb_2Te_3)_x$ system [46.15], are not electronic defects but are an intrinsic feature of the GST rock-salt structure [46.15, 24, 28]. Vacancies were also argued to account for the p-type conductivity of the crystalline phase of GeTe [46.29]. *Wuttig* et al. [46.28] demonstrated that introduction of vacancies into Ge/Sb sublattice decreased the total energy of the system.

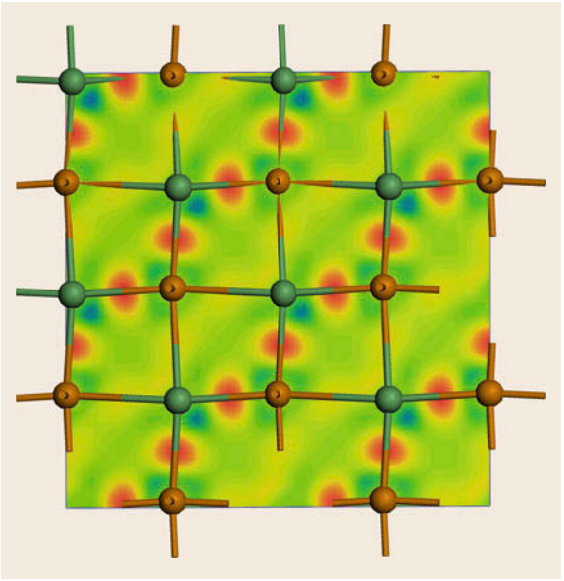

Fig. 46.3 Difference in electron charge density for GeTe at 0 K and isolated pseudo-atoms. A significant bonding charge can be seen midway along the shorter bonds which corresponds to covalent bonding. At the same time, the bonding localized along the longer bonds is *significantly* lower clear demonstrating a pronounced bonding energy difference between the short and long bonds. 46.1.2 Amorphous Phase

Experimental Studies

Of special interest may be the structure of amorphous binary GeTe (a-GeTe) that is the simplest phase-change material and an end point of the quasibinary GeTe-Sb_2Te_3 tie-line. Despite years of studies by various groups, there is still controversy regarding the structure of amorphous GeTe. X-ray diffraction structural studies made by *Betts* et al. [46.30] back in the 1970s revealed that the interatomic distance and the coordination number of a-GeTe are in poor agreement with those of c-GeTe. From a detailed analysis of the diffraction data, these authors concluded that a random covalent model with a 4(Ge):2(Te) local coordination was the most appropriate as a local coordination model for a-GeTe. Subsequent electron diffraction studies [46.31, 32] obtained similar radial distribution functions. The 4(Ge):2(Te)-coordinated structure was also suggested on the basis of EXAFS measurements around both Ge and Te *K*-edges [46.33–35]. The Ge-Te bond length (2.59 Å) was also found to be consistent with the 4(Ge):2(Te) bonding geometry [46.35]. Raman scattering and far-infrared absorption spectra for a-GeTe [46.36] were equally interpreted in terms of the presence of $GeTe_4$ tetrahedra. These results strongly supported a random covalent network model of the 4(Ge):2(Te)-coordinated atoms, and excluded the possibility of a c-GeTe microcrystalline structure. Combined photoemission and inverse photoemission studies [46.37] also favored the 4(Ge):2(Te) coordination.

On the other hand, neutron scattering [46.38] and Mossbauer spectrometry of ^{125}Te nuclei [46.39] studies suggested a 3(Ge):3(Te)-coordinated local structure, demonstrating that the local structure of a GeTe is still far from being resolved.

The first report on the local structure of the amorphous phase of GST alloys belongs to the LETI group in France [46.19]. These authors performed EXAFS studies on as-deposited and thermally crystallized layers of

GeTe and GST and obtained the bond lengths characteristic of the two states. In particular, they found the Ge-Te bond to be 2.62 Å and the Sb-Te bond to be 2.84 Å (as compared to 2.83 and 2.94 Å, respectively in the crystalline phase), that is, the bonds are *shorter* in the amorphous phase. This work, however, only reported the obtained numerical values and stayed short of drawing further conclusions.

Kolobov et al. [46.20] were the first to go beyond simple measurements and proposed structural models. Their results are described as follows in more detail. It should be noted that in this work laser-crystallized and laser-amorphized states of GST were studied, that is, exactly the structures that are used in optical memory devices (the measurements were performed on real-device structures).

For the amorphous phase, it was found that Ge-Te and Sb-Te bonds become shorter and the structure possessed more local order than the crystalline phase as evidenced by the more intense and narrower peaks in the spectra corresponding to the amorphous phase (Fig. 46.4). It is informative to note that the measured Ge-Te and Sb-Te bond lengths are very close to the sum of the corresponding covalent radii for the elements ($r_{Ge} = 1.21$ Å, $r_{Sb} = 1.40$ Å, $r_{Te} = 1.36$ Å [46.40]). (We note here that the covalent radius for Ge is given assuming sp^3-hybridization).

The observed bond shortening and increased local order are highly unusual for covalent solids when, due to anharmonicity of the interatomic potential, disorder usually results in longer and weaker bonds and suggests that the local structures in the two cases are significantly different. It should also be noted that despite the bond shortening, the density of the amorphous phase is about 5% lower than that of the crystalline phase.

The conclusion that a significant change occurs in the local structure finds more support in the experimentally measured x-ray absorption near-edge structure (XANES) spectra [46.20], where the overall observed changes in XANES upon the phase transition could be reproduced by first-principles multiple-scattering (FEFF) simulations [46.41] when the Ge atoms were placed into tetrahedral symmetry sites [46.20].

Amorphous $Ge_2Sb_2Te_5$ has subsequently been studied using EXAFS by other groups [46.42–44] and similar results were obtained although in addition the presence of Ge-Ge bonds was also reported. It is interesting to note that the obtained values of the fraction of Ge-Ge bonds were similar to the concentration of tetrahedral Ge sites, suggesting a correlation between the two.

Bond shortening in the as-deposited amorphous phase of $Ge_2Sb_2Te_5$ has also been observed by high-energy x-ray scattering experiments [46.45].

A gradual upwards drift in the electrical resistance of Ge-Sb-Te alloys has been observed after switching to the amorphous state that potentially can cause problems for multilevel storage applications in PRAM. This phenomena, often referred to as *drift* of the amorphous state, is usually attributed to the gradual [46.46, 47] relaxation of bonds toward a lower energy state. In particular, the loss of Ge-Ge bonds in the amorphous state leads to a widening of the bandgap and a gradual increase in resistivity.

Computer Simulations

Welnic et al. [46.48] were the first to apply ab-initio simulations based on density functional theory for phase-change materials, using the spinel structure (in which Ge atoms are tetrahedrally coordinated) to model

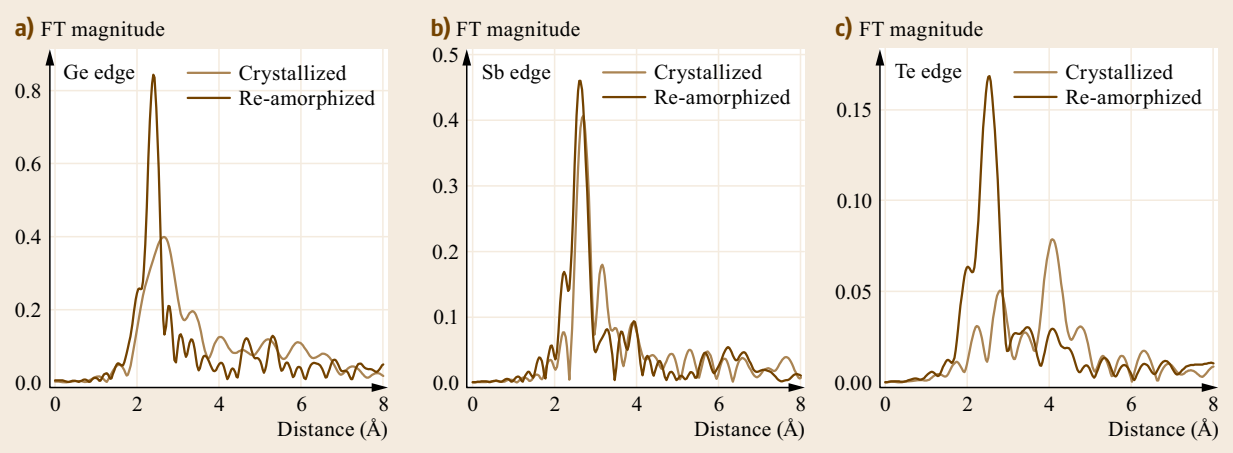

Fig. 46.4a–c Fourier transformed EXAFS spectra for Ge **(a)**, Sb **(b)**, and Te **(c)** K-edges for laser crystallized and laser amorphized $Ge_2Sb_2Te_5$. (Reprinted from [46.20] by permission from Macmillan Publishers Ltd, copyright (2004))

the amorphous phase. Calculations of the band structure showed a band opening at the Γ point upon transformation from the rock-salt to the spinel phase in agreement with experiment.

A significant step forward was the in-silico generation of the melt-quenched amorphous phase. The first simulation of the melt-quenched amorphous $Ge_2Sb_2Te_5$ was reported by *Caravati* et al. [46.49]. The liquid structure (270 atom) generated at 2300 K was equilibrated for 6 ps and then quenched in 16 ps and further equilibrated for 18 ps at 990 K. In order to generate a model of a-$Ge_2Sb_2Te_5$, the liquid was then brought to 300 K in 18 ps. Subsequently these studies were extended [46.50]. The obtained results can be summarized as follows. Ge and Sb atoms are mostly fourfold coordinated and form bonds preferentially with Te atoms. A large fraction of Ge atoms ($\approx 33\%$) were found on tetrahedral sites. It was additionally found that the presence of bonds with Ge or Sb favors a tetrahedral geometry.

Akola and *Jones* [46.51, 52] performed similar simulations using significantly larger cells (460 atom as opposed to the 270 atom of [46.49]) and carried out molecular dynamics simulations over hundreds of picoseconds, times that are comparable to the experimentally observed (ca. 1 ns) amorphization times.

The Ge-Sb (2.78 Å) and Sb-Te (2.93 Å) bond lengths of a GST were found to be shorter than in the crystalline form, but longer than those obtained from experimental studies. The most prominent topologies reported were Ge-Te_4, Sb-Te_3, and Te-$Ge(Sb)_3$. The total coordination numbers using a distance cut-off of 3.2 Å were 4.2 (Ge), 3.7 (Sb), and 2.9 (Te). About 60% of Ge atoms were found to be fourfold coordinated but only 34% were tetrahedrally bonded.

The study found square fragments dominated the structure of a GST. Denoting Te atoms as A and Ge/Sb atoms as B, the authors introduced ABAB squares as the building blocks of the a GST structure (Fig. 46.5). The rapid amorphous-to-crystalline transition was viewed by the authors as a vacancy-supported reorientation of ABAB squares. The same authors subsequently studied the $Ge_8Sb_2Te_{11}$ composition used in Blu-ray disks [46.53].

Hegedüs and *Elliott* [46.54] performed a comprehensive study of phase-change atomistics in $Ge_2Sb_2Te_5$ throughout the phase-change cycle. Starting with the liquid phase, they found the existence of four-membered rings (4-rings), analogous to the ABAB blocks of [46.51], even at temperatures as high as 1073 K. They found that the concentration of 4-rings increased as the temperature decreased and this increase was found to be correlated with the size of the maximal cluster of *connected square rings*.

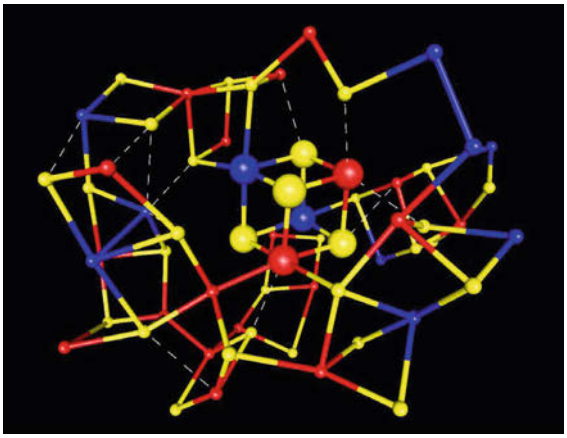

Fig. 46.5 A fragment of the amorphous structure showing an ABAB cube [46.51]. (Copyright 2007 by the American Physical Society. Reprinted with permission)

The results obtained using the DFT simulations described earlier clearly demonstrated that not all Ge atoms acquire tetrahedral symmetry positions in the amorphous phase, although it was argued that the concentration of the tetrahedral Ge sites depends on the simulation details and can reach a value of 50% [46.55].

Krbal et al. [46.56] performed a detailed Ge *K*-edge XANES analysis on the MQ amorphous model of *Hegedüs* and *Elliott* [46.54] that contained 90 atom in the simulation cell, including 20 Ge atoms. The analysis of this amorphous model of GST [46.54] revealed that the local structure around Ge atoms can be grouped into three characteristic bonding configurations with respect to the first-nearest neighbor geometry:

1. Purely tetrahedral (T_d) configurations
2. Pyramids (P_y), with a Ge atom at the apex and with Te-Ge-Te angles very close to 90°
3. Highly distorted octahedral (O_h) structures.

What makes the group-IV element Ge form P_y configurations in the MQ amorphous phase? The answer to this question derives from the definition of a covalent bond, a concept that is characterized by the sharing of a pair of electrons between two bonded atoms [46.57]. Germanium has a $s^2p_x^1p_y^1p_z^0$ electronic configuration in its outer shell. In most materials, these orbitals hybridize and the electronic configuration changes to sp^3, allowing for the formation of four equivalent covalent bonds.

A rather special situation is created when Ge bonds to a chalcogen. The electronic configuration of Te is $(s^2)p_x^1p_y^1p_z^2$, that is, there are two unpaired p electrons and a nonbonding lone-pair in the outer shell. The Te lone-pair p electrons have the option of interact-

ing with the empty p-orbital of an unhybridized Ge atom, forming a two-electron dative bond, which, once formed, is indistinguishable from usual covalent bonds. A similar approach was used to explain the existence of Ge(3):Te(3) configurations in [46.58], where the authors also considered the formation of Ge-Te bonds that involved the lone-pair electrons of Te.

How does the incorporation of Sb atoms affect the structure and properties of this type of material? An Sb atom has one unpaired valence electron on each of its three p-orbitals and can thus form three conventional covalent bonds. On the other hand, Te atoms can form two conventional covalent bonds with Sb atoms; its lone-pair electrons cannot be used. As a result, two Sb atoms (shown in magenta in Fig. 46.6) are needed to replace three Ge atoms to ensure that all interatomic bonds are saturated, which determines the stability of the GeTe-Sb_2Te_3 tie-line. This substitution generates a vacancy on a Ge site. The three Te atoms (a Te triad) located next to the vacancy are twofold coordinated and possess unused lone-pair electrons. Because the Te atoms are low (twofold) coordinated, they can rather easily move in space in the directions show by the arrows in the figure. With 20% of Ge sites being vacant in a typical GST alloy $Ge_2Sb_2Te_5$, the concentration of lone pairs is on the order of 10^{21} cm^{-3}.

The presence of lone-pair orbitals nearly aligned with covalent Ge-Te bonds leads to the formation of three-center four-electron (3c–4e) Te-Ge-Te bonds [46.59] as illustrated in Fig. 46.7. The creation of such

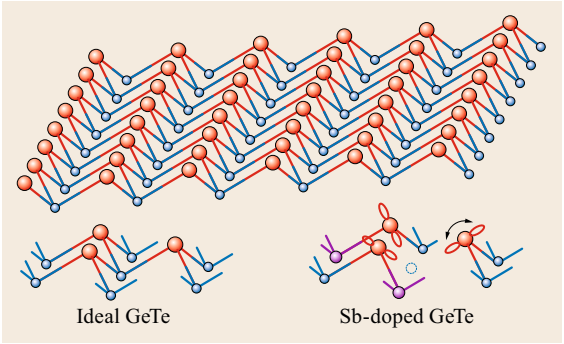

Fig. 46.6 Schematic of the formation of a vacancy and twofold coordinated Te atoms as a result of Sb substitution in GeTe [46.59]. Ge atoms – *blue*, Sb atoms – *magenta*, Te atoms – *orange*. (Copyright 2013 by the American Physical Society. Reprinted with permission)

bonds with equal Te-Ge and Ge-Te distances on both sides of the central Ge atom has several important consequences. First, it leads to the strengthening of interlayer interactions reducing the bonding energy hierarchy characteristic of the ideal binary rhombohedral GeTe phase and makes the structure locally more *cubic*. Second, the similarity in the bond-lengths and energies lead to a more conducive environment for resonance bonding in the structure with 3c–4e bonds, making quasibinary GeTe-Sb_2Te_3 different from the ideal GeTe case that is characterized by a strong bond energy hierarchy.

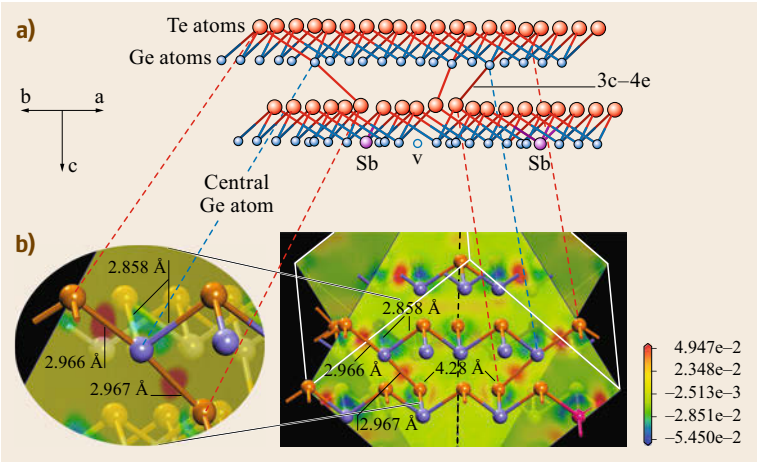

Fig. 46.7a,b Schematic of the formation of three-center four-electron Te-Ge-Te bonds **(a)** utilizing Te lone-pair electrons of the twofold coordinated Te atoms located around the Ge vacancy. Te atoms are shown in *orange*, Ge atoms in *blue*, Sb atoms in *magenta*, and the Ge-site vacancy is shown as an *empty circle*. **(b)** Shows the result of DFT simulation of the three-center Te-Ge-Te bond complexes. Two CDD slice – separated by a *black dashed line* – one for each of the two 3c–4e bonds, are shown on the *right*. The *red spots* of similar size and color midway between the Ge and Te atoms in the CDD map indicate covalent (like) interaction of similar strength on *both* sides of the central Ge atom along the Te-Ge-Te bond direction [46.59]. 46.2 Mechanism of the Phase-Change Process

46.2.1 Structural Studies

In early work, it was tacitly assumed that upon exposure of the crystalline phase to an intense laser or current pulse, phase-change materials melt and are subsequently quenched into a (completely) disordered amorphous state. Recent years have witnessed significant progress in the understanding of the atomistic mechanism of phase change.

The first model that attempted to provide an atomistic description of the phase-change process was the umbrella-flip model [46.20]. Subsequent ab initio studies performed by different groups have not only confirmed the existence of Ge atoms on tetrahedral symmetry sites (about 30% of the total number of Ge atoms) but also found the presence of regular ABAB building blocks (A = Ge, Sb, B = Te) alternatively referred to as four-membered rings, square rings, or even-membered rings [46.45, 51, 52, 54] in amorphous GST. The crystallization was explained by the ordering of pre-existing four-membered rings.

The proposal that the bonding in the crystalline state of GST is resonant while in the amorphous state it is purely covalent [46.23–25] implicitly suggested that the underlying mechanism of the phase transition consisted of the establishment – or destruction – of resonance bonding between the covalently bonded fragments. In the crystalline phase, resonant bonding leads to the ordering and alignment of p orbitals on adjacent molecular units. This alignment is lost in the amorphous phase and this has a drastic effect on materials's properties such as optical contrast and resistivity [46.26].

The phase-change (amorphization) process can be viewed as the destruction of three-centre bonds with the transformation of symmetrical three-center Te-Ge-Te bonds in the crystalline phase with equal Ge-Te distances on both sides of the central Ge atom into asymmetric structures with different Ge-Te distances in the amorphous phase [46.59] as illustrated in Fig. 46.8. This process requires very small atomic displacements and may alternatively be viewed as the formation/destruction of connected four-membered rings [46.54] or ABAB blocks [46.51], provided the bond cut-off distances are properly chosen to account for the formation and/or destruction of the 3c–4e bonds.

Subsequently, it was argued that Ge-Ge bonds in the amorphous phase are formed as a result of the formation of dynamic three-center bonds [46.60], which becomes possible due to the presence of lone-pair electrons subtended at partially hybridized threefold coordinated Ge atoms [46.61]. The Ge-Ge bonds serve to stabilize the amorphous phase. The process is illustrated in Fig. 46.9.

Finally, it is important that the *destabilization of the subsystem of* the weaker bonds with the preserved covalent backbone not only allows for the low-temperature amorphization of the material, however, the preserved covalent backbone also ensures the memory of the initial crystalline structure making the (reverse) crystallization process fast and ensuring high cyclability of the crystallization–amorphization process.

46.2.2 Photo-Assisted Amorphization of $Ge_2Sb_2Te_5$

While it is generally believed that the role of light in the phase-change process is to heat the material above the melting point – which is likely to be correct for longer pulses – exposure to shorter pulses is different. The photo-induced amorphization of $Ge_2Sb_2Te_5$ upon exposure to 600 ps pulses was first studied using in-situ x-ray absorption spectroscopy [46.62].

It was found that following exposure to a short laser pulse the white-line intensity (the spectra maximum after the absorption edge) first monotonically decreases and reaches a minimum value in about 1 ns. This fast initial decrease in the white-line intensity is followed by its partial recovery and within ≈ 2 ns a new saturation value is reached. Most interestingly, the minimum value of the white-line intensity during the amorphization

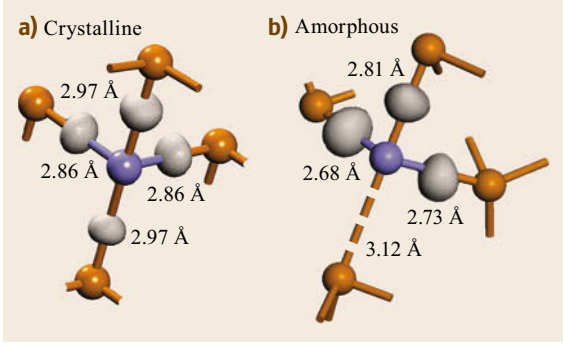

Fig. 46.8a,b Fragments of *defective octahedral Ge sites* in the crystalline **(a)** and amorphous **(b)** phases. Despite very similar *atomic* structures, indicating minute atomic motion, the character of interatomic interaction changes drastically as illustrated by the shown CDD isosurfaces (*gray*) obtained through DFT simulations. While in the crystalline phase the central Ge atom has covalent like interactions with four Te neighbors, in the amorphous phase, it is covalently bonded to only three Te atoms [46.59]. (Copyright 2013 by the American Physical Society. Reprinted with permission)

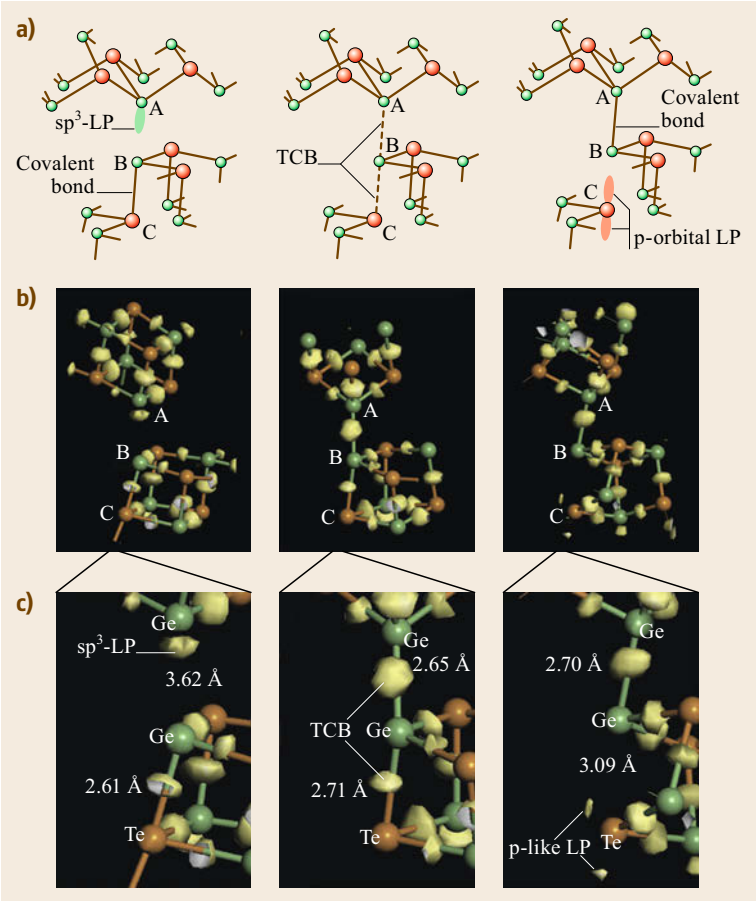

Fig. 46.9 **(a)** Schematic of the formation of a tetrahedral Ge configuration. Ge atoms are shown in *green* and Te atoms are shown in *orange*. When a Ge atom with an LP-orbital (*marked* A) comes close to another Ge atom (B) and is aligned with the neighboring Ge-Te bond (between atoms B–C) (*left panel*), a three-center A–B–C bond is established (*middle*), whose subsequent rupture at the opposite arm results in the formation of a GeTd–GePy configuration (between atoms A–B), leaving behind a twofold coordinated Te atom (C) (*right*). **(b)** Evolution of CDD clouds during the in-silico amorphization process using DFT simulations substantiating the schematic shown in the *upper panel*. CDD clouds corresponding to the LP-electrons of an sp^3 hybridized Ge orbital and a Te lone-pair p-orbital can be seen in the *left* and *right panels*, respectively, in addition to increased CDD midway between Ge and Te atoms that are signatures of covalent bonds. The presence of CDD clouds on both sides of the Ge atom (*marked* B in the figure) in the central panel is evidence of the formation of a transient three-center Ge-Ge-Te bond. **(c)** Zooms into vicinities of the atoms that participate in the formation of three-center bonds. (Reproduced from [46.60])

process is *significantly higher* than that corresponding to the static liquid state [46.63] suggesting that $Ge_2Sb_2Te_5$ does not melt in the conventional sense upon its transformation from the crystalline to the amorphous phase [46.62].

The role of electronic excitation in the phase-change process was also investigated theoretically [46.64]. The electronic excitation was modeled by removing electrons from the high lying valence band states according to the strength of the excitation, where the authors used a jellium background charge to compensate for the loss of charged carriers. From these studies it was concluded that electronic excitation considerably lowers the critical amorphization temperature and reduces the atomic diffusion coefficient with respect to that of the corresponding liquid phase by at least one order of magnitude.

Experimental evidence for the important role of nonthermal processes is gradually growing. Thus, rapid nonthermal control of resonant bonding was demonstrated in [46.65] using a combination of single-shot femtosecond electron diffraction and optical spec-

troscopy. In line with this, in [46.66], ultrafast time-resolved electron diffraction and single-shot optical pump-probe measurements were used to study lattice dynamics in polycrystalline $Ge_2Sb_2Te_5$ initiated by a femtosecond near-ultraviolet pulse and it was concluded that a nonthermal crystal-to-amorphous phase transition was initiated by the displacement of Ge atoms.

46.3 Present Applications and Future Trends

Phase-change memory alloys have been used since the 1990s in rewritable optical disks such as compact disks (CD), and later also in digital versatile disks (DVD) and BluRay disks (BD). The structure of these disks is essentially the same and is shown in Fig. 46.10. What varies is the thickness of individual layers, which is determined by the optics used (the length of the numerical aperture and laser wavelength), and the exact composition of the PCM material. Thus, in DVDs $Ge_2Sb_2Te_5$ is used but in order to optimize the optical contrast at shorter wavelengths $Ge_8Sb_2Te_{11}$ is used in BDs. Figure 46.11 shows the different phase change alloys used for rewritable optical disks on a Ge-Sb-Te ternary phase diagram.

Electrical cell designs for the large-scale integration of phase-change devices have reached commercial development. While lateral device designs such as that proposed by NXP Semiconductors (Fig. 46.12) showed early initial promise [46.68], industry has focused on variations of the mushroom cell design (Fig. 46.13) with a layer of phase-change material (typically GST) sandwiched between two conducting electrodes due to the greater areal density achievable as well as the possibility for three-dimensional stacking of cells. Energy requirements for mushroom like cells have been found to scale roughly linearly with contact area down to effective contact diameters of 3 nm [46.69, 70]. In 2010, Samsung reported on the commercial production of 512 Mbit PRAM chips for use its cellular phones. In 2012, a 20 nm sized mushroom-type device was also announced in a 8 Gb chip by Samsung [46.71]. In 2012, Micron also reported full-scale commercial production of 45 nm node, 1 Gbit PRAM cells. Micron and Intel in July 2015 jointly announced a new generation of what is believed to be a new stackable form of PRAM called *3-D cross-point memory* with the initial chips produced reportedly having a capacity of 128 Gbit. These chips were slated to reach the market in 2017. Considering the widespread use of memory devices, for example, in computers or mobile phones, it may be fair to say that most households in the world have phase-change memory devices. Few other electronic materials can compete with this.

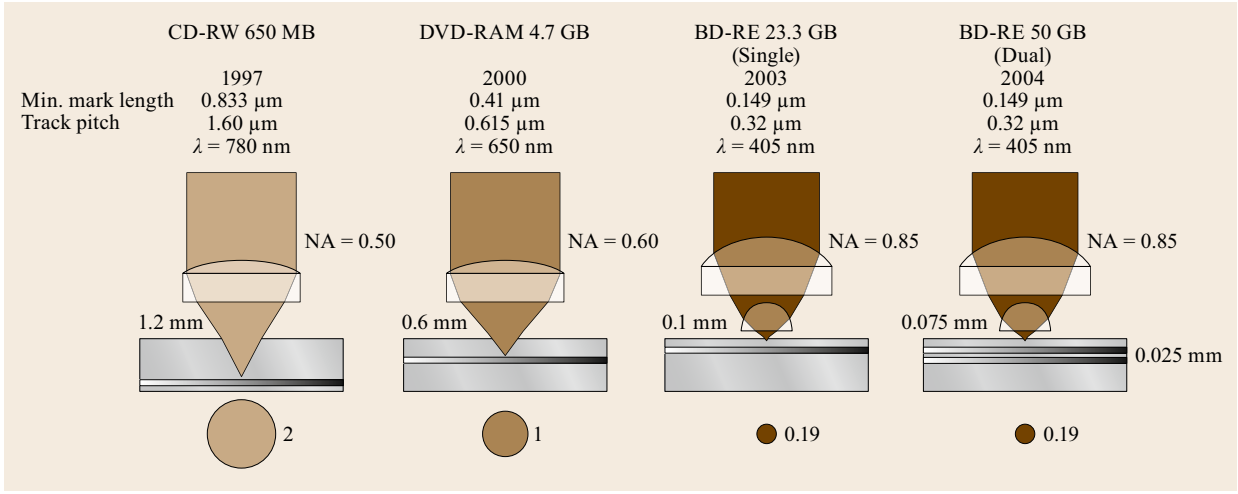

Fig. 46.10 Comparison of optics, recording densities, recording capacities and disk structures used for CD, DVD, and BD. Changes in the lens system are shown in the upper portion; the disk structure is depicted beneath. The change in beam cross-section is displayed at the bottom. From CD to DVD and DVD to BD, the effective laser beam cross section has been reduced by a factor of 2 and 5, respectively. The recording density increased by a factor of 7 going from CD to DVD. Going from DVD to the dual-layer BD another increase by a factor of 11 has been accomplished. (Reprinted from [46.67] by permission from Macmillan Publishers Ltd., copyright (2007))

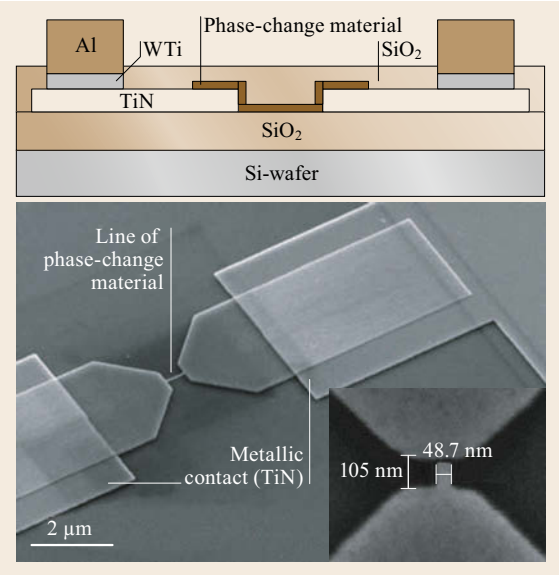

Fig. 46.12 A schematic of a lateral type line cell along with a SEM image of an actual cell. (Reprinted from [46.68] by permission from Macmillan Publishers Ltd., copyright (2005))

A major development in energy efficiency was realized by the spatial separation of GeTe and Sb_2Te_3 into atomically thin layers. Devices based upon this structure were recently shown to result in a significant reduction (by 90%) in energy consumption, which was interpreted as being due to significantly decreased entropic losses [46.72] arising from the one-dimensional motion of Ge atoms at interfaces [46.72, 73]. As a consequence, this kind of memory materials was named interfacial phase-change memory (iPCM).

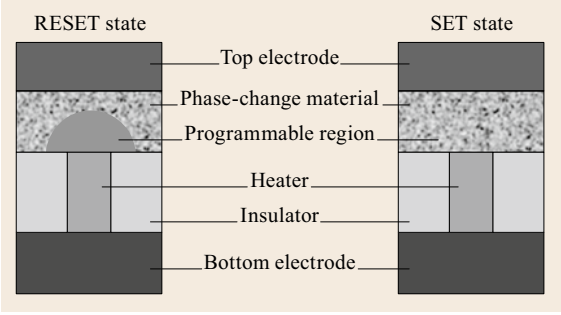

Fig. 46.13 A schematic of a mushroom-type cell in both RESET and SET states

Subsequent studies demonstrated that iPCM, as well as hexagonal $Ge_2Sb_2Te_5$ with certain stacking order, can be a topological insulator or a Dirac semimetal [46.74, 75]. In addition, interesting magnetic responses from iPCM were observed [46.76, 77] that were not present in composite material of the same average composition, making iPCM-based structures promising for spintronic and topotronic applications.

In another development, researchers have grown PRAM on flexible (Kapton) substrates with bottom electrode dimensions of 150 nm. Problems with conventional submicron lithography and flexible substrates were avoided by using a Si-based block co-polymer for patterning in lieu of conventional optical lithography [46.78]. Repeated cycling even after flexing of the substrate demonstrated the potential application of such cell designs to future wearable electronics.

Although the ideas behind neuron-based computing date back to the 1940s with the advent the theory of threshold computing [46.79], the development of electrical devices capable of carrying out such operations in a physical system came much later. In the 1980s

with the pioneering work of *Hopfield* et al. [46.80], the concept of neural networks came into vogue. *Ovshinksky* was the first person to discuss the cognitive computing and neural networks in the context of phase change materials [46.81]. An example of $Ge_2Sb_2Te_5$ based synapses exhibiting the spike-timing-dependent plasticity required for neuromorphic computing was reported in 2012 [46.82]. More recently, a large-scale 165 000 synapse neural network based upon phase-change materials was fabricated and in a prototypical use applied to the recognition of handwriting [46.83].

With the commercial realization of phase-change memory, the field of phase-change materials is primed for further progress. With parallel developments occurring in diverse areas such as neuromorphic computing, iPCM structures, as well as manipulation of the topological properties of chalcogenide-based superlattices, the next 10 year of research will bring a rich array of different devices to the forefront of technology.

47. Carbon Nanotubes and Bucky Materials

Mark Baxendale

The chapter details the underlying phenomena that underpin electronic applications that have followed from the discoveries of C_{60} and carbon nanotubes. The reduced dimensionality of these self-organised structures, high electron mobility, weak electromigration, and the plethora of quantum electronic effects exhibited by these structures suggest they are serious candidates for molecular electronics. The detail of the surface chemistry and conditions of synthesis assume greater importance than for conventional electronic materials since all atoms are on the exterior of these structures, as is outlined with references to the wider literature. Essential electronic structure information is given with reference to the transport measurements that have contributed greatly to the evolution of the field with emphasis on the Coulomb blockade and ballistic transport phenomena. The major electronic applications are then outlined, giving the state-of-the-art figures of merit for performance and comments on prospects for realisation.

The discovery of C_{60} (Fig. 47.1) in 1986, and subsequently higher fullerenes, followed by that of carbon nanotubes in 1991 accelerated the interest in carbon-based molecules and compounds as electronically or optically active materials that had begun in the early 1970s. The award of the 2010 Physics Nobel Prize to Andre Geim and Konstantin Novoselov for the isolation and groundbreaking experiments on graphene emphasized the importance of carbon-based electronic materials. The emergence of the interdisciplinary field of nanotechnology has beneficially attracted attention and methodologies from other fields of science and engineering that have considerably enhanced the physical electronics research effort [47.1, 2].

47.1 Carbon Nanotubes

47.1.1 General

The electronic and structural description of carbon nanotubes and other sp^2-bonded carbon nanostructures with curved surfaces (bucky materials, the term *bucky* is derived from buckminsterfullerene: the name given to C_{60} soon after discovery) will inevitably contain references to that of the familiar two-dimensional (2-D) planar counterpart, graphite. The strength of the in-plane covalent bond of the hexagonal graphitic network produces a short C–C distance of 0.142 nm and high mechanical stiffness.

Carbon nanotube is a generic term that includes both single- and multi-walled structures. Single-wall carbon nanotubes (SWNTs) are seamless cylindrical graphitic macromolecules of nanoscale diameter and micrometer length, capped by hemispherical ends. The closure of the cylinder is a result of pentagonal inclusions in the hexagonal carbon network of the nanotube walls, Fig. 47.2. For SWNTs, every carbon atom is a surface atom. The smallest SWNT diameter reported to date, 4 Å, corresponds to the predicted lower limit for stable SWNT formation from consideration of the stress energy built into the cylindrical structure [47.3]. SWNTs tend to form closely packed bundles, or *ropes*, of several tens of individual single-wall nanotubes.

Multi-wall nanotubes (MWNTs) comprise several to tens of concentric cylinders of these graphitic shells with a layer spacing of 3.4 Å (the inter-planer spacing of graphite). SWNT diameters are typically ≈

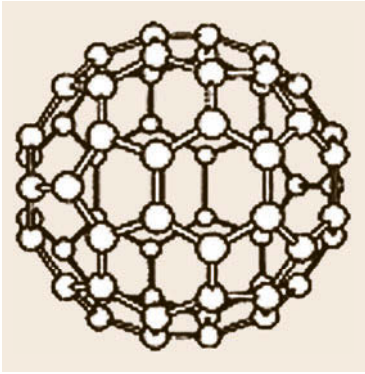

Fig. 47.1 The C_{60} molecule, diameter 0.7 nm

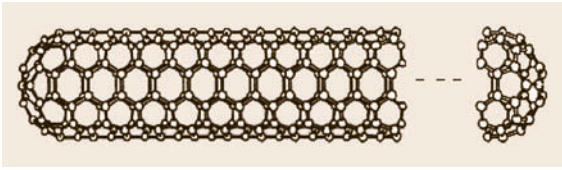

Fig. 47.2 Single-wall carbon nanotube, length 1–10 μm, diameter typically 1.4 to > 10 nm

1 nm and a MWNT diameter can be in the range 2–100 nm with typical values of 10–20 nm. Nanotube lengths are typically 1–10 μm but can be ≈ 1 mm, giving rise to astonishing aspect ratios (length/diameter) of > 1000. MWNTs of similar dimensions can also be formed from a single graphite sheet rolled into a scroll structure [47.4]. Double-wall carbon nanotubes are a recent addition to the set of carbon nanostructures.

A consequence of the high C–C bond strength is that the in-plane Young's modulus of a carbon nanotube is ≅ 1 TPa, making the carbon nanotube one of the stiffest known materials, while the tensile strength is ≅ 150 Gpa (nanotubes have 600 times the strength/weight ratio of steel). Nanotubes deform elastically by buckling, have very low defect density over hundreds to thousands of interatomic spacings, and the strain energy built into the cylindrical structure tends to promote self-repair. The stiff nanotube structure means that the optical-phonon population is minimal even at room temperature; the result can be ballistic electron transport over micrometer length scales (several orders of magnitude greater than that in conventional semiconductor nanostructures).

Another consequence of the short C–C distance is spatially extensive overlapping hybridised atomic orbitals – a π-electron system – with highly mobile delocalised electrons on the interior and exterior of the structure. One carbon atom contributes one unpaired π-electron to the nanotube. The promise of very high carrier mobility in the π-electron system is one motivation for carbon-based electronics; mobilities of circa $10^5\,\mathrm{cm^2V^{-1}s^{-1}}$ have been measured in SWNTs at 50 K and suspended graphene flakes at 240 K [47.5, 6].

Another is the range of electronic attributes that are displayed by the carbon allotropes, e.g., room-temperature resistivity can range from $10^{-8}\,\Omega$m for SWNTs to $> 10^{18}\,\Omega$m for crystalline C_{60}.

The π-electron system and stiff structure produce electrical conductivity, very high current-carrying capacity with weak electromigration. The best figures of merit for nanotube systems that have been measured since discovery are: electrical conductivity, $10^8\,\Omega^{-1}\mathrm{m}^{-1}$ (comparable with that of copper), carrier mobility: $10^4\,\mathrm{cm^2/Vs}$ (comparable with that of high-quality GaAs), thermal conductivity $10^4\,\mathrm{W/mK}$ (comparable with that of diamond), and sustainable current density of $10^{13}\,\mathrm{A/m^2}$ (> 1000 times greater than that of a metal nanowire).

Nanotube circumferential crystal momentum vectors are quantised due to the periodic boundary conditions imposed by the finite nanoscale diameter whereas those directed along the micrometer-scale axis show continuous variation; thus, one-dimensional (1-D) electronic transport is intrinsic for the SWNT. Electronic systems of reduced dimensionality – dots, wires and sheets of charge – created by top-down silicon processing have assumed importance in conventional microelectronics. Carbon nanostructures offer the possibility of self-organised molecular-level low-dimensional electronic systems, e.g.: zero-dimensional (0-D) (C_{60} and short SWNTs), 1-D (SWNTs), 2-D (graphene, large-diameter MWNT outer shell), and three-dimensional (3-D) (coupled-layer MWNTs).

Electronic modification of carbon nanotubes by insertion of C_{60} and other fullerenes into the central capillary to form a mixed-dimensionality hybrid structure called the *peapod* is a science promises a rich future for research and applications [47.7].

Carbon nanotubes are chemically stable in ambient conditions and structurally stable in vacuum for temperatures far greater than 1000 °C. Viewed in total, the above properties potentially make carbon nanotubes excellent electronic materials. These considerations place carbon nanotube electronics among a number of competing technologies poised to complement or replace silicon-based complementary metal–oxide–semiconductor (CMOS) technology in the < 100 nm-feature-size domain. Individual SWNT-based field effect transistors, unipolar and bipolar, show potential for integrated optoelectronic applications. Much recently attention has been given to the production of large-area flexible transparent conducting SWNT networks with indium-doped tin oxide-matching electrical and optical performance [47.8].

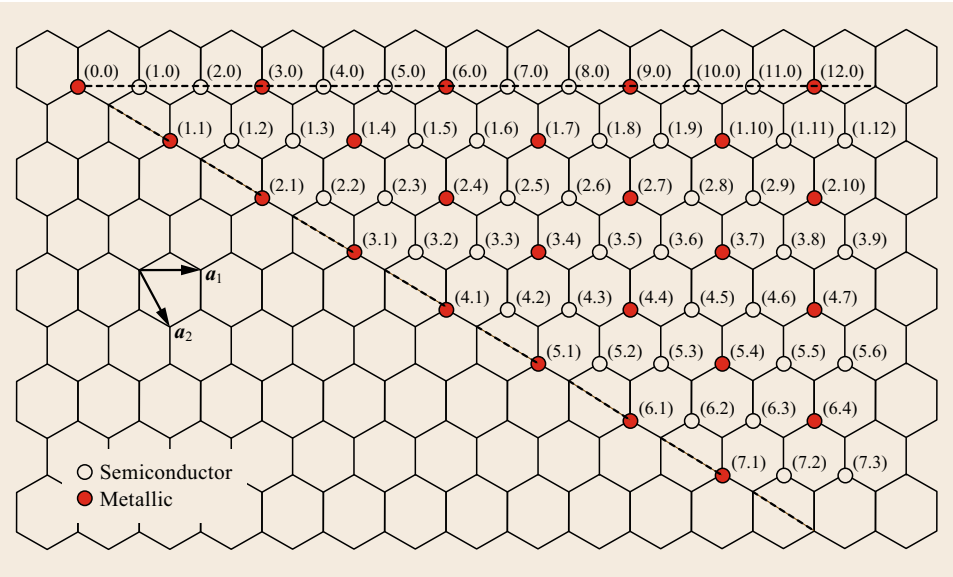

Fig. 47.3 A map of conductivity type for an individual SWNT indicating the n, and m indices of the chiral vector and the unit vectors $\mathbf{a}_1$ and $\mathbf{a}_2$

47.1.2 Geometry

The unique feature of the electronic structure of carbon nanotubes is that it can range from the metallic to the semiconductor depending on the details of the microstructure. Essentially, the way the hexagonal network connects to itself to form a cylinder determines the electronic structure: the chiral vector usually used to describe the wrapping of the network is

$$\boldsymbol{C} = n\boldsymbol{a}_1 + m\boldsymbol{a}_2 \equiv (n, m)\,,$$

where $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ are the unit vectors of the hexagonal network, and n and m are integers. The resulting nanotube can then be described in the form (n, m), Fig. 47.3.

Electronic band-structure calculations show that an (n, m) nanotube is metallic at room temperature if $2n + m$ is a multiple of 3, otherwise it is a semiconductor with a band gap of $E_g = 0.9\,d\,\mathrm{eV}$, where d is the nanotube diameter expressed in nanometers, i. e., typically $E_g \approx 0.5\,\mathrm{eV}$. This remarkable property signals the possibility of band-gap engineering by control of the microstructure. The wrapping angle, or chiral angle, is given by the angle between $\boldsymbol{a}_1$ and $\boldsymbol{C}$. From geometric and symmetry considerations,

$$0 < |m| < n\,, \quad 0° = \theta = 30°\,,$$
$$\cos(\theta) = 2n + \frac{m}{2\sqrt{(n^2 + m^2 + nm)}}\,,$$

and nanotube diameter $d = 0.078\sqrt{(n^2 + m^2 + nm)}$ nanometers. The general case (n, m) is referred to as the chiral nanotube; there are two special cases: (a) the zigzag nanotube ($m = 0$, $\theta = 0°$), and (b) the armchair nanotube ($n = m$, $\theta = 30°$, all metallic) [47.2]. Assuming a random distribution of nanotube diameters in the reaction products, the relative populations of metallic to semiconducting electronic structure is 1 : 3. Single-symmetry (n, m) synthesis or post-synthesis sorting according to electronic structure are key fields for research effort. The task is proving rather difficult but there appear to be no fundamental barriers to progress.

A stable defect in the hexagonal network is the pentagon–heptagon pair (Stone–Wales or 5–7 defect). This defect will cause a sharp bend in an otherwise well-graphitised SWNT. Controlled introduction of defects allows the possibility of constructing Y- and T-junctions and other complex geometries from nanotubes, including rings and coils. Moreover, a 5–7 defect can connect a metallic to a semiconductor nanotube giving an Angstrom-scale heterojunction and hence a device density 10^4 times greater than present-day microelectronics [47.9].

47.1.3 Synthesis and Chemistry

The quality of carbon nanotubes in terms of crystallinity and impurity content depends on the conditions of synthesis by arc discharge using graphitic electrodes, laser vaporisation of graphite, or chemical vapour deposition (CVD) using hydrocarbon gas and metal nanoparticle catalysts. Each method produces different nanotube samples and sample-to-sample variation from the same source. An extensive review of synthesis methods was published by *Rakov* [47.10]. The key factor for crystallinity, and therefore electronic quality, is the forma-

tion temperature: > 2000 °C is required for complete graphitisation. Little is know about the preferences the various growth processes have for certain nanotube symmetries over others.

Reaction products can contain significant quantities of residual metal catalyst particles and non-tubular forms of carbon (typically 30 wt% of the raw material). Purification processes ranging from the simple to complex are commonly used: oxidation and acid washing [47.10], solvent treatment followed by ultrafiltration [47.11], or flocculation using aqueous surfactants [47.12]. Controlled growth of MWNTs perpendicular to a substrate has been widely explored due to its technological importance [47.13]

Surface functionalisation of SWNTs is required for several applications as a means of modifying charge exchange with the ambient. Oxidation of nanotubes with the acid mixture H_2SO_4–HNO_3 leads to high concentrations of carboxylic, carbonyl, and hydroxyl groups on the surface and removal of the tips to expose the interior surface. Carboxyl (−COOH) groups are then readily derivatised by a variety of reactions. Covalent functionalisation, however, necessarily disrupts the rigid structure and π-electron system with consequent degradation of mechanical and electrical properties but provides the best stability and accessibility [47.14]. Non-covalent routes to nanotube functionalisation offer ease of synthesis and minimum disruption of the tubular structure [47.15].

Exposure to ambient humidity, oxygen and other gases profoundly affects the measured electronic properties of nanotubes through charge exchange and the quality of metallic electrical contacts made to nanotubes. The electronic properties of carbon nanotube systems are extremely sensitive to the presence of molecular oxygen due to the formation of the charge-transfer complex $C_p^{+\delta}$–$O_2^{-\delta}$, i. e., oxygen-exposed nanotubes are p-type [47.16]. Nanotubes exhibit ultrahigh sensitivity at room temperature to O_2, N_2O, NH_3 but not H_2 [47.17]. Nanotubes must be elevated to temperatures > 700 °C in ultrahigh vacuum to completely remove absorbents.

47.1.4 Electronic Structure and Transport

The electronic structure of SWNTs is predicted by tight-binding calculations extended from the 2-D approach for graphite to the cylindrical 1-D nanotube system [47.2], Fig. 47.4. The tight-binding modelling follows from the original band structure calculations of graphite by *Wallace* in 1947 [47.18].

In the case of nanotubes circumferential crystal momentum vectors are quantised due to the periodic boundary conditions imposed by a finite nanoscale diameter. This simple approach has been proven, mainly by low-temperature scanning tunnelling spectroscopy, to be a good description of the electronic structure of carbon nanotubes [47.19]. The curvature of the nanotubes is ignored in this model but can introduce some important modifications [47.20]. However, the original model is, nevertheless, adequate for the classification of nanotubes into metallic and semiconducting types according the simple rule outlined in Sect. 47.1.1. In common with other 1-D conductors with half-filled bands the expectation was that carbon nanotubes will undergo a Peierls distortion, i. e., and a gap will open in the band structure at the Fermi energy due to atomic displacement modifying the unit cell. However, it has been shown theoretically that the effect very quickly diminishes as a function of nanotube radius [47.2].

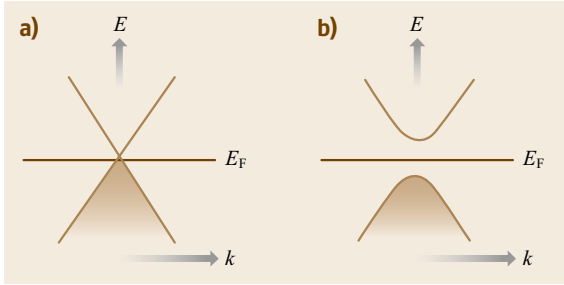

Fig. 47.4 **(a)** Electron energy E versus wavevector k showing the intersection of the dispersion relations of two bands at the Fermi energy E_F; electron occupancy is indicated by shading. The essentially zero-gap semiconductor structure is common to those sp^2-bonded carbon allotropes for which k can vary in two dimensions resulting in a conical shape of the E-k plots (graphene, carbon nanotubes). **(b)** The case of semiconducting SWNT; a band-gap appears owing to the combination of the conical E-k shape and quantisation of the circumferential crystal momentum vector

Electrical transport measurements on individual SWNTs, SWNT ropes, and MWNTs have produced diverse results in the decade since discovery and are still the focus of intense research effort. The picture is complicated by several factors:

1. The current pathway through MWNTs is greatly complicated by interlayer coupling.
2. Two-terminal resistances in the range 100 Ω–100 MΩ were first reported [47.21].
3. The processing, contacting, and manipulation methods used undoubtedly introduced non-intrinsic resistances and potential barriers.

Nevertheless, the best transport parameters that have emerged since discovery, quoted in Sect. 47.1, are highly desirable from many device points of view. The

quality of lithographically defined contacts is critical for electrical transport measurements. There are three possible outcomes of the contacting process:

1. The contacts are of good quality; then the total resistance will be the diffusive or quantum resistance for that structure (6.5 kΩ for a ballistic SWNT) [47.22].
2. No contact is made and the nanotube is isolated by tunnel barriers; in this case the nanotube will act as a Coulomb island and blockade phenomena will be observed at low temperature [47.23].
3. The contacts are of an intermediate type that allows the nanotube to act as a cavity and Fabry–Perot interference phenomena are observed [47.24].

The exact physics of contacting to carbon nanotubes is poorly understood; the exact atomic arrangement at the interface is likely to play a role as are the ambient gases.

Successful transport measurements have yielded a plethora of quantum-electronic and low-dimensional transport phenomena. *Tans* et al. [47.23] demonstrated true quantum wire behaviour; the remarkable feature of this work was to identification of an electron phase-coherence length on the micrometer scale at 4 K for nanotubes: several orders of magnitude greater than that in conventional semiconductor nanostructures. With an extraordinarily skilful experiment *Bachtold* et al. [47.25] demonstrated the Aharonov–Bohm effect by circulating circumferential current in a contacted MWNT with the axis parallel to a magnetic field. The periodicity of the magneto-conductance variation with applied field corresponded to an interferometer diameter equal to that of the outer MWNT shell. This finding gave weight to an earlier conclusion from quantum conductance measurements of *Frank* et al. [47.26], namely that current is only carried in the outer shell for MWNTs. This was posed as a general statement but was contradicted by the controlled layer-by-layer conductivity analysis of *Collins* et al. [47.27] in which the current-carrying contribution of each MWNT layer was determined by vaporisation of successive MWNT layers. This work concluded that at least eight layers contribute to the current-carrying capacity of a MWNT.

The landmark paper of *Frank* et al. identified ballistic conductance in MWNT systems at room temperature by controlled lowering of a MWNT bundle into a liquid mercury contact [47.26]. This was a remarkable result since the implication is that the electron mean free path is on the micrometer scale at room temperature. A ballistic conductor has a conductance given by the Landauer formula

$$G = 2\left(\frac{e^2}{h}\right)\sum_{i}^{N} T_i \,,$$

where N is the number of conducting channels, T is the transmission factor (experimental result: $T = 1$ for most nanotube systems), and $G_0 = 2e^2/h$ is the quantum conductance (the factor of 2 is due to spin degeneracy). Frank et al. measured a conductance of $1G_0 >$ per MWNT, implying that current is carried in the outer shell only and there is a *missing* $1G_0$ since a metallic carbon nanotube has two crossing 1-D energy bands at the Fermi level, which yields a conductance of $2G_0$ for a single nanotube shell. However, subsequent results have shown the expected $2G_0$ result [47.28]. Therefore, the controversy over the experiment by Frank et al. remains unsolved.

SWNTs were expected to exhibit the predicted electron–electron interaction effects in 1-D systems, the so called Luttinger liquid (LL) state. In a strictly 1-D system the independent electron approximation breaks down and the normal 3-D Fermi gas picture is replaced by the LL. In the LL description electron–electron interactions dominate and the electrons are in a highly correlated state. The LL state requires a high degree of order since disorder destroys the correlated ground state. The main features of the LL are suppression of the density of states at the Fermi energy according to a power law and separation of spin and charge excitations. In transport measurements, the LL state is manifested as a tunnelling conductance from a normal electrode according to $G(T) \approx T^{\alpha}$, for $eV \ll k_{\mathrm{B}}T$, and at large voltages $G(V) = \mathrm{d}I/\mathrm{d}V \approx V^{\alpha}$ for $eV \gg k_{\mathrm{B}}T$, where the parameter α is determined by the strength of the interaction between the electrons. Such power laws have been observed in contacted SWNTs, although stronger evidence, such as a clear demonstration of spin–charge separation, in necessary to identify the LL state unambiguously [47.29].

Coulomb blockade phenomena have been observed in low-temperature transport measurements on carbon nanotube systems often by unintentional incorporation of tunnel junctions between the metal electrode and the nanotube. The effect occurs when a mesoscopic *island* with capacitance C (self-capacitance of the nanotube plus the barrier capacitance at the nanotube–electrode junction) is isolated by tunnel barriers from two electrodes. If the charging energy for a single electron on the island, e^2/C, is larger than the thermal energy $k_{\mathrm{B}}T$, then the system will not conduct due to electron–electron repulsion. Coulomb blockade can be modulated by a gate electrode from full blocking to a conducting state limited only by the tunnel barriers. Such a system forms a single-electron transistor (SET). The capacitance of a nanotube is $\approx 10^{-17}F$, thus SET operation conditions are fulfilled at temperatures below 10 K when the entire nanotube defines the Coulomb island. To minimise the capacitance and therefore el-

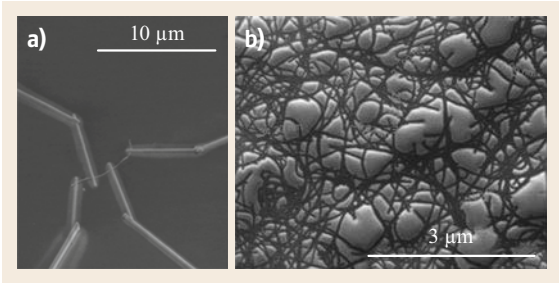

Fig. 47.5 **(a)** Example of a contacted individual MWNT on the insulating SiO_2 layer of a conducting silicon substrate. **(b)** Example of a network comprising SWNT ropes depostied on a quartz substrate

evate the operating temperature inter-tube islands can be defined by crossing nanotubes or intra-tube islands bending with a scanning probe microscope (kinks and bends in SWNTs can create tunnel barriers). The latter approach has been used to create a SET that operates close to room temperature [47.30]. Graphene is likely to be the carbon allotrope to produce usable SET devices owing to the ease with which flakes can be lithographically processed [47.31].

Superconductivity in nanotube systems was first observed as the proximity effect with SWNTs or SWNT ropes connecting two superconducting electrodes [47.32]. The first report signalling intrinsic superconductivity in SWNT ropes was by *Kociak* et al. in 2001 [47.33]. Subsequently, 1-D superconductivity has been observed in arrays of small-diameter SWNTs at 15 K and in indvidual MWNTs up to 12 K [47.34, 35].

Two broad categories of exploitation of the above electronic attributes have arisen; nanoelectronic devices, with an individual SWNT or MWNT as the acive channel in a source-drain configuration deposited on the top SiO_2 layer of a heavily doped silicon substrate (which serves as a backgate), and applications which exploit networks of *ropes* or bundled SWNTs, Fig. 47.5. Although, the intermediate approach of using highly aligned SWNT arrays as the active channel has had some success [47.36].

47.1.5 Nanoelectronic Devices

Semiconducting nanotubes are especially important for nanoelectronic device applications. Semiconducting behaviour has been observed in individual SWNTs; in SWNT ropes and MWNTs mixed metallic and semiconducting current pathways greatly complicate the I–V characteristic. Field-effect transistors (FETs) with individual SWNT channels have been demonstrated and found to have higher transconductance than can be achieved with state-of-the-art metal–oxide–semiconductor field-effect transistors (MOSFETs) [47.37]. The conducting state is attained with negative gate voltages, implying that the carbon nanotube forms a normally off p-type conduction channel (probably due to unintentional doping by exposure to oxygen). Logic gates made from nanotube FETs have been demonstrated [47.38]. The nature of the metal electrode–SWNT Schottky barrier is still not fully understood.

The prospects for highly integrated circuits consisting of nanotube elements must be considered remote at this time for several reasons (some previously mentioned):

1. Current synthesis techniques produce mixtures of metallic or semiconductor nanotubes and these tend to form ropes or bundles.
2. The precise nature of the metal electrode–nanotube contact is poorly understood.
3. Scanning probe manipulation techniques used to fabricate prototype individual devices are not scalable.

Nevertheless, carbon nanotube-based FETs, both unipolar and bipolar, show some promise for intergrated optoelectronic applications [47.39].

47.1.6 Networks

This work is largely driven by the necessity to find an alternative to the conventional transparent conducting electrode material, indium-doped tin oxide (ITO), owing to the terrestrial rarity of indium and the desirability of flexibility for some emerging technologies. Individual SWNTs constitute ideal elements for flexible transparent conducting networks with ITO-matching electrical and optical performance, namely, that is, sheet resistance much less than $< 100\,\Omega/\mathrm{sq}$ optical transmission of 90% at 550 nm wavelength. The basic network element is unavoidably a bundle rather than an individual SWNT. Electrical transport within the bundle and the inter-bundle contact resistance has greatest influence on the electrical transport within the network; contact resistances can be minimised by careful removal of residual surfactant introduced by solution processing [47.5, 6, 11]. SWNT networks have been modelled as metallic filamentary pathways interrupted by thin tunnel barriers, backscattering by zone-boundary phonons, fluctuation-assisted tunnelling, and variable-range hopping (VRH). The contribution of each component is a function of network thickness; VRH dominates in the thinnest networks and metallic conduc-

tivity increases with thickness [47.16, 17]. Approaches to transparent conducting electrode production include chemical doping and electrical modification by various methods, including acid treatment [47.11, 12], decoration by metal nanoparticles [47.3, 13, 40], conducting polymer composites, graphene-SWNT hybrids [47.14, 15], metallic enrichment, and purification through ultracentrifugation [47.7].

Many approaches for the production of such hybrid networks have been reported, including, physical evaporation of metal nanoparticles onto the SWNT network, nanoparticle attachment by chemical reaction with functionalised SWNTs, and electroless nanoparticle deposition methods [47.24, 29–33].

The room temperature sheet resistance of the resultant hybrid networks has been reported to be both increased and decreased relative to the un-decorated SWNT network [47.29, 34, 35]. A 1/1500 reduction of room temperature sheet resistance of SWNT network by Au-nanoparticle decoration with an optical transmittance of 90% at 550 nm wavelength has been reported [47.40].

Metal nanoparticle-decorated SWNT networks show promise for selective gas sensing based on differential analyte-nanoparticle reactivity and charge exchanges with the network. There are also useful plasmonic and thermoelectric benefits from such hybrid systems [47.20–22]. The metal nanoparticle-network interaction is not well understood. Decoration of individual SWNTs with gold nanoparticles results in electron transfer from the nanotube to the nanoparticle and the formation of a potential barrier at the SWNT-metal interface; the barrier characteristics depend on the work function of the metal [47.13, 23, 24, 26–28, 36].

47.1.7 Other Electronic Applications

Although nanoelectronics has been the driving force for carbon nanotube research, many other electronic applications are being explored; this section outlines some of them.

Interconnects

Ballistic transport on the micrometer scale at room temperature and high current-carrying capacity suggests carbon nanotubes are good candidates for high-bandwidth dissipation-less interconnect for nanoscale circuit elements. Since chemical processing tends to degrade nanotube electrical properties, methods of directed growth are being explored as a means of *wiring* integrated circuits, e.g., guiding through via holes [47.41], by electric field [47.42], or surface modification [47.43].

Field-Emission Displays

The nanoscale diameter, aspect ratio of ≈ 1000, and high conductivity make carbon nanotubes ideal candidates for field emitters [47.44]. Field-emission currents from single nanotubes and aligned or randomly oriented nanotube thin films have been extensively studied. The promise is of low-threshold-field electron emission with a current density sufficient to drive a phosphor screen for display purposes. SWNTs and MWNTs have proved to be remarkably good field emitters with threshold emission fields in the range $1-10\,\mathrm{V}/\mu\mathrm{m}$ and capable of carrying very high current density. The exact emission mechanism, the role played by surface absorbents, and the cause of emission current saturation are under debate. Nevertheless, major manufacturers have recently produced prototype field-emission displays with carbon nanotube sources; with further development, this is likely to be the first major application of carbon nanotubes to reach the marketplace [47.45].

Electron-Beam Lithography

The present minimum feature size for silicon microelectronics is 130 nm, which is achieved using extreme-UV optical lithography. Alternative technologies are being explored for the future production of < 100 nm devices. Conventional electron-beam lithography can achieve a 5-nm line width but is limited by writing time because a single beam is used to write the entire pattern. Thus arrays of electron guns operating in parallel are being considered as a route to reduction of the writing time while maintaining the high resolution of electron-beam lithography. Carbon nanotubes are currently the most promising candidates for use as the emission source [47.46].

Electro-Optic Materials

Polymer–nanotube composite materials have been studied from the point of view of applications in electro-optics. Loading the layers of organic light-emitting diodes (LEDs) with low concentrations of nanotubes effectively increased the lifetime of the devices by preventing the build up of local hot spots thorough the high thermal conductivity that can be achieved in a nanotube percolation network [47.47]. Nanotube-induced local ordering of the matrix polymer suggests efficiency improvements may also be possible [47.48]. Using nanotube mats as an electrode in solar-cell applications apparently gave no improvement in device performance; however, these early measurement were performed with defective MWNTs so there may be a case for further investigation using the high-quality SWNTs available today.

Nanofabricators

Carbon-nanotube atomic force microscopy tips for fabricating oxide nanostructures in Si and Ti by anodisation is a rapidly expanding field aimed at Tbit/cm^2 data storage [47.49]. The technique utilises ambient moisture in the oxidation process with the tip biased negative relative to the surface. Line widths of 5–10 nm suitable for antidotes and tunnel junctions can be achieved.

Actuators

Electromechanical actuators based on SWNT sheets have been shown to generate higher stresses than natural muscle when operating in physiological conditions and higher strains than high-modulus ferroelectrics [47.50]. The actuation mechanism is a geometrical expansion of the carbon–carbon covalent bond caused by electrochemical double-layer charging. Work densities per cycle substantially higher than any previously known technology are predicted for SWNT sheets with mechanical properties close to those of individual SWNTs. This can be achieved by inter-tube binding and alignment optimisation.

Sensors

The conductivity of nanotube systems is highly sensitive to gaseous ambients, which affect the sign and amount of injected charge. The dimensions of a nanotube sensing element is such that very low quantities of analyte species will produce a measurable response. Nanotube gas sensors certainly have prospects to challenge conventional gas sensors for certain uses [47.19]. In addition to transduction, bio-sensors require a bioreceptor (e.g., enzyme or cell) immobilisation matrix. Carbon-nanotube-based bio-sensors meet both requirements and have been found to promote homogeneous electron-transfer reactions.

47.2 Bucky Materials

Over the last decade the field of bucky materials has been dominated by carbon nanotubes, as the number of publications and patent submissions testify. After intense research activity since their discovery, the most noteworthy of C_{60}-based electronic materials are superconducting heterofullerides of composition K_2MC_{60}, where M = Fe, Ni, Cu, Ag, Co ..., with $T_c \approx 15$ K. However the future for encapsulation of species in the C_{60}, and higher fullerene, cage appears promising, in particular as the basis of devices for quantum information processing. Other non-carbon-nanotube structures are now under intense investigation; these include BN, W, MoS_2, heterogeneous nanotubes and the ternary compound $Mo_6C_{9-x}H_x$ (C = chalcogen, H = halogen, $3 < x < 6$). The science of these structures is still in its infancy but, given the rich experience of over a decade of carbon nanotube research, there is reason to be optimistic of exciting new science and technology.

48. Graphene

Henry H. Radamson

More than a decade has passed since the graphene was synthesized for the first time but still there are many applications that have not been explored. The first intended application for graphene was its high mobility property for high-speed electronics. This task became more difficult when the problem with zero bandgap of graphene made an obstacle to close the current flow of transistor. Different remedies, for example, downscaling the dimensions to nano-ribbons and bilayer structures were proposed to create a reasonable bandgap in graphene for electronic applications. The main idea was to improve the figure of merit I_{on}/I_{off} for RF devices. Although many important achievements were made, but later graphene was considered as a better choice for photonic applications. For example, graphene was used as light absorber in the lateral direction for modulators, or sensitive to light in photodetectors when it is vertically illuminated. Nowadays the graphene has inaugurated a new platform in flexible and transparent electronics. As example, electronics giant producers have already integrated graphene for flexible screens.

During recent years, many research efforts have been spent on other two-dimensional (2-D) crystals (transition metal dichalcogenides, silicene, and germanene) as competitors to graphene but it is still a long way to integrate such materials for industrial applications.

Carbon is the most fascinating material in the universe which may be constructed into different forms and shapes. The electrical, optical, and mechanical properties of carbon depend on how the atoms are packed in relation to their adjacent atoms. As an example, diamond is a single crystalline form of carbon atoms with sp^3 hybridzation while graphene is a single-sheet arrangement of carbon atoms in a honeycomb shape with sp^2 hybridzation (Fig. 48.1a). These configurations place diamond in the group of wide bandgap materials while graphene is almost a zero bandgap material.

In nature, stacks of graphene planes can be found in graphite material and they can be ordered in the hexagonal or rhombohedral sequence. Graphene as a two-dimensional crystal material was experimentally detached from graphite by Geim and Novoselov in 2004. The discovery led to Nobel prize in 2010 with motivation of the synthesis of a 2-D carbon sheet with sp^2 bonds in comparison with sp^3, which is the most common form and is quantum mechanically favorable for bonding of carbon atoms [48.1].

In graphene, sp^2 hybrids establish σ bonds with the neighboring atoms (Fig. 48.1b). These bonds have a length of 0.142 nm and are the main reason behind the tremendous Young's modulus close to 1 TPa, which makes the strong mechanical property of graphene. This amazing Young modulus value is roughly 100 times larger than for steel with similar film thickness [48.1]. The remaining 2p orbital is half filled and it creates an extended π-bond where the electrons play the main role in electrical conduction and determine the photonic and electrical characteristics of graphene [48.2].

Graphene is mostly known for its high electron mobility, which is $2.5\times10^5\,\mathrm{cm^{-2}V^{-1}s^{-1}}$ at room temperature. This high mobility value is a result of decreased electron–phonon interaction resulting in significantly lower carrier scattering. The electron mobility in graphene is almost 200 times higher than Si [48.4] and 4 times larger than III–V semiconductors [48.5]. This would make graphene a very attractive material for high-speed transistors.

Graphene has demonstrated excellent electron and thermal conduction. The electron saturation velocities up to $7\times10^7\,\mathrm{cm\,s^{-1}}$ have been observed, which is remarkably higher than high field saturation velocities for III–V and Si materials [48.6]. Similarly, current density close to $108\,\mathrm{A/cm^2}$ have been measured, which is almost five orders of magnitude larger than copper. The optical properties of graphene have also been widely studied. Graphene has optical opacity of 2.3% within a broad spectrum, which is wavelength independent in the interval of far-infrared and blue light [48.7].

Graphene absorbs more photons per unit thickness and surface. This means that graphene has larger efficiency per volume and bigger chances to saturate with high-intensity light pulses. Finally, graphene is a material with many outstanding properties, which is not seen altogether in one material alone. However, due to some undesired properties, there are still obstacles for graphene to replace materials for electronic technology in the present time. For example, graphene will not probably replace Si or III–V materials in high-frequency electronics in very near future. Meanwhile, graphene could be integrated in transparent electronics instead of today's most used material, indium-tin oxide (ITO) which is expensive and difficult to synthesize for mass production. Graphene has attracted attention for this purpose for electronics giant manufacturers such as Samsung and Sony [48.8].

More work is also required to decrease the graphene's parasitic contact in order to integrate for high frequency and flexible electronic applications. Recently, graphene has inaugurated totally a new domain within THz electronics, millimeter waves, and room-temperature ballistic electronics [48.9].

48.1 Graphene Synthesis

There are many ways to synthesize graphene (Fig. 48.2). The first article about isolating graphene sheet from graphite was published in 2004 by *Novoselov* and *Geim* [48.1]. Their method is the so-called exfoliation and uses a scotch-tape to attach flakes of graphene monolayers. The detached graphene can be transferred directly on Si (or BN) wafers or dissolved in acetone. The size of flakes is usually some micrometers and in the best case a few millimeters.

This method is simple, easy accessible, and flakes have relative low defect density. The high-quality graphene is the key for the high electron mobility and exfoliated graphene layers have demonstrated typical values of 2×10^4 and $2.5\times10^5\,\mathrm{cm^2\,V^{-1}s^{-1}}$ on SiO_2 and hexagonal-BN (h-BN) substrates at room temperature, respectively [48.10]. Similar mobility values have been demonstrated for suspended graphene [48.11] when the substrate interaction in this case is eliminated.

In many cases, the exfoliated graphene can be suspended in nonaqueous solvents or water-based surfactants [48.12]. The benefit of this method is using the surface tension of these solvents to make graphite to split in thinner platelets. Another approach is to oxidize graphite to form graphene oxide, which is easily soluble in water. Using ultrasound sonication may cause thining of the graphene stack to a monolayer. However, a total removal of all oxide is hard to achieve [48.13]. There are many reports about patterning reduced graphene oxide (RGO) and using laser scribing [48.14]. These materials can be used for supercapacitors, printed, and flexible electronics. However the complexity of such manufacturing techniques makes them limited to lab research and not suitable for any industrial application.

Another method to synthesize graphene is thermal decomposition of SiC. This method was demonstrated for the first time by *Berger* et al. [48.15] and it is based on the thermal annealing of SiC where sublimation of

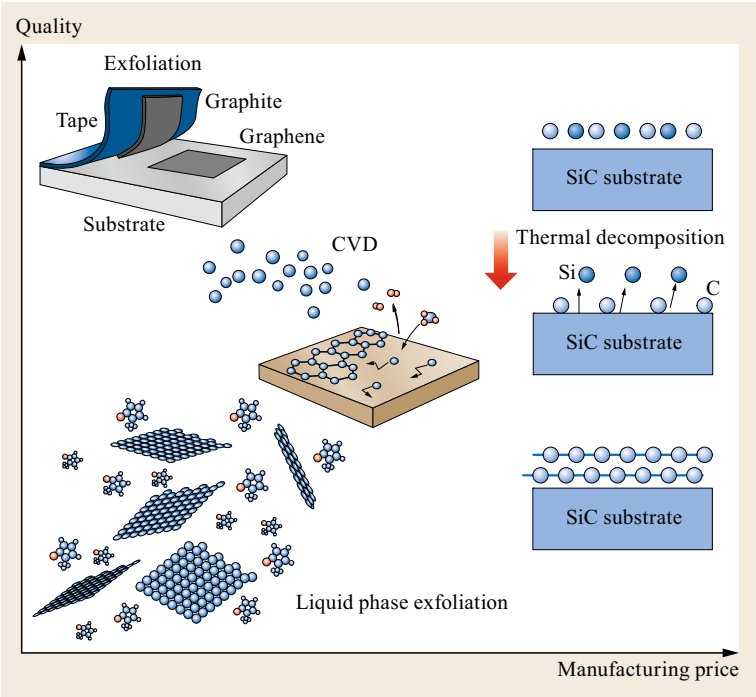

Fig. 48.2 A drawing of graphene quality versus manufacturing cost for different synthesis methods

Si occurs and the C atoms are segregated on Si- and the C-face of the wafer and form graphene layers. The process temperatures are around 1600 °C in 100 mbar for Si-face and 1450 °C and 0.1 μbar for C-face in Ar atmosphere [48.16]. As a result of Si desorption, the surface of SiC holds narrow terraces of graphene and they are connected by steps.

This method has demonstrated electron mobility values of around $3.0 \times 10^4\,\mathrm{cm^2V^{-1}s^{-1}}$ [48.17] depending on the alignment of SiC substrate terraces with the direction of carrier transport through graphene stack.

This method provides high quality graphene layers but has the drawbacks of the high cost of SiC substrates wafers and formation of small-sized graphene of a few micrometers which is too small for industrial applications to process a complete transistor.

The formed graphene stack on SiC demonstrates a bandgap of ≈ 260 meV. This value may vary depending on the stack thickness and it reaches almost zero for 4 graphene monolayers [48.18] due to substrate interaction or induced strain by SiC [48.19].

During recent years, chemical vapor deposition (CVD) of graphene has become very popular method to synthesize graphene. The method is based on the decomposition of a carbon precursor, for example, methane (CH_4) or ethanol (C_2H_6O) around 1000 °C on a foil of a transition metal, for example, Cu, Ni, Fe as catalyst material [48.20]. Later the formed graphene is separated or peeled off from surface of catalyst metal by using a transfer polymer (typically polymethylmethacrylate (PMMA) or polydimethylsiloxane (PDMS)) where the catalyst is etched away [48.21]. However, there is a high risk to damage the graphene sheet by the mechanical stress during the removal action and the quality of the graphene also depends on the surface roughness of catalyst metal. Different electronic component producers have stepped in using CVD method [48.22]. Nowadays very large area graphene is produced and developed for transparent electronics for displayer application. Using this method, carrier mobility of $0.5\,\mathrm{cm^2V^{-1}s^{-1}}$ has been demonstrated on SiO_2 surface.

48.2 Band Structure and Electronic Applications

Six carbon atoms are bonded in graphene honeycomb configuration with hexagonal lattice. Therefore, graphene can be considered as a triangular lattice consisting of a basis of two atoms per unit cell present at the two equivalent lattice sites A and B. A simple calculation gives the 2 lattice vectors, where $a = 0.142\,\text{nm}$ is the nearest-neighbor C-C spacing (Fig. 48.3a).

In principle, a honeycomb configuration has six points at the corners of the first Brillouin zone (FBZ) where they are distinguished in two groups of three equivalent points. These points are denoted by K and K′ (Fig. 48.3b). These corners are called Dirac points and the electrons and holes in the vicinity of those points are massless and follow linear relations (not the quadratic form) of energy momentum dispersion.

Graphene acts as a massless Dirac fermion and its electronic properties are described by the Dirac equation instead of the Schrodinger equation [48.23].

The graphene band structure has two notable properties: at first, at the Dirac point positions the valence and conduction band edges are very close (or intersecting), resulting in almost no energy gap (Fig. 48.3c). This places graphene in the category of zero bandgap semiconductors or as a semimetal. Secondly, as mentioned above the energy momentum dispersion has linear behavior and this leads to a constant carrier group velocity over energy (where is the Fermi velocity and estimated to $8\times10^5\,\text{ms}^{-1}$). As a result, the carriers have effective masses, which are directly related to momentum and have zero value at zero energy. This is an exceptional characteristic of graphene which is distinguished from common semiconductors, where the dispersion curves have parabolic shape and carrier velocity is dependent on the second derivative of the dispersion curves (Fig. 48.4).

Graphene has a linear density of states (DOS) as well. Each point q appears with twofold spin degenerate ($g_s = 2$) and since there are two Dirac points K and K′ hence another twofold valley degenerate ($g_v = 2$). Therefore DOS is written as [48.25]

$$\rho(E) = \frac{g_s g_v}{2\pi(\hbar v_F)^2}|E|\,, \tag{48.1}$$

where E stands for energy and v_F for Fermi velocity. This makes the DOS distribution of graphene very different from metals and semiconductors (Fig. 48.5). The integral of DOS equation times the Fermi–Dirac distribution at a given temperature results in a noticeable electron-sheet density for graphene. Furthermore, graphene sheet is not perfectly planar and has some ripples and this makes charge inhomogeneities in graphene.

Graphene possesses an ambipolar characteristic against an applied electric field. It means in contrary to metals, in the semimetal graphene, electrons may convert to holes in response to an applied electric field [48.26]. This means that n-type or p-type graphene is not predefined.

Graphene has extremely high carrier mobility. There are three macroscopic forces, which can affect the carrier mobility in graphene. These forces are diffusion, drift, and drag force. Diffusion force is an outcome of carriers' random motion, drift force is generated by electrostatic field and drag is the force due to the carrier scattering within the lattice [48.22]. In graphene, four scattering mechanisms have influence on the mobility. These mechanisms are addressed to the charged impurities, acoustic or optical phonons, and surface roughness. Experimentally, it has been demonstrated that the charged impurities in graphene have the crucial

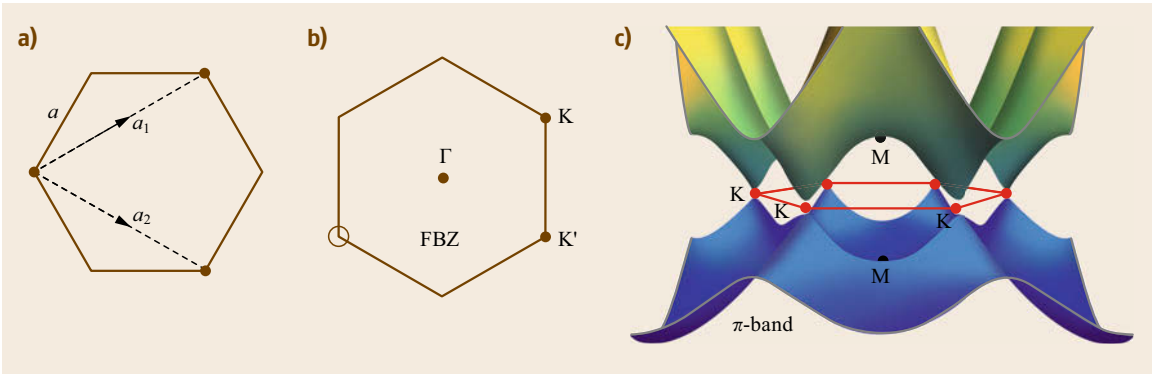

Fig. 48.3a–c A schematic view of graphene (a) honeycomb shape, (b) the first Brillouin zone, and (c) the band structure of graphene. (After [48.24])

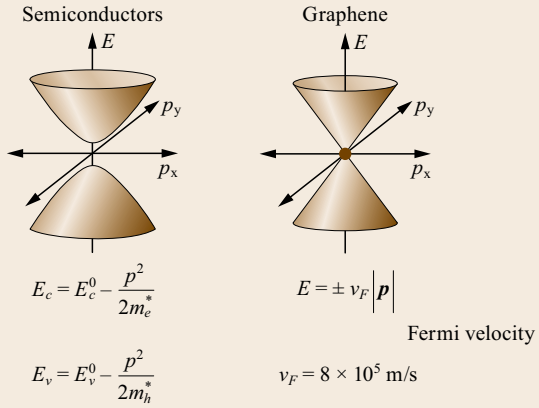

Fig. 48.4 The energy band diagram in semiconductors and graphene

effect on the carrier mobility. The charged impurities can be reduced in graphene by annealing or by using a high-k dielectric [48.27].

Application of graphene in high speed electronics has been shadowed for years since the lack of a bandgap makes it impossible to close the current flow. This blocks the application of graphene for logics since a bandgap around 400–500 meV is sought for this application. Integration of graphene as a channel material in field effect transistors (FETs) offers a high transconductance; however, the absence of a well-defined saturation region diminishes the benefit of a graphene power amplifier. A high I_{on}/I_{off} ratio is the key criteria for RF application.

One way to solve this problem is to decrease the lateral size of graphene to few a nanometers (so-called graphene nanoribbon (GNR)) where the electronic wavefunction could be localized and a quasi 1-D structure could be established (Fig. 48.6). In this way, a ballistic quantum transport is built up in graphene which is compatible with High Electron Mobility Transistor (HEMT) devices.

Another way to create a small bandgap in graphene is to form a bilayer graphene (BLG) [48.29] (or so-called Bernal stacked graphene), where the two graphene monolayers are placed on each other with a misalignment (Fig. 48.6).

Unfortunately Bernal BLG can mainly be synthesized by exfoliation method. Using BLG, a bandgap of 130 meV and the I_{on}/I_{off} value of ≈ 100 have been obtained [48.29].

Many research studies have proposed another alternative: vertical graphene transistor. This type of transistor functions by current tunneling from an electrode through a thin dielectric layer to graphene. In a more practical way, another graphene layer can be deposited to act as a second electrode. This extra gate allows triode modulation of the tunnel current [48.30]. This design has demonstrated an I_{on}/I_{off} ratio around 50 but no RF action has been shown so far.

An alternative to the above configuration is integration of graphene in a graphene hot-electron transistor,

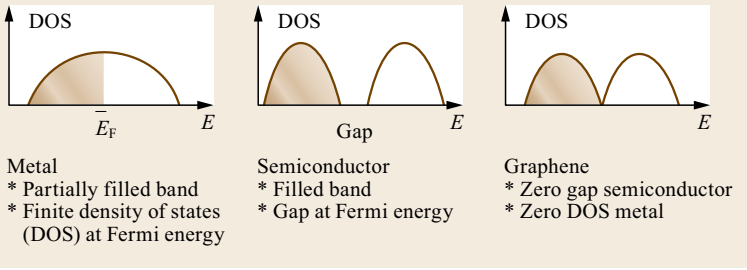

Fig. 48.5 Electronic structure and DOS for metals, semiconductors and graphene

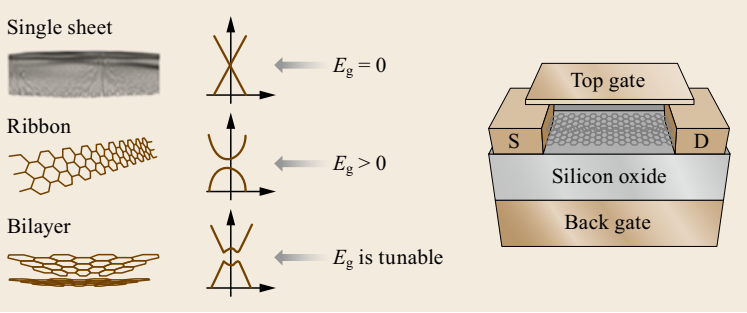

Fig. 48.6 Schematic of band diagram for different graphene material and GNR transistor. (After [48.28])

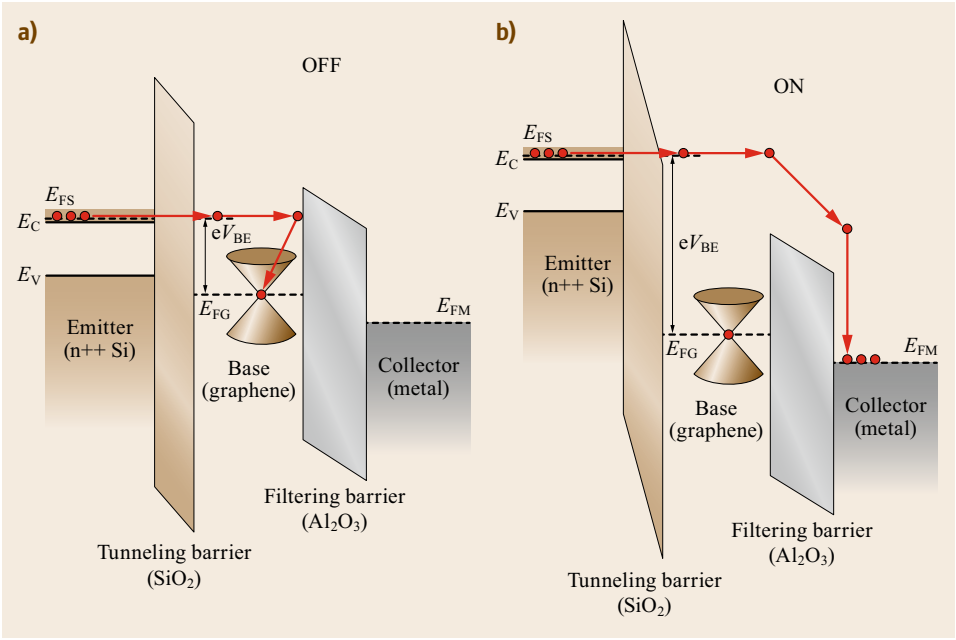

Fig. 48.7a,b Vertical graphene transistor **(a)** in off and **(b)** on state. (After [48.31])

which is the application of hot electrons in a metal-insulator-metal-insulator-metal (MI-M-I-M) transistor, an approach similar to Bipolar Junction Transistor (BJT). In this type of transistor, graphene is applied as low-resistivity base electrode and consists of an emitter base tunnel junction and a base collector filtering dielectric (Fig. 48.7a,b). Although these transistors have shown I_{on}/I_{off} ratio around 10^5 they have a very low current gain, which leads to collector currents 10 orders of magnitude less than the other types of transistors [48.32].

48.3 Characterization of Graphene Material

Graphene material is usually in a few monolayers on a specific substrate and it is difficult to be distinguished by optical microscopes. The characterization techniques, for example, atomic force microscopy (AFM), transmission electron microscopy (TEM), x-ray diffraction (XRD), and Raman spectroscopy are mainly applied to study graphene.

48.3.1 AFM

AFM is a common technique to estimate the thickness of graphene material. In general, 2-D crystallites such as graphene are a few nanometers thick elevated on the surface. Tapping mode is mostly used for the thickness measurements [48.33]. However, AFM technique has low throughput and therefore the measured data are not without error.

As an example, *Novoselov* et al. [48.33] have shown a monolayer graphene has 0.4 nm height, and Gupta et al. showed a height of 0.7 nm for single monolayer of graphene. One explanation for these different outcomes in measurements could be that these groups used the different amplitudes of the cantilever for their experiments.

This shows that extra care has to be taken to analyze the AFM results in order to have a comparable and reliable method to measure the thickness of graphene [48.33, 34].

48.3.2 Transmission Electron Microscopy

Transmission electron microscopy (TEM) is one of the most accurate methods to study graphene and provide atomic resolution (Fig. 48.8a–c). Graphene appears both in single- and multilayers in a flat sheet or folded form. The electron beam is parallel to the folded graphene sheets and they appear as one dark line for single sheets (Fig. 48.8a) and double dark lines for bilayer sheets (Fig. 48.8b). In the case of multiple folded sheets the number of dark lines could appear in any shape [48.35]. This can make it difficult to determine the number of graphene sheets.

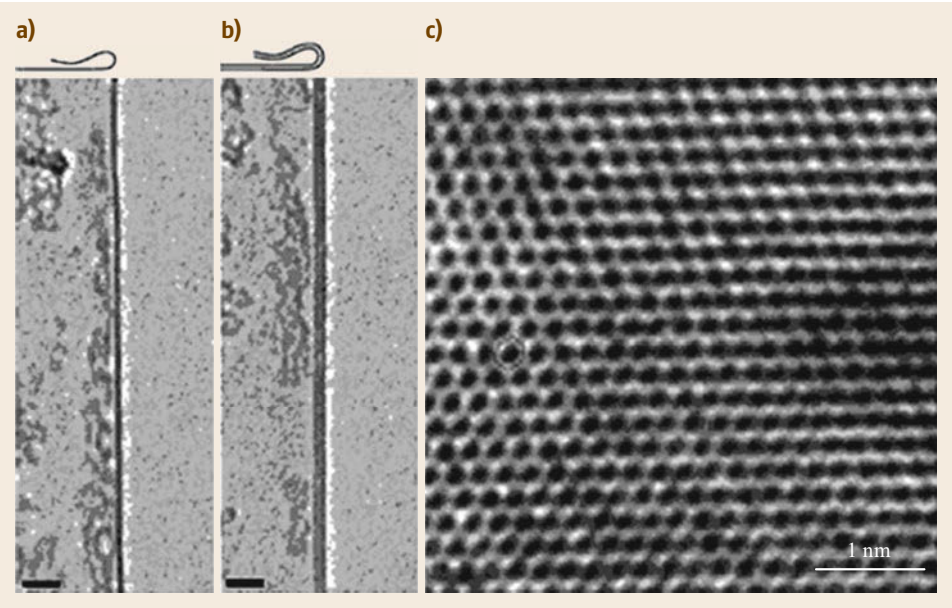

Fig. 48.8a–c TEM images: **(a)** cross-section of single-folded graphene, **(b)** cross-section of double-folded graphene and **(c)** top view of graphene material. (Reprinted from [48.36], with permission from Elsevier)

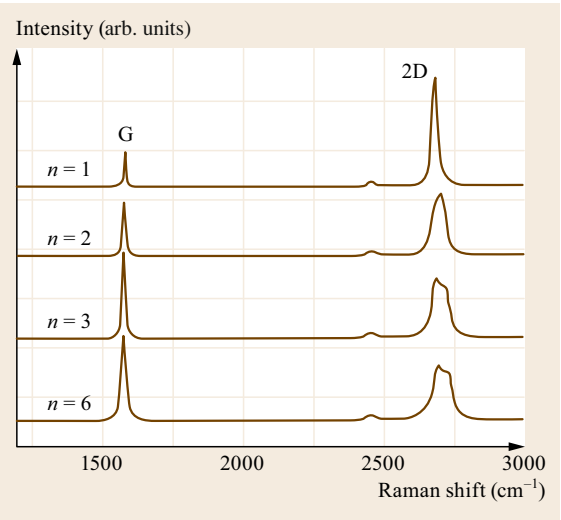

Fig. 48.9 Raman curves of graphene with n layers. (After [48.37])

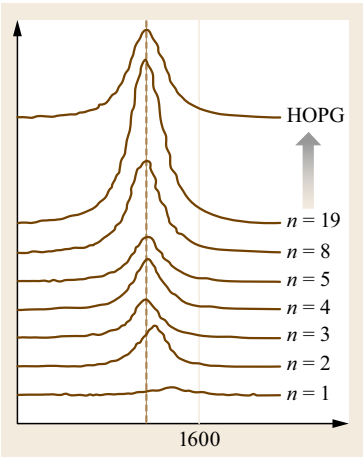

Fig. 48.10 G-band of graphene for a series of graphene layers n. (After [48.38])

48.3.3 Raman Spectroscopy

Raman spectroscopy is a technique that is based on inelastic interactions of phonons in a layer. For graphene, Raman can provide information about the number of monolayers and the quality of graphene material. There are three main bands in Raman analysis:

- The D band
- The 2-D band
- The G band.

The D Band

This band is an indicator of the defects in the graphene material and the presence of sp^3 bonds of carbon. The intensity of the D band is low for graphene (or graphite) with high quality. This peak normally appears at the edges of graphene flakes [48.39].

The 2-D Band

This band indicates the number of graphene sheets and also reveals if the graphene lies on a specific substrate. If the 2-D band is a single peak with narrow full-width-half-maximum (FWHM) then the graphene is a single sheet. However, if the graphene consists of multilayers then the shape of the peak is broad with small peaks. Figure 48.9 shows different cases for graphene

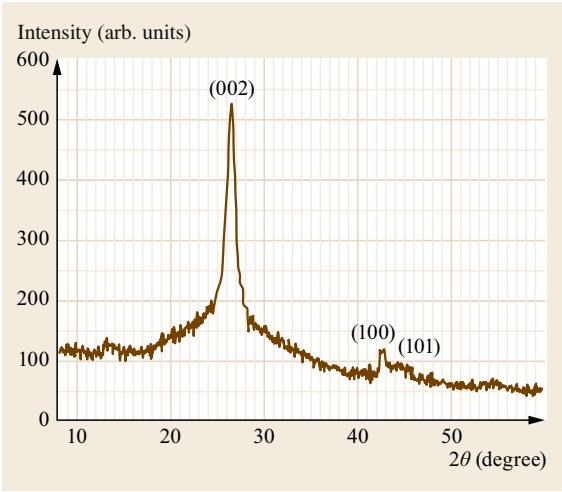

Fig. 48.11 X-ray curve for graphene. (After [48.40])

material. As an example, Raman results from a bilayer graphene shows peaks at wavelengths of 514 and 633 nm [48.41].

The G Band

The position of this band shows the number of graphene sheets. A peak is seen around $1587\,\mathrm{cm}^{-1}$ if the graphene consists of a single sheet, otherwise the G band moves downwards. Figure 48.10 shows the change of G band for graphene layers with different numbers of sheets [48.38].

48.3.4 XRD Analysis

X-ray diffraction is a technique that is usually used to study thin films. In the case of a very thin layer of graphene, a high-intensity x-ray beam is required. The XRD technique provides information about the crystalline quality and layer thickness of graphene. The latter parameter could be relatively determined by the intensity of the peaks. The XRD data of the graphene material gives three main peaks at reflections:

- (002) at 26.3°
- (101) 44.6°
- (100) 43.2° (Fig. 48.11) [48.40, 42].

48.4 Photonic Applications

Graphene has very promising optical properties for modulators [48.43, 44], photodetectors [48.45, 46], and plasmonic structures. Despite its thin thickness, it absorbs light in the vertical or lateral direction due to distinctive electronic structure [48.47]. The material absorbs a large variety of wavelengths within interband, intraband, and collective plasmon excitations. The extraordinary benefit of graphene is tuning the absorption by regulating the charge density.

The optical conductivity is written by a universal value of $\sigma_{\mathrm{uni}} = \pi e^2/2h$. For photons with higher energies, the optical conductivity is increased gradually towards peaks, which lie in UV range with energy of 4.62 eV (Fig. 48.12). This is related to nonlinear part of dispersion relation, which is labeled by interband transitions from the bonding to the antibonding π states in the graphene Brillouin zone [48.48].

Graphene absorbs ideally 2.3% of the normal incident light through intra- and interband transitions. This absorption may deviate from the ideal universal value of 2.3% depending on the underneath layer (Fig. 48.13a). This deviation is related to phonons (where interband absorption is allowed in the presence of phonons) [48.49].

Graphene can be placed on a waveguide to absorb light along the lateral direction (Fig. 48.13b). The length of graphene sheet may determine the amount of the absorption and for a long enough sheet a total absorption can be obtained. The absorption of light in the lateral direction occurs when a graphene sheet is placed on a waveguide. The length of graphene (or waveguide) sheet determines the amount of absorption and a complete absorption can be obtained if the length of graphene is long enough.

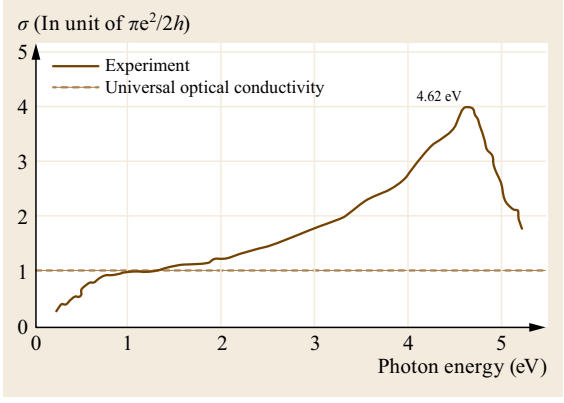

Fig. 48.12 Experimental optical conductivity (*solid line*) and the universal optical conductivity (*dashed line*) of a single graphene layer. The discrepancy of the optical data from the universal values at low energies is due to spontaneous doping. (After [48.48])

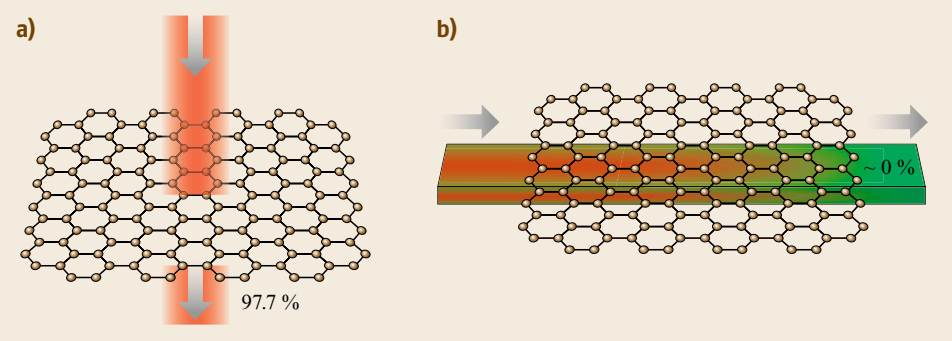

Fig. 48.13 **(a)** Normal incident light shines on a graphene layer. **(b)** Graphene on a waveguide and the light interacts with graphene along the waveguide sheet

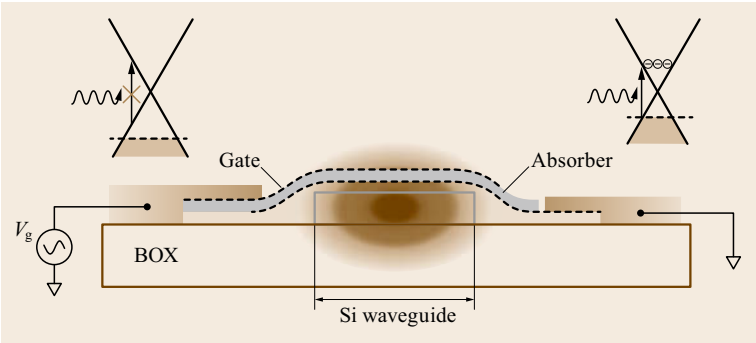

Fig. 48.14 A bilayer graphene modulator integrated on a waveguide. By applying a voltage to the gate, charge-sheet density in the first graphene layer is affected. (After [48.44])

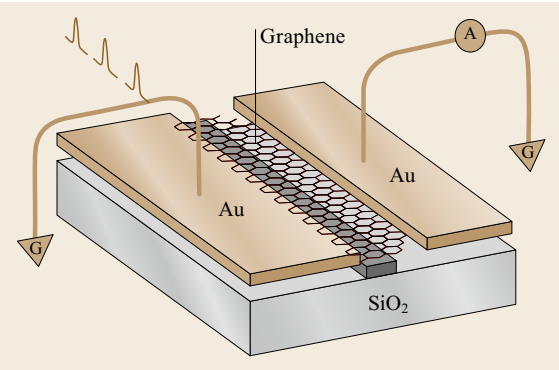

Fig. 48.15 A photodetector with graphene active layer. (After [48.46])

An innovative method to deal with graphene low DOS is to use two graphene sheets isolated by an oxide layer (Fig. 48.14). In this design, the first graphene sheet layer is for absorption, however, the second sheet operates as a gate.

Si is a material with a bandgap of 1.12 eV, and is transparent for $\lambda > 1.1\,\mu m$. Therefore, Si can be used as a waveguide to conduct telecom wavelengths.

The modulator in Fig. 48.14 may function when the first graphene sheet is grounded and the second one is biased with a gate voltage, V_g [48.44].

Graphene has also been used as active photonic material in photodetectors. An electrical current was generated when the contact electrode of graphene transistor was illuminated [48.50, 51] (Fig. 48.15). In order to increase the absorption, the detector can be formed on a waveguide processed on an SOI substrate with a high-k material beneath the graphene sheet.

Although graphene can absorb a broad wavelength a graphene detector has a low responsivity of 0.1 mA/W, which is remarkably lower than III-V detectors.

During recent years, many research efforts have been spent on other 2-D crystals (transition metal dichalcogenides, silicene, and germanene) as competitors to graphene [48.52].

The transition metal dichalcogenides are a group of materials which are known as MX_2, where M is a transition metal element from group IV (e.g., Ti, Zr or Hf), group V (e.g., V, Nb, or Ta), or group VI (e.g., Mo or W), and X is a chalcogen material (e.g., S, Se, or Te).

Even though, there are many reports about the synthesis and properties of these materials there is a long way to go before they can be mass-produced for industrial applications in near future [48.52].

49. Magnetic Information-Storage Materials

Charbel Tannous, R. Lawrence Comstock†

The purpose of this chapter is to review the current status of magnetic materials used in data storage. The emphasis is on magnetic materials used in disk drives and in the magnetic random-access memory (MRAM) technology. A wide range of magnetic materials is essential for the advance of magnetic recording both for heads and media, including high-magnetization soft-magnetic materials for write heads, antiferromagnetic alloys with high blocking temperatures and low corrosion propensity for pinning films in giant-magnetoresistive (GMR) sensors and ferromagnetic alloys with large values of giant magnetoresistance. For magnetic recording media, the advances are in high-magnetization metal alloys with large values of switching coercivity. A significant limitation to magnetic recording is found to be the superparamagnetic effect and advances have been made in multilayer ferromagnetic films to reduce the impact of the effect, but also to allow high-density recording have been developed. Perpendicular recording as compared to longitudinal recording is reviewed and it is shown that this technology will soon be replaced first by heat-assisted and later by bit-patterned magnetic recording in order to progress steadily toward areal densities well above 10^{12} bit/in^2 (1 Tbit/in^2 or 1000 Gbit/in^2). While an MRAM cell exploits some of the materials used in GMR sensors, its basic component is the magnetic tunneling junction in which magnetic films are coupled by a thin insulating film and conduction occurs by quantum mechanical tunneling. The status of MRAM cell technology and some closely related key problems are reviewed.

The purpose of this chapter is to summarize the status of magnetic materials used in high-capacity disk drives and magnetic-semiconductor memory devices. The technology of disk drives is selected since these devices have experienced the largest increase in data capacity over time and this has made disk drives the preeminent storage system for digital data. To illustrate this point, consider Fig. 49.1, which is a plot of the areal density (number of data tracks per inch times the number of bits per inch recorded on a track) for disk drives over time [49.1].

The increase in areal density is more than 100% per year up to about 2002, when it reduced to about 20–30%, then increased steeply by 600% between 2006 and now evolving from 150–900 Gbit/in^2, the current value at the time of writing. Practically it means that we are about to reach 1 Tbit/in^2, a value that is considered as a formal limit to (perpendicular) recording and requires a paradigm shift in order to keep further increasing areal density as explained below.

The total data capacity of a disk is approximately the areal density times the recording area, which is twice the number of platters since both faces are used and depends on the size of the disk (2.5 and 3.5 in (64 and 90 mm)) diameter being the most common.

For a 3.5 in disk, a simple rule of thumb implies that 900 Gbit/in^2 areal density means about 900 Gbyte storage per platter face.

Many technologies have contributed to this rapid increase in areal density, including advances in the technology of flying heads with reduced spacing to the disk surface, data codes and error detection and cor-

rection, advanced servo-control systems for accurate control of magnetic recording heads on data tracks, and improvements in the mechanical structures comprising a disk drive, including advances in motors used to drive the disks. However, this paper discusses only the fundamental technology associated with digital magnetic recording, including the devices used to record and read back the recorded data and the media on which the data is recorded. The discussion is also restricted to the materials and not to any of the mechanical structures associated with the recording heads or disks.

The discussion covers longitudinal magnetic recording (LMR), perpendicular magnetic recording (PMR) and the transition process between them allowing an increase in areal densities in hard disks. In PMR the remanent magnetization is perpendicular to the disk surface reducing the impact of the superparamagnetic limit. Technology underlying MRAM (magnetic random-access memory) is also discussed since it provides nonvolatility to RAM, blurring the borderline separating permanent storage and RAM.

Consequently, the operating system and application programs will always be present in RAM since the computer's very first boot, in sharp contrast with respect to the electronic RAM whose contents totally disappear every time the computer is switched off or when it is jammed and not responding.

MRAM is a possible replacement for the familiar semiconductor memories used in microcomputers – dynamic and static random-access memory (DRAM modules are placed on the computer motherboard close to central processing unit (CPU) whereas static random-access memory (SRAM) is used inside CPU cache memories).

MRAM technology combines a magnetic storage technology together with metal-oxide semiconductor (MOS) devices to result in fast and high-density data memory devices. The technology on which the magnetic part of MRAM is based is an extension of the technology used in magnetic recording devices – the magnetic tunneling junction (MTJ). MRAM technology will also be discussed in this chapter. Parts of this work have been previously published in the Journal of Materials Science: Materials in Electronics [49.2].

49.1 Magnetic Recording Technology

The technology of magnetic recording was one hundred years old [49.3] in 1999. The fundamental concept of magnetic recording is to use a magnetic structure (the write head) driven by current that represents the data to be recorded to generate a magnetic field that can change the state of the magnetization in a closely spaced magnetic recording medium, which in the earliest realization was magnetic wire, and today is either the familiar magnetic tape or a magnetic layer on a rigid disk substrate. The data are recovered by the generation of an output voltage in the read head by sensing the magnetization in the recording medium, e.g., by Faraday's law ($V = N\mathrm{d}\phi/\mathrm{d}t$), where N is the number of turns on the read head and ϕ is the magnetic flux coupled to the read head from the media. The magnetic recording system to be discussed here is that used to store digital data, in which case the current supplied to the write head is in the form of pulses encoded to represent the digital data [49.4, 5] (1 or 0).

In the case of disk drives the write and read heads are separate thin-film structures deposited on the back of a mechanical slider, which uses a hydrodynamic air bearing to fly over the surface of the disk [49.5]. Figure 49.2 is a schematic of a digital LMR system. The recording (write) and read elements are shown together with the magnetic recording surface, which in disk drive technology is a thin metallic film of a cobalt alloy (to be discussed). The digital data are recorded in the magnetic film as transitions between the two possible states of the magnetization (pointing to the left or right) and with the width approximately equal to the width of the write head and the width of a data track. The transi-

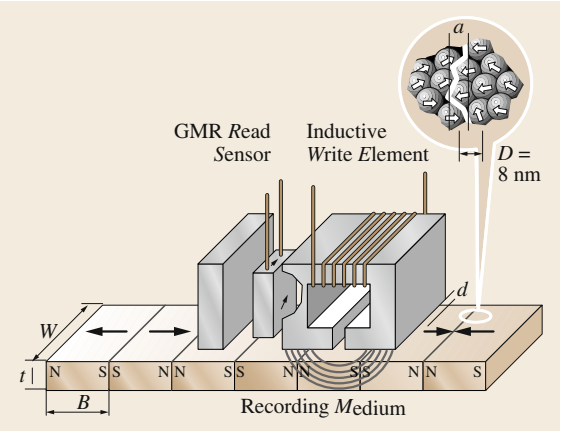

Fig. 49.2 Schematic illustration of a longitudinal magnetic GMR read sensor recording system showing a giant magnetoresistive (GMR) read sensor, write element and the recording medium. The parameters are: t the recording medium thickness (δ is also used), W the width of the recorded track, B the length of the recorded magnetization or bit length and d the head-media separation (HMS) or magnetic spacing (includes overcoats on the disk surface and undercoats on the slider surface). Shown in the *inset*: the transition region between the two directions of the magnetization; D is the media grain size and a is the transition parameter that characterizes the length of the transition region (length $l = \pi a$). (After [49.1])

tion region between the oppositely directed directions of the magnetization is similar to that between magnetic domains and has a length l. We will discuss the different parts of the recording system starting with the write head and including the read head, which in Fig. 49.2 is a giant-magnetoresistive sensor. First, we will discuss some aspects of thin magnetic films that are relevant to magnetic recording components. All magnetic recording components used in disk drives today are fabricated from thin films to allow mass production and for technology reasons, as we will discuss.

49.1.1 Magnetic Thin Films

Induced Uniaxial Anisotropy

In most applications of soft-magnetic films, a uniaxial anisotropy in the plane of the film is required. One way of introducing this uniaxial anisotropy is to induce it by applying a magnetic field in the plane of the film and the effect is referred to as magnetic annealing. The anisotropy can be induced during deposition of the film or induced by a subsequent annealing step, using temperature and a magnetic field to modify the anisotropy. The mechanism of the induced anisotropy is that of directional order, in which atomic pairs in an alloy tend to align with the local magnetization. In nickel-iron films the atomic pairs are the iron atoms and the induced uniaxial anisotropy energy density is typically $K_u \approx 1-3\,\mathrm{kerg/cm^3}$ ($0.1-0.3\,\mathrm{kJ/m^3}$), where the uniaxial energy density is

$$E_k = K_u \sin^2\theta\,, \tag{49.1}$$

where θ is the angle of the magnetization with respect to the direction of the induced anisotropy. To induce the anisotropy it is necessary to saturate the magnetization of the film with a small magnetic field, typically $50-100\,\mathrm{Oe}$ ($4000-8000\,\mathrm{A/m}$), since it is the magnetization not the magnetic field that is responsible for the magnetic annealing. If the anisotropy energy density is positive the energy is minimum is along the direction of the anisotropy, which is referred to as an *easy* axis.

A second method of introducing uniaxial anisotropy in thin films is by stress. If the magnetostriction constant is isotropic with value λ_s for a polycrystalline material then the magnetoelastic energy density is given by

$$E_{me} = \frac{3}{2}\lambda_s\sigma \sin^2\theta\,. \tag{49.2}$$

The angle θ is the angle of the magnetization in the film plane with respect to the direction of the stress (σ). If a sample is unmagnetized it will strain by λ_s as the sample is magnetized to saturation. A typical value of λ_s is $\approx 10^{-6}$. If the magnetostriction constant and the stress are both positive the direction for the minimum energy and hence the easy axis is for $\theta = 90°$. The magnetization, permeability, crystalline anisotropy constant and magnetostriction constant of nickel-iron alloys [49.6] $Ni_xFe_{(1-x)}$ are shown in Fig. 49.3. The maximum permeability is for the Permalloy composition $Ni_{80}Fe_{20}$. Increasing the atomic percentage of iron over that of Permalloy results in increased magnetization since the magnetic moment for iron is $2.2\,\mu_B$ (Bohr magnetons) per atom in the metal, while the value for nickel is $0.6\,\mu_B$ per atom in the metal.

Hysteresis in Soft-Magnetic Films

If we impose an external magnetic field H_e along the direction of the induced anisotropy (easy axis) of the thin film ($\theta = 0°$) the total energy density is given by

$$E_k = K_{eff} \sin^2\theta - MH_e \cos\theta\,. \tag{49.3}$$

K_{eff} is the sum of the uniaxial crystalline anisotropy (K_u) and the stress anisotropy $(3/2)\lambda_s\sigma$. The second term is the magnetostatic energy. The equilibrium angle

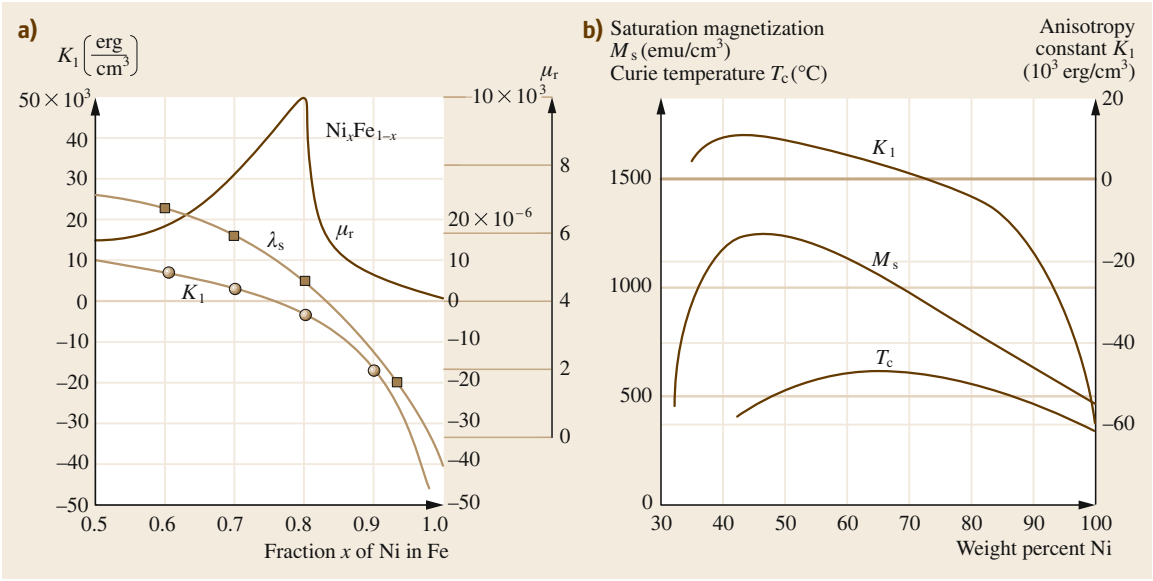

Fig. 49.3 **(a)** Magnetic properties of Ni_xFe_{1-x} alloys, including initial permeability, crystalline anisotropy and magnetostriction. **(b)** Magnetization, Curie temperature and crystalline anisotropy of Ni_xFe_{1-x} alloys. (After [49.7])

for the magnetization is given by minimizing the total energy, $dE/d\theta = 2K_{\text{eff}} \sin\theta \cos\theta + MH_e \sin\theta = 0$. The solution $\sin\theta = 0$ implies that the magnetization lies at either $\theta = 0$ or 180°. However, the energy must be a minimum for stability and the second derivative changes sign at a boundary between stability and instability

$$\frac{d^2E}{d\theta^2} = 2K_{\text{eff}}(\cos^2\theta - \sin^2\theta) + MH_e^* \cos\theta = 0\,.$$

The magnetic field that just satisfies this condition is

$$H_e^* = -H_c = \frac{-2K_{\text{eff}}}{M}\,. \qquad (49.4)$$

The critical magnetic field is the coercive field (H_c). A curve of the magnetization versus applied magnetic field for this case is shown in Fig. 49.4 (curve labeled *easy*), which was measured on a thin film of FeCoNi (to be discussed) [49.8]. The magnetization curve exhibits hysteresis and in the FeCoNi alloy the coercive field is small and the material is magnetically *soft*. Hysteresis is responsible for the use of magnetic materials as digital memory devices since the up or positive state of the magnetization could represent a binary 1 and the down or negative state could represent a binary 0 and these states can be stable even in zero applied field ($H_e = 0$).

The above analysis also applies to magnetically hard films, for which the coercive field is large. We will discuss magnetic recording media and here the coercive field is measured in units of kOe. With the magnetic

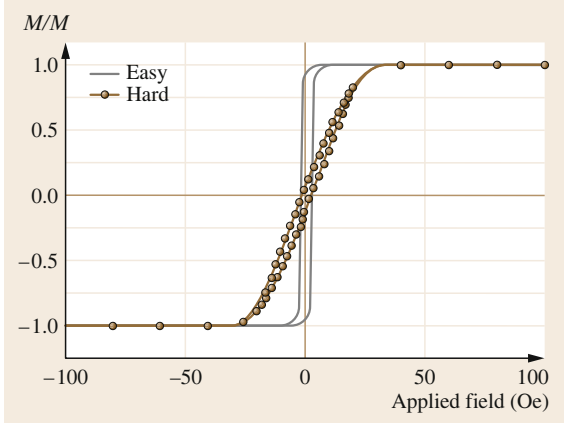

Fig. 49.4 Easy and hard magnetization curves of an electroplated FeCoNi alloy film. (After [49.8])

field applied perpendicular to the easy axis, along the hard axis, the energy density is given by

$$E_k = K_{\text{eff}} \sin^2\theta - MH_e \sin\theta\,.$$

The derivative of the total energy is given by

$$\frac{dE}{d\theta} = 2K_{\text{eff}} \sin\theta \cos\theta - MH_e \cos\theta = 0$$

resulting in the two solutions:

1. $\cos\theta = 0$, or $\theta = 90$ or 270°
2. $\sin\theta = H_e/(2K_{\text{eff}}/M)$.

The solution to this case is also shown in Fig. 49.4 (curve labeled *hard*) and is seen not to exhibit hysteresis. This is the hard-axis magnetization curve and the magnetic field where the magnetization saturates is known as the anisotropy field H_k. The hard-axis magnetization curve is used extensively for magnetic recording heads.

49.1.2 The Write Head

The write head is formed from thin films of soft ferromagnetic alloys patterned in the form of a magnetic yoke. A schematic of an eight-turn thin-film head is shown [49.9] as Fig. 49.5. Heads in disk drives typically have fewer than five turns to reduce inductance. The cross-hatched regions are the soft ferromagnetic material, and the leads that carry the write current are shown on the right-hand side of the top view. Note that the widths of the copper alloy turns are increased near the back region of the head to reduce resistance. The heads are fabricated using electroplating and the substrate (not shown) is a hard ceramic that can be machined to form the slider [49.5]. Electrical current in the form of pulses is coupled to the yoke to generate a magnetic field at the gap. The coil is insulated from the metallic magnetic yoke by layers of baked polymer photoresist. The alloy that has been used most frequently in the past for the magnetic films in the write head is $Ni_{80}Fe_{20}$ (Permalloy), which can be deposited in thin films using electroplating. Electroplating is discussed in *Comstock* [49.5] and in more detail by *Andricacos* and *Romankiw* [49.10].

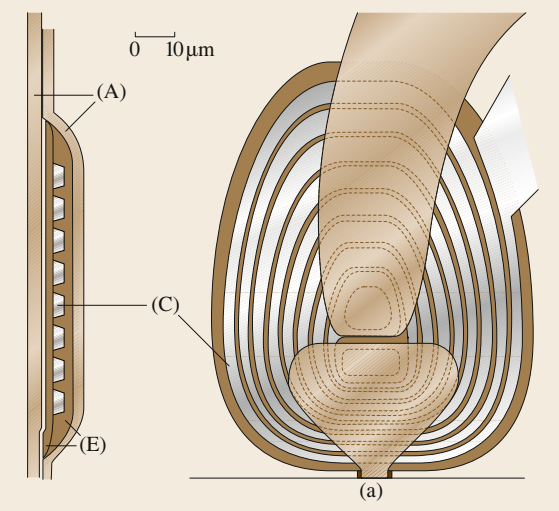

Fig. 49.5 Thin-film head with eight turns showing the poles and yoke structure. A is Permalloy, C is copper and E is baked photoresist. (After [49.9])

The maximum coercivity ($H_{c,max}$) of the recording medium that can be recorded by the write head is given by (49.4) (in Gaussian units) [49.5]

$$H_{c,\,max} = 0.20 \times 4\pi M_s \tan^{-1}\left(\frac{\frac{g}{2}}{d+\delta}\right), \qquad (49.5)$$

where $4\pi M_s$ (Gauss) is the saturation flux density of the material used in the recording or write head, g is the gap length of the write head, d is the HMS (see Fig. 49.2 caption) and δ is the thickness of the recording film (shown as t in Fig. 49.2).

To increase the linear density (transitions along a recorded track), it is necessary to increase the coercive field of the recording media. This is the case since the length of a transition between the two states of the magnetization is given by (49.5) (in Gaussian units) [49.5, 11, 12]

$$l = \pi a = \pi\left(\frac{d(1-S^*)}{\pi Q}\right) + \pi\left[\left(\frac{d(1-S^*)}{\pi Q}\right)^2 + \left(\frac{2M_r\delta}{H_c}\right)\left(\frac{2d}{Q}\right)\right]^{1/2}, \qquad (49.6)$$

where

$$S^* = 1 - \frac{M_r/H_c}{\left[(\mathrm{d}M/\mathrm{d}H)_{(H=-H_c)}\right]}$$

quantifies the slope of the hysteresis curve of the recording medium at the coercive field and

$$Q = \frac{(\mathrm{d}H_x/\mathrm{d}x)}{H_c/\mathrm{d}};$$

Q is the normalized slope of the horizontal component of the write-head magnetic field at the value $H = H_c$. A typical value of Q is 0.7.

M_r (emu/cm^3) is the remanent magnetization of the recording medium with thickness δ.

From (49.4) and (49.5) it is seen that for reduced transition length (and hence higher linear density) it is necessary to increase the coercive field (H_c) of the recording medium but to do so requires a concomitant increase in the magnetization of the write head (49.4).

Materials with magnetization larger than Permalloy ($4\pi M_s = 10$ kG ($M_s = 1$ T)) and which are magnetically soft (large permeability) are listed in Table 49.1.

The most common material used in disk drives is electroplated $Ni_{45}Fe_{50}$, with a saturation magnetization of $4\pi M_s = 16$ kG ($M_s = 1.6$ T) [49.13].

Table 49.1 Properties of materials used in magnetic recording heads

Material	B_s (kG) ($T \times 10^{-1}$)	μ_r	ρ ($\mu\Omega$ cm)	H_c (Oe)(A/m)	References

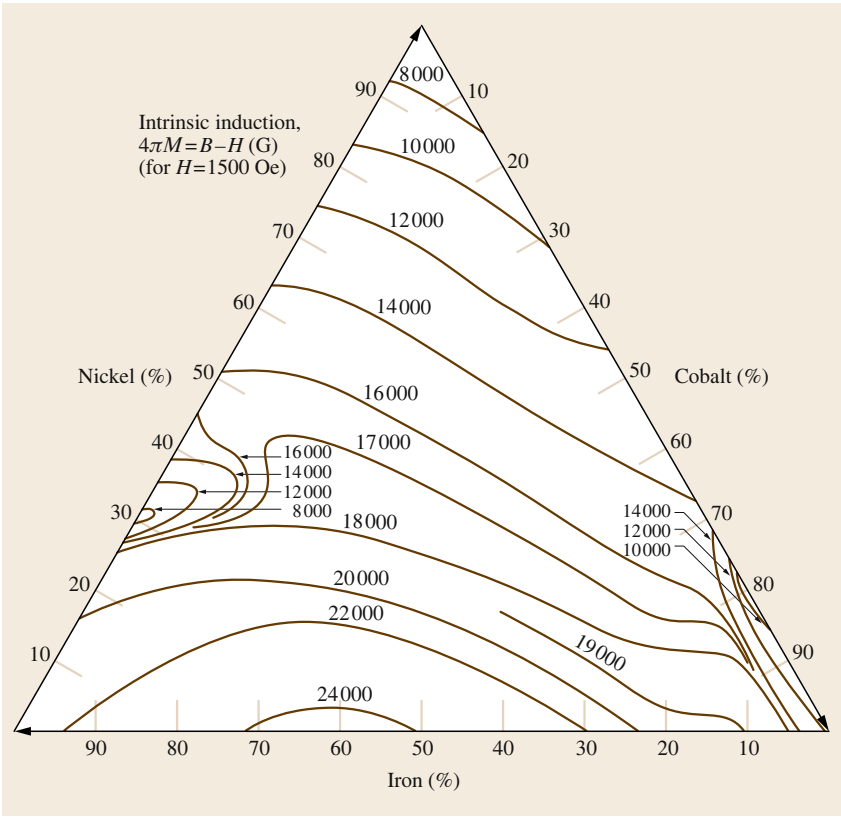

Fig. 49.6 FeCoNi saturation magnetization contours. (After [49.6])

Ternary alloys of Ni, Fe and Co also can be electroplated with saturation magnetization of $4\pi M_s \geq 20$ kG ($M_s = 2$ T). The composition region that results in the largest value of saturation magnetization but also large permeability is: $Co_{48-56}Fe_{30-31}Ni_{22-13}$ (Table 49.1). A useful guide to the selection of the composition of the ternary FeCoNi alloys is the composition diagram shown [49.6] as Fig. 49.6.

The data for Fig. 49.6 were accumulated in bulk materials. In a study of electroplating FeCoNi alloys for write heads [49.8] care was taken to avoid any impurities in the plating bath and the results showed the possibility of achieving $4\pi M_s$ values in the range of 21–21.5 kG and $H_c < 2$ Oe in the same region of the composition diagram (approximately $Fe_{35}Co_{45}Ni_{20}$).

However, experiments in a larger cell in conditions closer to those in a manufacturing plating system and with higher Fe content and an organic additive ascorbic acid used to reduce the formation of Fe^{3+} showed even larger values of $4\pi M_s$ (> 2.2 kG) but with increased coercivity [49.6] (> 8 Oe). The composition of ferromagnetic alloys can be selected to result in zero values for the magnetostriction constant and the Permalloy composition of nickel-iron alloys ($Ni_{80}Fe_{20}$)

has a zero magnetostriction constant (Fig. 49.3). The magnetostriction constant is frequently chosen to be small and negative so that the magnetoelastic energy defines an easy axis at right angles to the direction of the stress ($\theta = 90°$ in (49.2)).

In the case of thin-film write heads the stress is along the axis of the poles (upward in the patterned yoke in Fig. 49.4) and with negative magnetostriction constant the easy axis is across the pole width, which means that the direction of flux flow is along the hard axis with the desired linear relation between the magnetization and the magnetic field (Fig. 49.4). In the case of the ternary alloys of FeCoNi an alloy composition that results in zero magnetostriction is $Fe_{13}Co_{31}Ni_{56}$, in which the nickel content is too high to be a useful write-head material [49.8]. Alloys of FeAl (2% Al) [49.16] and FeTi ($\approx$ 2% Ti) [49.17] sputtered using a mixed N and Ar working gas offer desirable magnetic properties, as shown in Table 49.1, but have not replaced the electroplated alloys because of increased costs of sputtering.

A material of interest for even higher values of saturation magnetization is the α'' phase of $Fe_{16}N_2$, which has the potential for a saturation magnetization of 29 kG; however, this phase is metastable [49.7]. The actual values of saturation magnetization with this phase in thin-film form was 20 kG and required annealing at 200 °C [49.18].

To record on recording media with increased coercivity is not the only issue with the magnetic materials used in write heads. It is also important that the write heads have high efficiency. Efficiency (η) in this case is defined as the ratio

$$\eta = \frac{H_g g}{N_w I} , \tag{49.7}$$

where H_g is the value of the magnetic field in the gap of the write head and I is the amplitude of the write current pulse. High efficiency is important to allow write-current amplitudes that are easily supplied from integrated circuits. For high efficiency it is necessary that a large percentage of the magnetomotive force ($N_w I$) results in a magnetic field across the gap. However, the permeability of the yoke influences the efficiency

$$\eta = \frac{\frac{g}{A_g}}{\frac{g}{A_g} + \frac{l_c}{\mu_r A_c}} , \tag{49.8}$$

where A_g and A_c are the area of the gap and core respectively; l_c is the length of the core and μ_r is the relative permeability of the core or yoke material. As shown in Fig. 49.3, the relative permeability (μ_r) of nickel-iron alloys drops for compositions different from the Permalloy composition. This decrease in the permeability of nickel-iron alloys with composition different from that for Permalloy is the direct result of the increase in crystalline anisotropy and magnetostriction, as shown in Fig. 49.3. The lower permeability of the FeCoNi alloys can be obviated in a design of the write head in which the high-magnetization films are used only in the gap region in a design referred to as a stitched head. The values of coercivity of the recording medium (H_c) that can be recorded with recording heads with the saturation magnetization of Permalloy ($4\pi M_s = 10$ kG ($M_s = 1$ T)) and materials with saturation magnetization 2.5 times that for Permalloy ($4\pi M_s = 25$ kG ($M_s = 2.5$ T)) are shown versus the magnetic spacing (d) in Fig. 49.7.

In 2006, magnetic spacing values were 15 nm (carbon overcoat for head: 3 nm, pole tip recession tolerance: 3 nm, flying height: 5 nm, and media carbon overcoat: 4 nm).

In today's technology magnetic spacing values are 13 nm (carbon overcoat for head: 3 nm, pole tip recession tolerance: 3 nm, flying height: 3 nm, and media carbon overcoat: 4 nm).

The trend in coercivity (H_c) and flux ($M_r\delta$) versus areal density in commercial disk media is shown in Fig. 49.8 [49.7].

Areal density is determined by bit size where size is length in LMR whereas it corresponds to diameter in PMR.

Areal density plays a major role in magnetic recording similarly to minimal feature length F in electronic circuits (Table 49.15); additionally, most magnetic spacings scale with respect to it (Sect. 49.1).

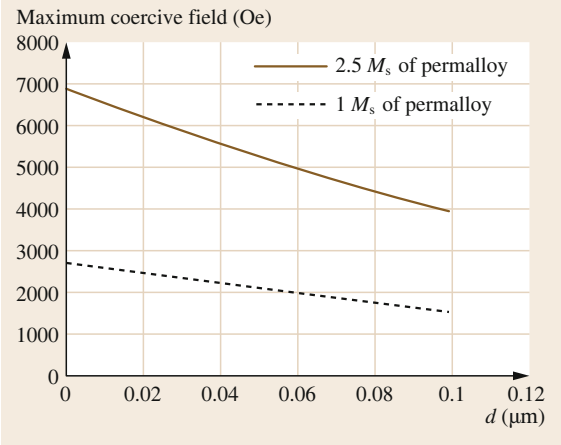

Fig. 49.7 Maximum coercivity of recording media versus magnetic spacing (d) for write heads fabricated from Permalloy and from a magnetic material with a saturation magnetization equal to 2.5 M_s of Permalloy

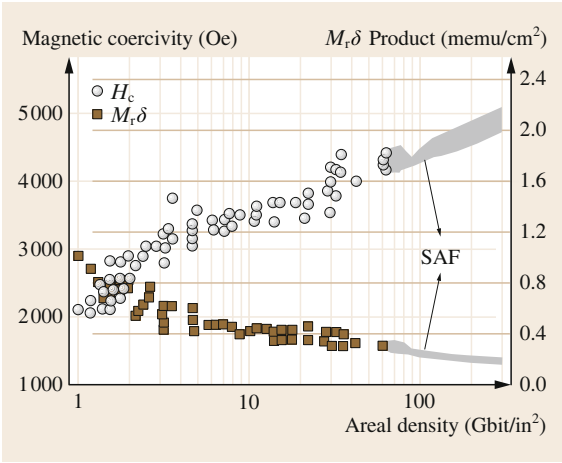

Fig. 49.8 Trend in coercive field (H_c) and media flux ($M_r\delta$) versus areal density in Gbit/in^2 for disk drives. (After [49.7])

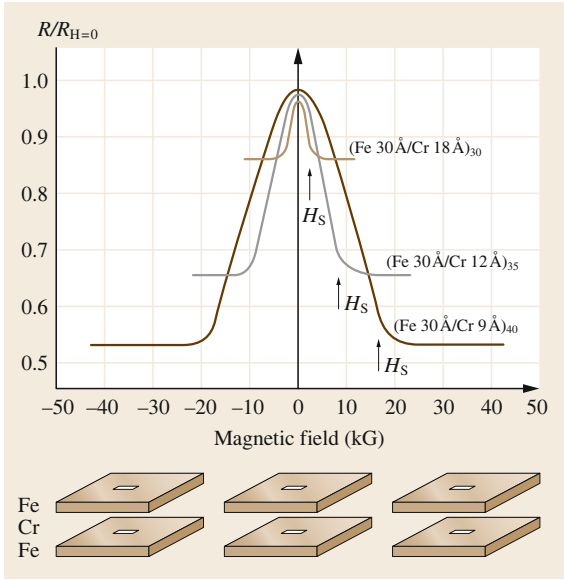

Fig. 49.9 The magnetoresistance of three (Fe/Cr)$_n$ superlattices at 4.2 K. The thickness of the layers in Angstroms is shown. (After [49.20])

We discuss synthetic antiferromagnetic media (SAF media) further below.

With the increased linear density associated with increased areal density in disk drives and with increases in the rotation speed of the disks, the rate at which data are recorded (and read back) has increased over time. This increase in data rate leads to a requirement that the magnetic fields in the gap of a write head switch in ever decreasing times. The switching time of thin magnetic films as used in write heads is limited by three factors [49.19]:

1. The fundamental switching time resulting from the fact that magnetic moments are always associated with angular momentum that cannot be changed instantaneously
2. The eddy currents associated with the changing magnetic fields both decrease the magnetic fields and slow down the switching speed
3. The inductance of the coil.

Data rates depend on the form factor of the disks and with high-end 3.5 in drives the data rates are larger than 50 Mb/s, while with 2.5 in drives the data rates are roughly one-half as large.

49.1.3 Spin-Valve Read Head

The technology that has evolved for sensing or reading the flux emanating from transitions in thin-film disk media is the spin valve. This technology is based on the giant-magnetoresistive (GMR) effect discovered in France and published in 1988 [49.20]. GMR results when thin ferromagnetic films are coupled by an even thinner spacer film of a nonmagnetic transition metal. A curve of resistance normalized to that with no magnetic field applied versus magnetic field for arrays of ferromagnetic films of Fe with thickness of 30 Å (3 nm) coupled by Cr with thickness varying from 9–18 Å (0.9–1.8 nm) is shown in Fig. 49.9 [49.20].

The number subscripted to the parenthesis characterizing the magnetic and transition-metal films is the number of such films, which are referred to as superlattices. With no applied magnetic field, the two films were antiferromagnetically coupled; that is, the magnetizations in the two films are equal in magnitude and oppositely directed. The application of a large in-plane magnetic field rotated the magnetization of the coupled films to a parallel configuration, reducing the resistance (to be discussed).

The current used to measure the magnetoresistance, the change in resistance with applied magnetic field, is applied in the plane of the films. This orientation of current is referred to as current-in-plane (CIP). Later we will discuss an alternative orientation of the current, the current-perpendicular-to-plane (CPP) case.

The initial discovery of GMR was done with a temperature of 4.2 K and the magnetic fields applied were measured in kOe ($10^6\,4\pi$ [A/m]).

The large change in resistance with magnetic field was in contrast to that observed in the anisotropic magnetoresistance (AMR) effect, which is the change in resistance observed when the magnetization in a single ferromagnetic film is rotated from an easy toward a hard axis. This latter technology, for which the resis-

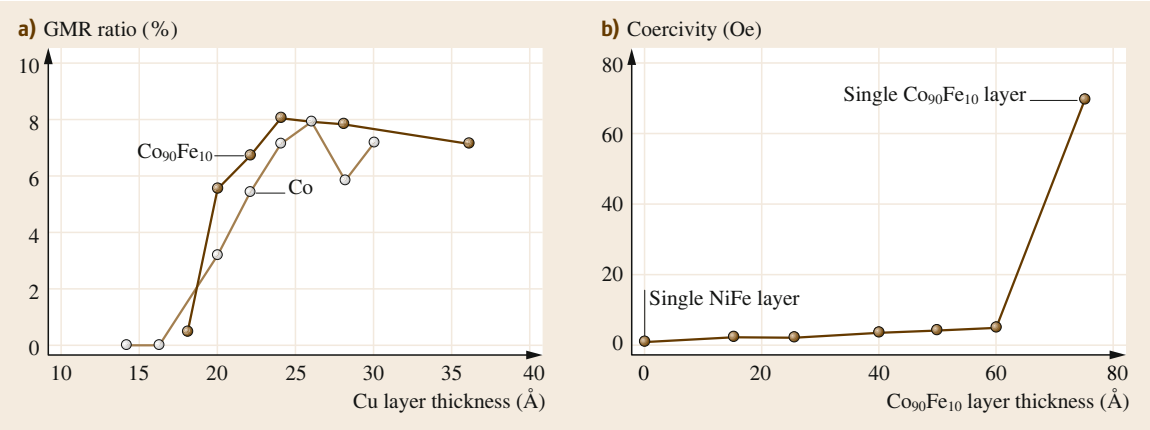

Fig. 49.10 **(a)** Comparison of GMR ratio ($\Delta\rho/\rho$) as a function of copper layer thickness in $Co_{90}Fe_{10}$ and Co films (see text). **(b)** Coercivity as a function of $Co_{90}Fe_{10}$ layer thickness in Ta (50 Å)/[$Ni_{80}Fe_{20}$/$Co_{90}Fe_{10}$] (75 Å) films. (After [49.21])

tance change with Permalloy was of the order of 2–3%, was being used in read heads during the time of research on the GMR effect.

By the early 1990s it was found to be possible to observe GMR in other film materials with increased spacer film thickness at 300 K and with magnetic fields of tens of Oersteds. For example, the GMR ratio for two coupled films of an alloy of cobalt and iron ($Co_{90}Fe_{10}$ for which the magnetostriction constant is zero) with a variable thickness of the spacing layer of copper is shown in Fig. 49.10 [49.21].

It is seen that the GMR ratio is considerably reduced from that for the Fe/Cr superlattices at 4.2 K (Fig. 49.8) but the ratio is larger than that for the AMR effect.

The discovery of the GMR effect led to the invention of the spin-valve read head, in which one of two ferromagnetic films coupled by a thin transition-metal film is maintained constant in direction (the pinned film) and the orientation of the other film (the free film) is allowed to rotate (in the plane of the magnetic film), resulting in a decrease in resistance [49.22]. We will discuss the technology of pinning later. By free, it is meant that the magnetization in the film is easily rotated, for example by the magnetic field arising from transitions in the recording medium.

It is surprising that cobalt is found to be useful in this application since cobalt is magnetically hard (pure cobalt metal has a high coercivity and is used in recording surfaces) and one of the requirements for the GMR effect is that the free film has high permeability and high efficiency (49.6).

The reason for this result is shown in Fig. 49.10, where the coercivity of a free film consisting of two films: $Ni_{80}Fe_{20}$ (60 Å (6 nm)) and $Co_{90}Fe_{10}$ is plotted versus the thickness of the $Co_{90}Fe_{10}$ film [49.21]. Even though the cobalt alloy would have a large coercivity in the bulk, the coercivity for thin films, together with the underlying $Ni_{80}Fe_{20}$ film, is low for thicknesses less than about 60 Å.

The advantage of the cobalt-iron film is the increased GMR ratio over $Ni_{80}Fe_{10}$. In order to increase the GMR ratio even more it has been found advantageous to deposit an interfacial nanolayer of cobalt metal on one or both sides of the free film [49.23]. We will learn in a discussion of the origin of GMR that cobalt has the potential for large GMR ratios.

A schematic of the spin-valve read head is shown in Fig. 49.11 [49.22]. The magnetization of the free film is shown rotated to an angle θ_1 and the pinned layer is shown with a fixed angle of θ_2. The pinning effect

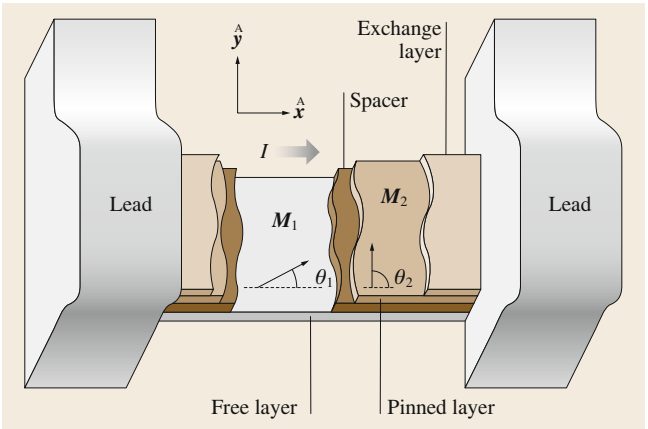

Fig. 49.11 Schematic of spin-valve read element. The magnetization of the free layer is shown at an angle θ_1 to the easy axis (and direction of the current) and the magnetization of the pinned layer is fixed at 90° to this axis. (After [49.22])

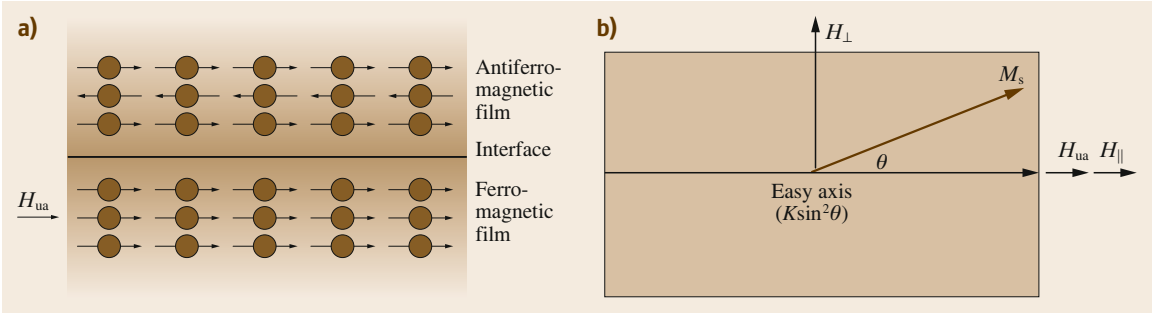

Fig. 49.12 **(a)** Schematic of the coupling of an antiferromagnetic to a ferromagnetic film. **(b)** Geometry of the ferromagnetic film showing the induced easy-axis field H_{ua}, the external magnetic fields $H_\parallel$ and $H_\perp$ and the magnetization of the film at an angle θ to the easy axis. (After [49.5])

is due to the coupling of the pinned film to an underlying antiferromagnetic film as we will discuss. The nonmagnetic spacing layer separates the two ferromagnetic films. The maximum output voltage for the spin valve with no external resistance (and no reduction in the flux due to shielding – to be discussed) is

$$\Delta V = \eta J W_r \Delta\rho \frac{(1-\sin\Delta\theta_1)}{2}\,, \qquad (49.9)$$

where η is the efficiency of the read head, which accounts for the fact that the angle θ_1 is not uniform over the height of the free film, J is the density of the current flowing through the films, W_r is the width of the read head (always less than the width of the written track) and $\Delta\rho$ is the change in resistivity of the stack of films with a change of θ_1 from $-90-+90°$, again with θ_2 fixed. The factor of 2 in the denominator is the result of the actual rotation of θ_1 being limited to $0-90°$.

The device senses magnetic field in the plane of the free film resulting from transitions in the recorded media ($H_{y,\,disk}$) through the rotation of the magnetization in the free film

$$\sin\theta_1 = \frac{H_{y,\,disk}}{H_k}\,, \qquad (49.10)$$

where H_k is the anisotropy field of the free film (see analysis of the hard-axis magnetization curve in Sect. 49.1.1). In the absence of any other magnetic fields, the magnetization will lie along the easy axis. The hard axis is perpendicular to the easy axis. The voltage is measured across the lead terminals using a sense current and the width of the track is just the spacing between the leads. Typically, when areal density is higher than 100 Gbit/in^2, in spin valves, peak output voltage per unit of track width must be larger than [49.24] about 10 mV/μm. Spin-valve read heads are shielded on each side of the stack of films to realize a narrow pulse width. The total width between the shields is G and the thickness of the stack of films comprising the spin valve is t. The read pulse is characterized by the amplitude but also by the width at one-half amplitude (PW_{50} in distance units) (discussed in [49.5, 12])

$$PW_{50} \approx \sqrt{4\left(d+a+\frac{\delta}{2}\right)^2 + \frac{(G^2+t^2)}{2}}\,, \qquad (49.11)$$

where G is the total spacing between the shields and δ is the thickness of the recording layer.

The read-head peak output voltage between shields [49.12] with no external resistance can be approximated by

$$V_{GMR}\ (\text{peak}) = \frac{\eta I \Delta R_{max} M_r^{rec}\delta}{\pi t M_s}\left(\frac{g+t}{g}\right) \times 2\tan^{-1}\frac{g}{2(d+a)}\,,$$
$$I\Delta R_{max} = J W_r R_\square t_{sv}\left(\frac{\Delta R_{max}}{R_0}\right), \qquad (49.12)$$

where η is read efficiency, defined as the fraction of the flux sensed by the head to the total flux, M_r^{rec} is the magnetization of the recording layer, M_s the saturation magnetization of the free layer, g the half-gap between the shields, $R_\square$ the head square resistance ($R_\square = \rho_r/t_r$, with ρ_r, t_r the head resistivity and thickness respectively), W_r the head width and t_{sv} the free layer thickness (modified from *Mallinson* [49.25]).

$$\left(\frac{\Delta R_{max}}{R_0}\right)$$

ratio is a typical measure of resistance variation used for GMR performance (see further below).

Pinning with an Antiferromagnetic Film

For a spin valve to function, the pinned ferromagnetic film must have its magnetization perpendicular to the

recorded track, as shown in Fig. 49.11 (the vertical magnetic field from the transitions in the disk is in the y-direction). This orientation of the magnetization in the pinned film is achieved by coupling the ferromagnetic film to an antiferromagnetic film and the coupling results from the layer of spins in the antiferromagnetic film adjacent to the top layer of spins in the ferromagnetic film and is characterized by a coupling or exchange field of value H_{ua}. The geometry for the coupling is shown in Fig. 49.12 and the ferromagnetic film geometry with a magnetic field along the easy axis ($H_{||}$) and the hard axis ($H_{\perp}$) as Fig. 49.12.

The coupling results in shifting the easy axis hysteresis curve ($M_{||}/M_s$ versus $H_{||}$) of the ferromagnetic film by an amount H_{ua}, as shown in Fig. 49.13 [49.5]. The magnetization of the pinned film is held constant at $-M_s$ over the range of magnetic fields from large negative fields to $H_{ua} + H_k$. Note that the magnetization could be held at $+M_s$ by reversing the direction of the lower layer of spins in the antiferromagnetic film. The coupling field depends on the temperature and vanishes at the blocking temperature. The direction of the coupling is established during an annealing step by heating the structure above the blocking temperature, where the film is paramagnetic, in the presence of a magnetic field and then cooling the film below the blocking temperature.

The choice of antiferromagnetic films to be used in this application is extensive as shown in Table 49.2 [49.26–29]. The parameters listed in Table 49.2 are the strength of the coupling field (H_{ua}), the blocking temperature and the susceptibility of the antiferromagnetic and ferromagnetic films to corrosion. Corrosion is of concern in recording heads because of the mechanical lapping process used to form the surface on the bottom of the slider on which the air-bearing contour is etched [49.4].

One antiferromagnetic film with particularly favorable corrosion propensity is NiO. This film is typically used in a bottom spin valve in which the antiferromagnetic film is closest to the substrate. The other

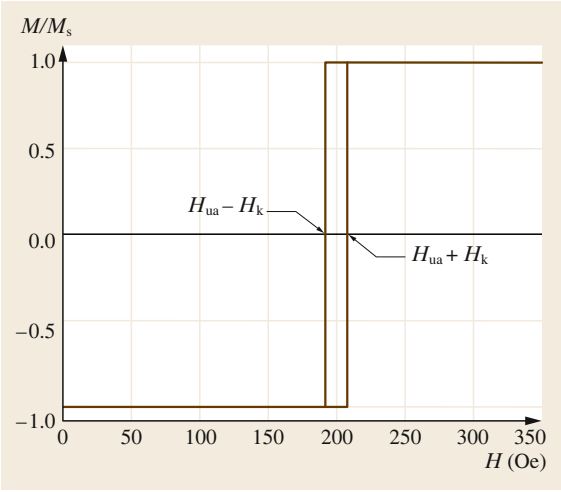

Fig. 49.13 Magnetization curve with the magnetic field along the easy axis ($M_{||}/M_s$ versus $H_{||}$) for coupled antiferromagnetic and ferromagnetic films. (After [49.5])

antiferromagnetic films are typically formed on top of the stack of films. Another advantageous film is the alloy of $Pd_{30}Pt_{20}Mn_{50}$ [49.29].

This ternary alloy has a favorable coupling strength H_{ua} but also a high blocking temperature (300 °C) and favorable corrosion resistance. $Pd_{30}Pt_{20}Mn_{50}$ does require annealing the stack at 220–240 °C. The advantage of using an antiferromagnetic film for the pinning film instead of a permanent magnetic film is that the antiferromagnetic film does not itself respond to any external magnetic field since the film has a zero net magnetization.

Synthetic Antiferromagnets

The magnetic coupling between magnetic films closely spaced by certain nonmagnetic metal films oscillates between antiferromagnetic and ferromagnetic coupling. Using this fact, it is possible to design film structures that have a desired magnitude and sign of the magnetic coupling [49.30]. A schematic of a structure of

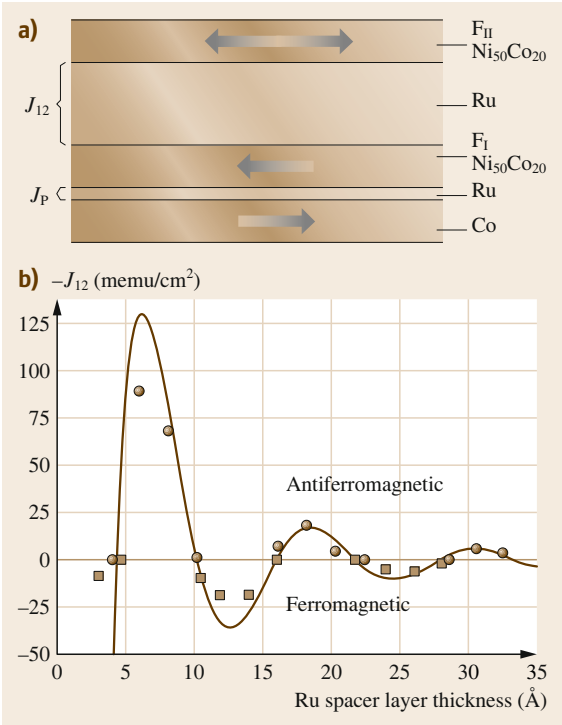

Fig. 49.14 **(a)** Geometry of ferromagnetic films coupled with thin layers of Ru. **(b)** Magnetic coupling constant per unit of film area between layers F_I and F_{II} of the films shown in **(a)** versus the thickness of the Ru layer. (After [49.30])

films that exhibits this variable coupling is shown in Fig. 49.14.

Here the strong antiferromagnetic coupling of Co through Ru to soft $Ni_{80}Co_{20}$ is used to pin the magnetization in the adjacent $Ni_{80}Co_{20}$ film (F_I) to the direction opposite to the Co film and the thickness of the second layer of Ru can be adjusted to change the sign of the coupling between the two soft-magnetic films (F_I and F_{II}). Ruthenium is selected for the coupling film since it has a strong and oscillating coupling between Co, $Ni_{80}Fe_{20}$ and $Ni_{80}Co_{20}$. Ruthenium has the hexagonal close-packed (hcp) crystal structure with ($a = 0.271\,\text{nm}$ and $c = 0.428\,\text{nm}$) while cobalt also has the hcp structure with ($a = 0.250\,\text{nm}$ and $c = 0.410\,\text{nm}$) and therefore the two metals are expected to grow epitaxially.

The experimental coupling constant (J_{12}) for this configuration of layers, where the soft-magnetic film is Ni_{80} Co_{20}, is shown in Fig. 49.14. The units of the coupling constant are $10^{-3}\,\text{emu/cm}^2$ or memu/cm^2 (10 A in SI units) (coupling per unit of film area). The coupling constant can be either antiferromagnetic ($J_{12} < 0$) or ferromagnetic ($J_{12} > 0$) and can have a magnitude varying between $+25 - -75\,\text{memu/cm}^2$ ($+250 - -750$ A). By varying the thickness of the Co layer it is possible to adjust the total magnetic field at the layer F_{II} to be zero.

An overall spin valve consists of a sequence of thin films such as: MnFe 21 Å/Co 30 Å/Ru 7 Å/Co 30 Å/Cu 25 Å/Co 30 Å/$Ni_{80}Fe_{20}$ 28 Å, where the first four films (MnFe/Co/Ru/Co) form a synthetic antiferromagnetic film since the final Co film of these four films is pinned to a direction opposite to that for the first Co film. This Co film then acts as a pinned film in a spin valve together with the final three films (Cu, Co, and $Ni_{80}Fe_{20}$). The thickness of ruthenium listed in the sequence of films is optimum for antiferromagnetic coupling between the Co films. The last Co film is a nanolayer, which increases the magnetoresistive coefficient, as we have discussed [49.23]. The advantages of the synthetic antiferromagnet for pinning the pinned film compared with just an antiferromagnetic film (e.g., FeMn, NiO, NiMn or IrMn) are:

1. The pinning coupling field is an order-of-magnitude larger.
2. The magnetostatic coupling field from the pinned layer to the free layer is reduced since the two Co films in the synthetic antiferromagnet are antiferromagnetically coupled and hence their magnetostatic fields at the free film cancel.

The synthetic antiferromagnet contributes to ensuring that the only magnetic field at the free film is that from the transitions in the recording medium. One last requirement for the proper operation of the spin valve is that there is abutted on the two ends of the structure a permanent magnetic film referred to as the hard bias film (discussed in [49.12]). The permanent magnetic films are similar to the cobalt alloy magnetic films used for disk recording surfaces (to be discussed).

The purpose of the hard bias is to reduce the presence of magnetic domains in the free film and to reduce Barkhausen jumps of the domain walls in the presence of the external magnetic fields from the transitions in the recording medium.

The stack of films used in a spin valve has been discussed. The films used in Fig. 49.15, which we used to illustrate the GMR effect in a $Co_{90}Fe_{10}/Ni_{80}Fe_{20}$ free film, was: Ta (50 Å)/$Ni_{80}Fe_{20}$ (60 Å)/$Co_{90}Fe_{10}$ (55 Å)/Cu (variable)/$Co_{90}Fe_{10}$ (55 Å)/FeMn (100 Å)/Ta (70 Å) [49.21]. In this case the antiferromagnetic film was FeMn (typically about 50%, 50%) and the Ta films are used to protect the rest of the stack.

Origin of GMR

The physical origin of the GMR effect lies in the differential scattering of electrons with spins in the same

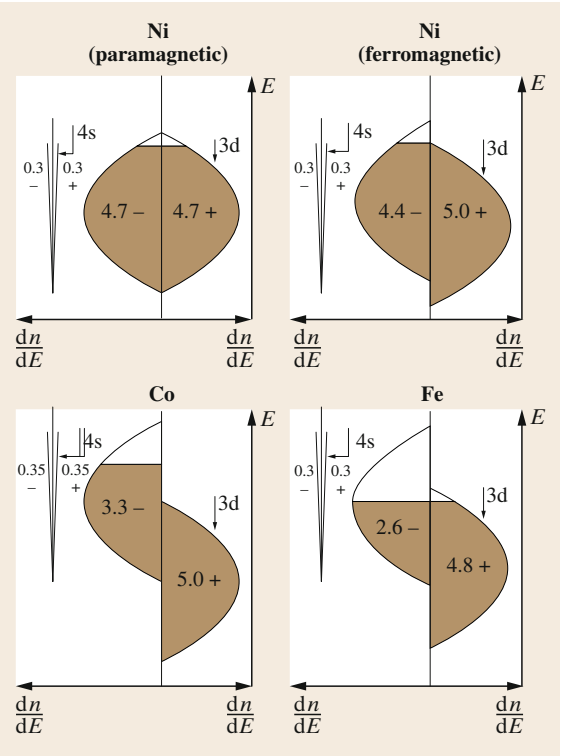

Fig. 49.15 Schematic of density-of-states curves for the ferromagnetic transition elements (Ni, Co and Fe). Both the 4s and 3d bands are shown. The magnetization of the elements is due to the difference between the spins in the spin-up and spin-down bands and the bands are full of electrons to the Fermi level (the *shaded region*). (After [49.31])

direction as the local magnetization (spin-up electrons) or opposite to this direction (spin-down electrons) at the interfaces and in the bulk part of the thin films comprising the GMR stack of films. The ferromagnetic transition elements (Fe, Co and Ni) have different 3d band structures, as shown in Fig. 49.15 [49.31] and discussed by [49.5]. This figure illustrates the energy of electrons in the two half-bands for spin-up and spin-down electrons versus the density of states $D(E)$ (number of states per unit energy per unit volume) in the 3d band for the ferromagnetic transition metals. The 4s bands are also shown. Electrons in the 4s bands make only a small contribution to the net spin, however, due to the larger mobility (inversely proportional to the curvature of the bands), they are largely responsible for the current.

The bands are filled to the Fermi energy at 0 K, and states above, but close to, the Fermi level are occupied at room temperature (illustrated by the shaded region in Fig. 49.15). The conductivity of a metal is given by $\sigma = e^2 v_F^2 \tau D(E_F)/3$, where e is the electron charge, v_F is the velocity of electrons at the Fermi energy, τ is the mean scattering time and $D(E_F)$ is the density of states at the Fermi energy [49.32]. If the mean scattering time (τ) is held constant then it is seen that the conductivity increases with the density of states at the Fermi energy; however, the scattering of the 4s electrons with a given spin is large when there are a large number of scattering centers and empty states with the same spin in the 3d band, i. e., the density of states at the Fermi energy $D(E_F)$ in the 3d band is large.

In ferromagnetic transition metals this is the larger effect [49.33] leading to $\rho = \frac{1}{\sigma} \propto D(E_F)$.

The scattering is due to spin-spin scattering, and spin-orbit scattering is believed to be small [49.34, 35]. The magnetic moment per atom can be deduced as the difference in the number of electrons/atom with spin-up (the majority) versus those with spin-down. For example, the magnetic moment per atom for iron is $4.8-2.6 = 2.2$ Bohr magnetons (μ_B) per atom. From Fig. 49.15 we conclude that the differential scattering will be large in cobalt since for this element the difference in the density of states at the Fermi level is large (approximately 8–10 to 1 [49.31]). A schematic of the density of states versus energy for the three films comprising the spin-valve structure from the two extreme cases of the orientation of the ferromagnetic films (ferromagnetic configuration and antiferromagnetic configuration) is shown [49.31, 36] in Fig. 49.16. All films have same Fermi energy. *Mathon* [49.31] described the GMR effect by discussing the differential scattering of holes in the 3d bands, but by concentrating on the scattering of electrons from the 4s to the 3d band we can make the same conclusions [49.34, 36].

It is assumed that the mean free path for the electrons is large compared with the thickness of any layer in the superlattice. Consider the ferromagnetic configuration case (top of Fig. 49.16): here the majority electrons have spin-up and the scattering of 4s electrons is low in both ferromagnetic films since both have a low density of states at the Fermi level. The nonmagnetic film has a larger density of states and will scatter electrons regardless of the orientation of the ferromagnetic films, which is why this film must be thin. Now consider the antiferromagnetic configuration case in Fig. 49.16: from the density of states at the Fermi level in the three films it is seen that the scattering is large in the right-hand ferromagnetic film for the electrons leaving the left-hand ferromagnetic film with spin-up (top density-of-states curve), resulting in large resistivity for this class of electrons. Similarly, the scattering of spin-down electrons is large for the left-hand ferromagnetic film.

The GMR ratio (%) resistivity for the spin-up and spin-down electrons for the three films (ferromag-

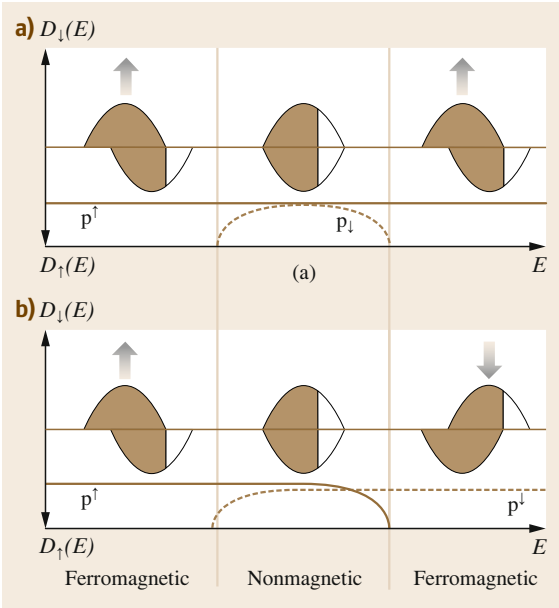

Fig. 49.16 Density-of-states curves for the spin-valve structure in the ferromagnetic spin configuration **(a)** and the antiferromagnetic spin configuration **(b)**. The resistivities of the layers are shown on the *bottom* part of the figures. (After [49.31])

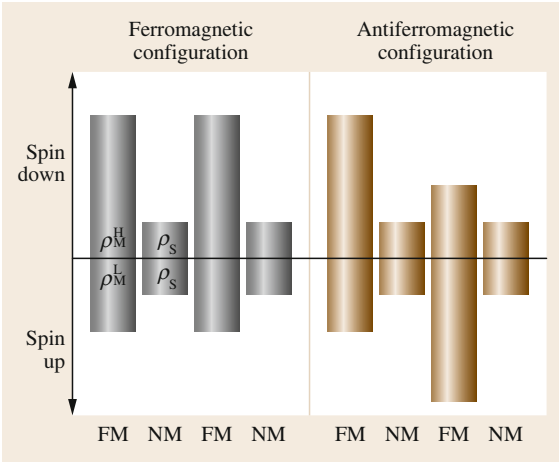

Fig. 49.17 Distributions of local resistivities for the spin-up and spin-down electrons in the ferromagnetic and antiferromagnetic spin configurations. (After [49.31])

netic – FM, nonmagnetic – NM and ferromagnetic – FM) in the ferromagnetic and antiferromagnetic orientation cases is shown as a schematic in Fig. 49.17 [49.31], where it is shown that the ferromagnetic orientation of the ferromagnetic films has a (relatively) low resistivity path for the spin-up electrons while the resistivity for the antiferromagnetic

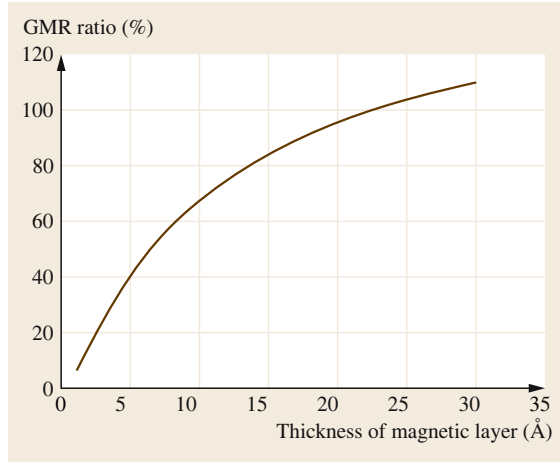

Fig. 49.18 $\Delta R/R$ versus the thickness of the magnetic layer for a nonmagnetic layer thickness of 10 Å for a Co/Cu spin valve. (After [49.31])

orientation of the ferromagnetic films is high for both spin-up and spin-down electrons.

The change in resistance of the spin-valve structure can be analyzed in terms of the different resistivities for the ferromagnetic and antiferromagnetic orientation of the two ferromagnetic films shown in Fig. 49.16 [49.31]

$$\frac{\Delta R_{\max}}{R_0} = \frac{(\alpha-\beta)^2}{4\left(\alpha+\frac{t_{NM}}{t_M}\right)\left(\beta+\frac{t_{NM}}{t_M}\right)}\,, \qquad (49.13)$$

where

$$\alpha = \frac{\rho_M^H}{\rho_s}\,, \quad \beta = \frac{\rho_M^L}{\rho_s}$$

with t_{NM} the thickness of the nonmagnetic film (spacer) and t_M the thickness of the magnetic film. ρ_M^H and ρ_M^L are respectively the high and low resistivities for two spin orientations of the magnetic (M) films, whereas ρ_s is the nonmagnetic (NM) spacer resistivity.

Figure 49.18 shows the variation of $\Delta R_{\max}/R_0$ for $t_{NM} = 10$ Å versus t_M for assumed values of $\alpha = 8.0$ and $\beta = 1.0$, which is appropriate for a Co/Cu superlattice [49.31].

When magnetic film thickness is beyond approximately 10 Å, the change in $\Delta R/R$ decreases. Figure 49.19 shows the variation of $\Delta R/R$ for $t_M = 20$ Å versus t_{NM}.

The decrease in $\Delta R/R$ is rapid with increasing thickness of the NM layer.

This combination of films is not used in spin valves since the cobalt film is not magnetically soft; the usual choice is Permalloy with a variety of nonmagnetic transition metals and the resulting $\Delta R/R$ is lower.

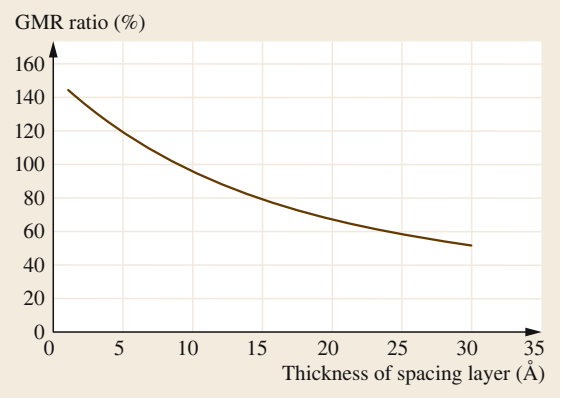

Fig. 49.19 $\Delta R/R$ versus the thickness of the nonmagnetic layer for a magnetic layer thickness of 20 Å for a Co/Cu spin valve. (After [49.31])

49.1.4 Longitudinal Recording Media (LMR)

Magnetic recording media used in disk drives are all sputter-deposited thin films of cobalt alloys for high coercivity and media flux ($M_r\delta$). Coercivities of 4000–5000 Oe are used (2006) and are limited by the ability of the write head to record on the media. The alloys that have evolved are four- or five-element alloys of CoPtCrX, where X is Ta or B or both. A typical atomic concentration of the four-element media is $Co_{64}Cr_{24}Pt_8B_4$. It has been found necessary to form a microstructure in the magnetic film that consists of a phase of small magnetic grains isolated by a nonmagnetic phase. The isolation of the magnetic grains results in less exchange coupling between grains and reduced noise – as we will discuss. Chemical segregation of $Co_{100-x}Cr_x$ alloys forms a nonmagnetic phase (Cr-rich) and a magnetic phase (Co-rich) and the nonmagnetic phase forms at the grain boundaries. The microstructure is controlled by undercoats that promote grain growth with the axes of the grains in the plane of the film. Platinum results in higher crystalline anisotropy and boron promotes the formation of an amorphous alloy of CoCrB, which grows at the grain boundaries, further reducing exchange coupling.

Figure 49.20 shows the microstructure for a magnetic recording surface, illustrating the separation of the grains by the amorphous CoCr phase and, in the lower image, the c-axis stacking of the hcp grains [49.37]. In five-element alloys (CoCrPtBTa), Ta assists the segregation of Cr at the grain boundaries [49.38]. Some recording media use as many as three magnetic layers with the saturation magnetization increasing towards the read head, so that the average saturation magnetization is reduced while the magnetization nearest to the read head is increased.

The layer of films comprising a recording layer at the areal densities for a 130 Gbit/in^2 case were: NiP-plated aluminum substrate with mechanical texturing in the data-recording zone/Cr seed layer/a CrMoX (X = grain-boundary segregation-enhancement element) underlayer/a CoCrT intermediate layer/two ferromagnetic layers (one with high Cr/low B concentration and the second with low Cr/high B concentration) and a double-layer amorphous carbon overcoat [49.39].

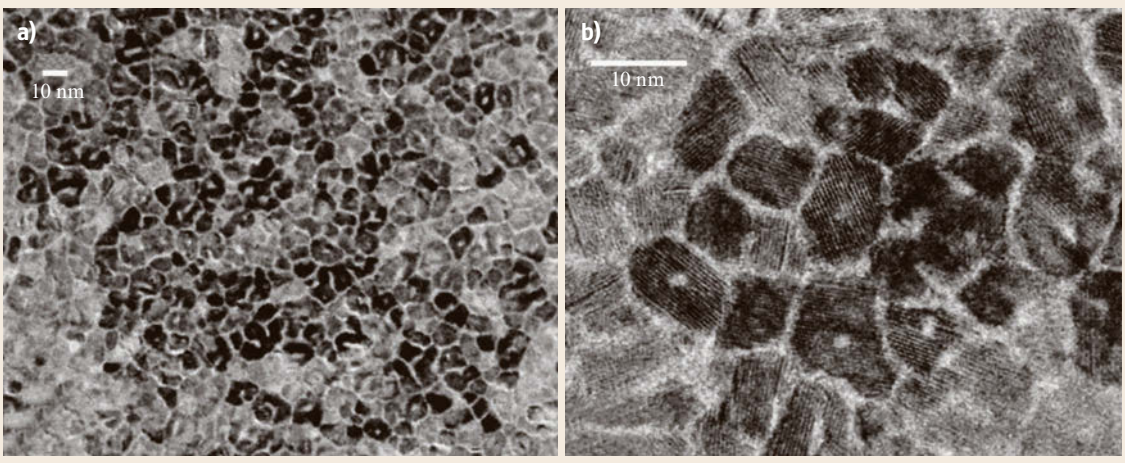

Fig. 49.20a,b Plan-view electron microscope images ((**a**) is lower resolution and (**b**) is higher resolution) of the CoPtCrB magnetic alloy layer used in the 35 Gbit/in^2 case made by IBM. The amorphous grain boundaries are seen as *white* and the *c*-axis stacking of the hcp grains can be seen within the grains in the higher-resolution image. (After [49.37])

The substrate used for the samples in Fig. 49.20 was glass. Glass substrates have several advantages over aluminum with electroless Ni(P) (for hardness) substrates, including increased stiffness, which leads to reduced flutter, increased hardness and reduced propensity to corrosion. However, aluminum substrates continue to be used in nonportable applications because of reduced cost.

The amorphous carbon is required to protect the magnetic film and to give a mechanically rigid surface on which the slider can fly at less than 25 nm.

Media Noise

In digital recording systems the dominant noise voltage, which appears simultaneously with the desired read signal at the terminals of the read head, is that from the recording media, assuming that the resistance from the read head is not excessive. Noise in the read channel is caused by random variations in the location of the recorded transitions.

Transitions are not straight across the recorded track, as we assumed in our discussion of the transition parameter, but instead form zig-zag patterns in order to reduce the large demagnetizing field and demagnetizing energy associated with the longitudinal transition (discussed in [49.5, 12]). Transitions also tend to follow the grain boundaries in the polycrystalline media. To achieve low media noise, it is required to have a small grain size so that the random nature of the grains is averaged over the width of the read head (the track width). An analysis of the signal-to-noise ratio, defined as the base-to-peak signal voltage amplitude (S_0) over the media noise voltage amplitude (N) has been published [49.40]

$$\left(\frac{S_0}{N}\right)^2 = 0.31\left(\frac{B}{a}\right)^2\left(\frac{\mathrm{PW}_{50}}{B}\right)\frac{W_\mathrm{r}}{W_\mathrm{c}}\,, \tag{49.14}$$

where W_r is the width of read head, PW_{50} is the width of the read pulse at 50% of the peak amplitude, W_c is the cross-track correlation width, which has been approximated as the grain or cluster size of the recording media. The grain size has a log-normal distribution and W_c is the mean of the distribution, a is the transition parameter discussed above, and B is the length between bits.

For a reliable low error rate the value of $20\log S_0/N$ is required to be above 26–27 dB and this has required an increasingly smaller grain size as the width of the read head has decreased, resulting in higher track densities. For a 10 Gbit/in^2 system, the value of W_r was 0.505 μm and the required mean of the grain size was 12 nm [49.41].

The ratio B/a has been ≈ 3 to avoid severe distortion of the transition across the track, referred to as percolation (discussed in [49.5]) and the ratio PW_{50}/B has been in the region 2.5–2.8 for the type of detection channels used in disk drives (partial response maximum likelihood – PRML).

Therefore, to maintain constant S_0/N the ratio of the track width to the grain size must be kept constant and, with the decreased track width, the grain size must decrease in proportion. Increased areal density has required decreased mean grain size but, equally important, tighter distributions of grain size. The distributions are closely matched by log-normal distributions of the form

$$y = \frac{1}{\sigma_\mathrm{Z}\sqrt{2\pi}}\exp\left(-\frac{(Z-\bar{Z})^2}{2\sigma_\mathrm{Z}^2}\right), \tag{49.15}$$

where Z is the $\log_{10}$ value of the grain diameter, $\bar{Z}$ is the mean value of Z and σ_Z is the standard deviation of Z.

Grain-size distributions are measured on foils by tunneling electron microscopy (TEM). Figure 49.20 shows the microstructure of a typical recording surface, emphasizing the segregation of the grains by the nonmagnetic constituents of the alloy.

The distribution of the grain sizes in recording media for 20 GB/platter (counting both sides of the platter) and the higher density 80 GB/platter are shown in Table 49.3 [49.7]. Both the mean and standard deviation for the 80 GB/platter are reduced from those of the 20 GB/platter media.

We will discuss the decay rates shown in Table 49.3 in the next section. The trend in the mean grain size and grains per bit for recording films versus areal density is shown in Fig. 49.21 [49.7]. A serious problem with this trend is the fact that the ratio of magnetic to nonmagnetic volume in the film is decreasing faster than the average grain size, which results in the number of grains per bit decreasing faster than the average grain size. The price to be paid for the increasingly small grain size is the stability of the recorded data over time as we discuss in the next section.

Table 49.3 Comparison of 20 and 80 GB/platter disk characteristics. (After [49.7])

	20 GB/90 mm disk	80 GB/90 mm disk
H_c (Oe)	2700	4200

Average grain size (nm)	10.8	9.1
Distribution sigma	0.41	0.24
Amplitude decay rate (%/decade)	0.7	0.4

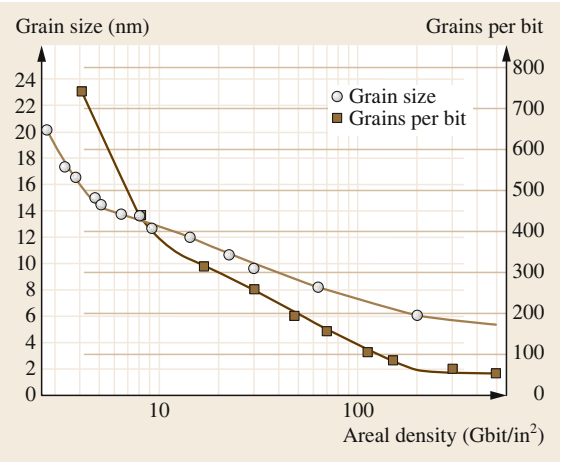

Fig. 49.21 Grain size and grain/bit for sputtered cobalt alloys as a function of areal density in Gbit/in^2. (After [49.7])

To investigate how far the areal density can be extended with LMR, use has been made of the signal-to-noise ratio calculation to see if an areal density of 200 Gbit/in^2 is feasible. To ensure that the signal-to-noise ratio does not degrade when extending the areal density from 60 to 200 Gbit/in^2, it is required that: (a) the transition parameter be reduced from 12.8–6.2 nm, to achieve which the coercive field (H_c) must be increased from 4000–5000 Oe, and (b) the product of the magnetization and thickness ($M_r\delta$) be reduced from 0.32–0.2 memu/cm^3. In addition, the HMS must be reduced from 30–15 nm [49.7].

Superparamagnetic Effect

To maintain the growth in areal density as shown in Fig. 49.1, it is necessary to reduce the physical dimensions of the recording system components and to maintain the signal-to-noise ratio at levels required for satisfactory error rates. This includes reducing the mean grain size of the recording media. However, at some grain size the thermally driven fluctuations of the orientation of the magnetization in the isolated grains result in increased probability of the magnetization being switched from the desired orientation, as initially recorded, to the opposite direction. This instability of the magnetization is the superparamagnetic effect. The magnetic energy in an isolated grain is K_uV, where K_u is the uniaxial anisotropy consisting of crystalline, magnetostriction and shape contributions whereas $V = (\pi(D/2)^2\delta)$ is the volume of the particle or grain with diameter D.

Thermal energy supplied from the environment to the particle is k_BT, where k_B is the Boltzmann constant (0.8619×10^{-4} eV/K). An analysis of

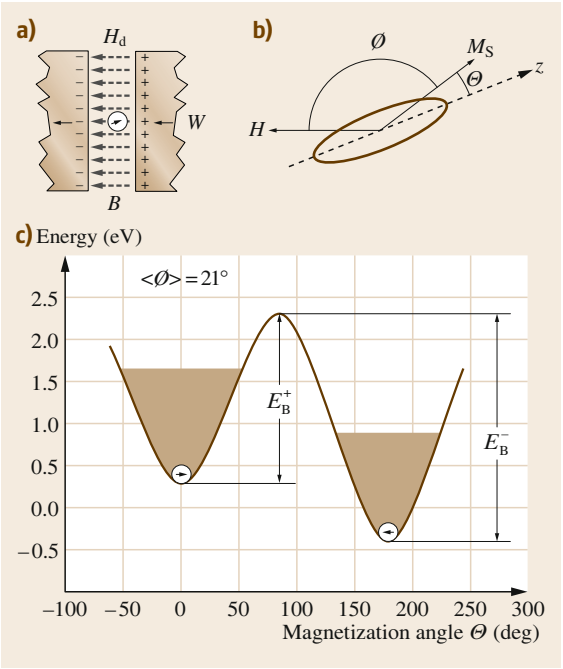

Fig. 49.22 Calculated energy **(c)** of an isolated single-domain particle **(b)** at the center of an 80 nm-long dibit **(a)** (double transition). The properties of the particle are listed in Table 49.4. The ratio of the barrier height to thermal energy is 43 (see text) and the height $43k_BT$ is shown *shaded*. There is margin between the top of the shaded region and E_B^+ and the particle is stable for the time t_x of 10 y. (After [49.42])

the superparamagnetic effect using an isolated small single-domain asymmetrical particle is summarized in Fig. 49.22 [49.42]. Here, the magnetic particle is assumed to be in the center of two transitions and the energy contour results from an analysis using only shape and crystalline anisotropy (combined into K_u) and magnetostatic energy terms

$$E(\theta,\phi) = K_uV\sin^2\theta + HM_s\cos(\theta-\phi)\,. \qquad (49.16)$$

It is assumed in Fig. 49.22 that the angle ϕ has a mean value $\phi = 21°$. The energy contour shown in Fig. 49.22 results from the application of (49.15) with the parameters listed in Table 49.4. The energy required to switch the particle from the initially magnetized direction is shown as E_B^+. In the absence of an external or demagnetizing field, the energy barrier is $E_B^+ = K_uV$.

With a demagnetizing field (H_d) the switching field is reduced since the field is in the direction of the switched magnetization

$$E_B^+ = K_uV\left(1-\frac{|H_d|}{H_0}\right)^{\frac{1}{2}}\,. \qquad (49.17)$$

Table 49.4 Energy of single-domain particle in a magnetic field of two transitions. K_u is particle anisotropy energy, consisting of shape and crystalline anisotropy contributions, H_d is the demagnetizing field between transitions and ϕ is mean field angle with respect to grain or particle axis. A dibit is a double transition corresponding to a double change in magnetization orientation. (After [49.42])

Parameter	Value
B (dibit length)	80 nm
K_u	1.5×10^6 erg/cm^3 (1.5×10^5 J/m^3)
$M_r\delta$	0.39 memu/cm^2 (3.9 mA)
M_s	375 emu/cm^3 (375×10^3 A/m)
D (grain/particle diameter)	15 nm
δ (media thickness)	13 nm
V (grain/particle volume)	$\pi(D/2)^2\delta$
H_d	780 Oe (62 kA/m)
ϕ	21°

With a random two-dimensional (2-D) system $H_0 = 2K_u/M_s$. The magnetization of the particle will switch when $H_0 = H_d$. When the magnetization of the particle is switched, the new energy barrier is E_B^- and is increased in depth since the demagnetizing field is now in the same direction as the magnetization. Using the set of parameters listed in Table 49.4, the depth of E_B^+ (with a demagnetizing field of 780 Oe (62 kA/m)) is approximately 1.9 eV.

The time constant for the thermally driven switching of the magnetic particle in the presence of a magnetic field, which in the case under consideration is the demagnetizing field acting on the magnetic particle, can be found using an Arrhenius–Néel model

$$\tau = \tau_0 \exp\left(-\frac{E_B^+(H)}{k_B T}\right), \tag{49.18}$$

where $\tau_0 = 1/f_0$ and f_0 is an *attempt frequency*, usually taken as $\approx 10^9$ Hz [49.42]. The energy barrier depends on the thermal energy and the fraction x ($0 < x < 1$) of the retained magnetization and the storage time t_x

$$E_B^+(H) = k_B T \ln\left(\frac{t_x f_0}{|\ln x|}\right),$$
$$t_x = |\ln x|\, \tau_0 \exp\left(\frac{E_B^+(H)}{k_B T}\right). \tag{49.19}$$

As an example, if the required storage time is $\approx 10^8$ s (10 years) and the percentage loss of data amplitude is 5%, then $x = 0.95$ and $|\ln 0.95| = 0.05$ and

$$\frac{E_B^+(H)}{k_B T} \approx 43\,.$$

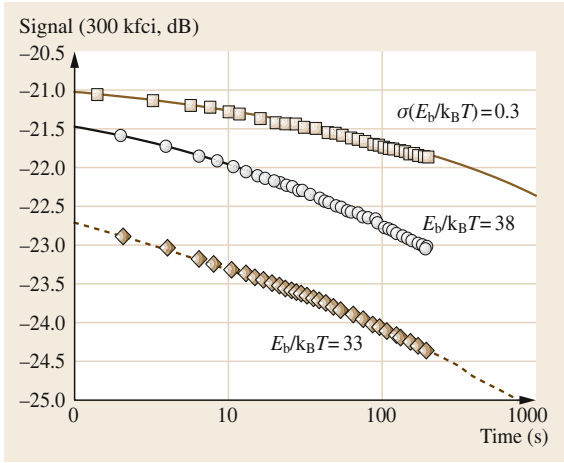

Fig. 49.23 Signal loss versus time at room temperature and 300 kflux changes per inch (kfc/in) for three magnetic recording surfaces: The first two (*from the top*) are SFM or AFC media with layer thicknesses of: [12 nm/0.7 nm/4 nm] (*open square*), [12 nm/1.4 nm/4 nm] (*open circle*). The lower curve is for a 12 nm single layer (*solid diamond*). (After [49.43])

The thermal energy $k_B T$ at 350 K (the assumed operating temperature of a typical disk drive) is 0.03 eV, 43 $k_B T \approx 1.29$ eV and the shaded region in Fig. 49.22 has this energy level. Since there is some margin between the thermally driven contribution to switching and the top of the barrier, the particle is stable (over the 10 year period). However, for smaller volumes (V) the value of E_B^+ decreases and the particle could become unstable.

For example, if the thickness of the recording media is reduced from that assumed in Fig. 49.22 (13 nm) to 6 nm, the value of E_B^+ is reduced to ≈ 0.9 eV and the thermal energy would easily switch the particle. A dramatic loss of data over time is observed with recording media with media flux ($M_r\delta$) less than about 0.25 memu/cm^2. Figure 49.23 shows amplitude loss of recorded data for three different media at a linear density of 300 kfc/in (kflux changes per inch) at room temperature [49.43]. The three media are: a single-layer of CoCrPtB (lowest curve with a thickness of 12 nm); and two recording surfaces we will discuss in the next section. The signal decay rate R is defined as

$$R(H_d, T) = 100\frac{\left(\frac{A(t)}{A(t_0)} - 1\right)}{\log\left(\frac{t}{t_0}\right)}, \tag{49.20}$$

where the signal amplitude of a square-wave pattern is $A(t)$. With $t_0 = 1$ s, the decay rate per decade for the

media shown as the lower curve in Fig. 49.23 is found to be −7.19%.

The decay rate for the other media will be discussed in the next section. The decay rates for the two recording films shown in Table 49.3 are −0.7%/decade and −0.4%/decade for the 20 GB/platter and 80 GB/platter media respectively. In a conventional disk recording system this superparamagnetic effect was judged to limit the areal density to somewhere in the range 36–100 Gbit/in^2 (reviewed in [49.42]). Formally the superparamagnetic limit to areal density in LMR is set at 100 Gbit/in^2.

The superparamagnetic effect and the requirement for low media noise result in recording-system designers being caught in two inconsistent requirements: first, a small grain size for the recording media is required for adequate signal-to-noise ratio, so that the number of grains per bit remains constant (49.13), and second, a large grain size is required for small data loss over time because of the superparamagnetic effect ((49.16) and (49.17)). The requirement to reduce the thickness of the recording media can be deduced from the need for low values of $M_r\delta$ for short transition lengths (49.5). The approach of increasing the anisotropy of the grains to increase K_uV to resolve the superparamagnetic effect is limited by the ability of write heads to record on the media with the resulting increased media coercivity.

Table 49.3 shows that the decay rates observed with the smaller grain size/higher density media is actually smaller than that for the larger grain size/lower density media. A possible explanation is that the K_uV values for the smaller grains are higher than for the larger grains [49.7]. In the next section we discuss a novel approach that has extended the progression in areal density.

Antiferromagnetically Coupled (AFC) or Synthetic Ferrimagnetic (SFM) Media

The invention of a novel recording media decreasing the impact of the superparamagnetic effect was accomplished simultaneously by teams of researchers at the Fujitsu and IBM Almaden Research Laboratories [49.44, 45].

The recording media consists of two ferromagnetic layers coupled by a thin layer of ruthenium (antiferromagnetically coupled – AFC or synthetic ferrimagnetic media – SFM), which results in an antiferromagnetic coupling of the two films, similar to that used in the spin valve for a synthetic antiferromagnet. In order for the coupling between the two ferromagnetic layers to be antiferromagnetic, the thickness of the ruthenium layer, referred to by IBM as *pixie dust*, is required to be approximately 0.6 nm [49.45]. A schematic of the antiferromagnetic coupled media and the resulting hysteresis curve is shown in Fig. 49.24 [49.43]. The sharp reduction in the remanent magnetization at ≈ 80 Oe is due to the switching of the thinner lower layer (M_rt_2) and the lowered value of the remanence is advantageous for reduced transition noise and transition length.

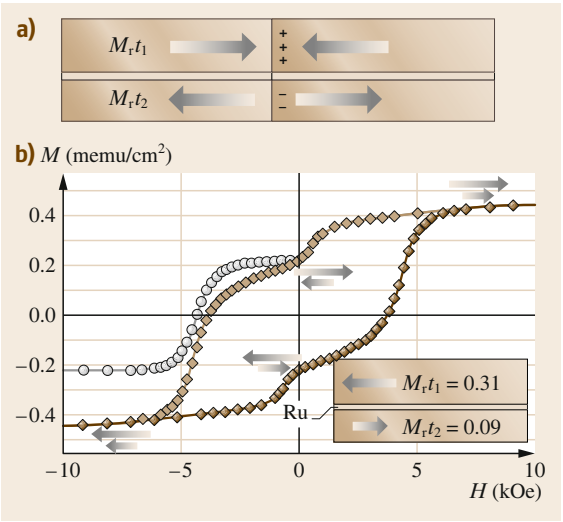

Fig. 49.24 (a) Schematic of the antiferromagnetically coupled (SFM or AFC) media showing the two ferromagnetic layers coupled by a thin layer of ruthenium (*pixie dust*) and with a single magnetic transition for which the magnetizations in the two layers are oppositely directed. **(b)** Magnetic hysteresis curve for the SFM or AFC media with remanent thickness products for the two ferromagnetic layers shown in the inset and measured at 350 K. The *filled triangles* are the major hysteresis curve and the *filled circles* are the remanence hysteresis curve. The *arrows* show the directions of the magnetization in the two films. (After [49.43])

The curve with solid circles is a remanence hysteresis curve measured by subjecting the sample to a negative reversing field and then increasing the field in a positive direction to zero and plotting the remanent magnetization. This measurement is an attempt to simulate what happens when a recording medium leaves the vicinity of the recording head.

By analyzing the read pulse from the transition in the upper layer combined with the read pulse from the transition with reversed sign from the lower layer (the layers are antiferromagnetically coupled), it can be shown that no degradation of the resolution (PW_{50}) of the system results from having two as opposed to one recording layer [49.45]. The advantage of the AFC or SFM configuration is that the medium is in fact thicker than would be required for the given recording density using a single layer and hence is less susceptible to the superparamagnetic effect (49.17).

The effective volume is bounded by $K_u V_1 < K_u V_{\text{eff}} < K_u V_1 + K_u V_2$. In the case of tight coupling and alignment of grain axes, the upper limit can be approached. The effective remanent magnetization-thickness ($M_r\delta$) product while close to $M_r t_1 - M_r t_2$, reduces the pulse width over that of a single-layer recording medium (49.10). Because of the antiferromagnetic coupling, an exchange magnetic field $H_{ex,2}$ acts on the lower magnetic film

$$H_{ex,2} = \frac{J_{ex,2}}{M_2 t_2}$$

and a typical value for the antiferromagnetic exchange constant $J_{ex,2}$ is $0.06\,\text{erg/cm}^3$ ($6\,\text{mJ/m}^3$) [49.46].

For the magnetization of the lower layer to assume the opposite direction to that of the top layer, before the field H is reduced to zero, it is required that $H_{ex,2} > H_{c2}$. The antiferromagnetic exchange constant can be increased by adding thin layers of cobalt or cobalt alloys known as *E layers* to both sides of the ruthenium layer [49.47]. The increase in the antiferromagnetic exchange constant is rapid with increasing thickness of the *E layers* and we show in Table 49.5 a listing of J_{ex} for several *E layers* [49.47].

The largest increase in J_{ex} is with cobalt, but this material suffers from significant degradation on overwrite and poor signal-to-noise ratio compared with cobalt alloys. To illustrate that the AFM or SFM media configuration actually results in reduced amplitude loss over time, we show in Fig. 49.23 the amplitude loss with two SFM media: 12/0.7/4 (open squares) and 12/1.4/4 (open circles), where the numbers are the thickness of the three layers in nm and the value of E_B/k_BT is 38 [49.43]. The signal decay rate is -4.14% per decade for the top curve (open squares) and -6.45% per decade for the middle curve (open circles) [49.43].

The coupling between the two magnetic films is antiferromagnetic for the top curve and ferromagnetic for the middle curve and the lower curve is a single magnetic layer. The AFM or SFM media clearly reduces the decay rate. The improvement is even more significant with a larger value for E_B/k_BT and values of R less than 1%/decade with $M_r t$ values lower than $0.2\,\text{memu/cm}^2$ have been reported by IBM researchers using static magnetization measurements with a reversing magnetic field to mimic the demagnetizing field [49.45].

AFM media started out being used in IBM portable disk-drive applications [49.45]. Areal densities larger than $100\,\text{Gbit/in}^2$ have been used with LMR using AFM media [49.48].

The magnetic recording layers were alloys of CoCrPtB with an average grain size of 9.4 nm. The write head was trimmed on the air-bearing surface to the final track width using a focused ion beam and the track density was 149 ktracks/in and the bit density was 720 kbits/in [49.48].

The data shown in Table 49.3 also shows that it is possible to achieve low decay rates with single recording layers [49.7]. Analysis comparing SAF and single-layer media has shown that the single layer media is preferred unless the media flux drops below about $0.25\,\text{memu/cm}^2$ with H_c values constrained below 4300 Oe. If recording heads are able to record with adequate overwrite on media with coercivity greater than 4300 Oe, then the single-layer media is preferred [49.49].

Table 49.5 Comparison of materials for *E layers*: J_{ex} values and degradation in overwrite and signal to media noise. Note that negative dB values of overwrite degradation indicate improved overwrite. Both degradations in overwrite and S/N_m are considered without *E layers*. (After [49.47])

Material for *E layers* (all 1 nm thick)	Co	Co-Cr	Co-Cr-X
J_{ex} (erg/cm^2)	0.73	0.59	0.24
Degradation in overwrite (dB) with respect to SFM media	10	≈ 3	≈ -6
Degradation in $(S/N)_m$ (dB) with respect to SFM media	≈ 4.5	≈ 1.6	≈ 1.5

Dynamic Coercivity

Another manifestation of thermal effects on magnetic properties is a change in coercivity with switching time. With long periods of time the probability that a particle will switch is increased by thermal excitation and with short periods this probability is decreased, leading to a change in the coercivity of the particle. An experimental study of this effect was done on a test stand in which a stationary write head is driven by a current pulse of variable duration over a previously magnetically saturated recording medium. The current pulse records two transitions (a dibit). The width of each transition is essentially the gap of the write head and the length of the reversed magnetization region varies with the pulse width (t_p). The dibit is read with a magnetoresistive sensor moved across the recorded transitions resulting in a dibit pulse. By measuring the amplitude of the dibit signal as a function of the pulse width and varying the magnitude of the reverse field and measuring $H_{head}(I)$ (head field versus current) it is possible to deduce the remanent coercivity (H_{CR}) as a function of t_p. The resulting curves of H_{CR}/H_{CR} (1 ns) are shown in Fig. 49.25 [49.42]. The experimental slope C increases as the thickness decreases.

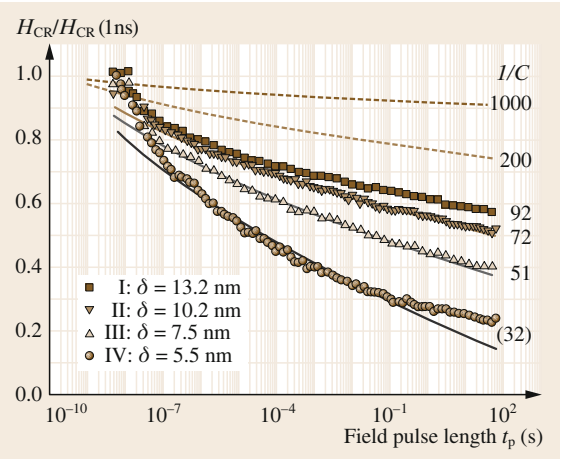

Fig. 49.25 Dynamic coercivity $H_{CR}(t)$ normalized by its value at $t = 1$ ns for a series of $Co_{64}Pt_{14}Cr_{22}$ films with variable thickness. (After [49.42])

The inverse slope parameter is given by

$$\frac{1}{C} \approx \frac{K_u V}{k_B T} ,$$

which is the superparamagnetic stability parameter discussed above and it is observed that, even with a stability factor larger than 51, for which the superparamagnetic region is avoided, the coercivity increases significantly for short switching times. This is the actual coercivity that must be exceeded by the write-head magnetic fields to switch a recording film.

49.1.5 Perpendicular Magnetic Recording

The technology that supplanted LMR is perpendicular magnetic recording (PMR). Perpendicular recording offers a way out of the conundrum caused by the need for thinner recording media for improvements in recording density and the need for larger particles to reduce the impact of superparamagnetism.

While smaller particles are needed to increase areal density in LMR, particle size in PMR has kept its value around 7–9 nm since it was introduced for the first time in 2006.

In perpendicular recording the magnetization in the recording media is held perpendicular to the surface of the recording media by a perpendicular anisotropy large enough to overcome the large demagnetizing field with this orientation of the magnetization. A schematic of a perpendicular recording system including a probe write element and a magnetically soft underlayer (SUL) is shown in Fig. 49.26. It is also possible to have a perpendicular recording system with a ring write head and a single-layer media, but this approach has not been developed.

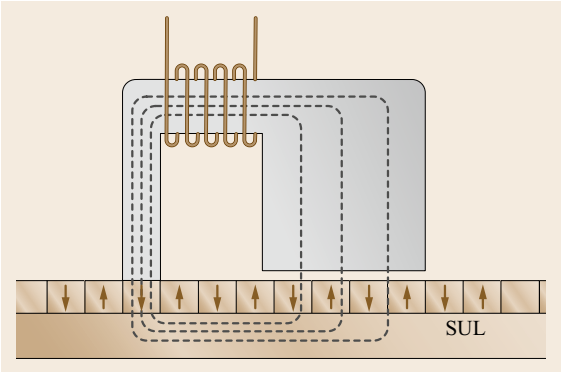

Fig. 49.26 Schematic of a perpendicular recording system. (After [49.5])

In contrast to LMR, the SUL is required for a low-reluctance path for the magnetic flux generated by the coil on the write element. One advantage of perpendicular recording is that the magnetic field for recording is larger than that for LMR since the magnetic field from the write pole is in the gap of the write head, in contrast to LMR where the field leaks from the write gap. A schematic of the total geometry for LMR and PMR is shown in Fig. 49.27 [49.1]. Reading for PMR is accomplished with a GMR sensor as with LMR evolving later into tunnel magnetoresistance (TMR).

Historically, when areal density was around 100 Mbit/in^2 (at the beginning of the 1990s) the read sensor was based on simple magnetoresistance. In the mid-1990s it evolved into a spin-valve GMR sensor for areal densities larger than 1 Gbit/in^2. In 2006 TMR valves were used for areal densities larger than 100 Gbit/in^2 and in 2011, CPP-GMR read heads started to be used for areal densities close to 1 Tbit/in^2. Typically a TMR head is about 70 nm wide whereas a CPP-GMR head is about 30 nm in width.

The major difference in the write head is that it uses a single pole to generate the perpendicular magnetic field with a wider return pole (to reduce reluctance). The write head for perpendicular recording is imaged in the SUL and this results in an increase in the strength of the magnetic field by approximately a factor of two. In addition, due to imaging effects, the effective number of turns on the write head is doubled for perpendicular recording. It is important for perpendicular recording that the magnetization of the SUL magnetic material be larger than that for the pole of the write head [49.50].

This is the case to prevent the SUL from saturating before the pole tip saturates, resulting in a decrease in the gradient of the head field, which would result in an increased transition length (to be discussed). A large

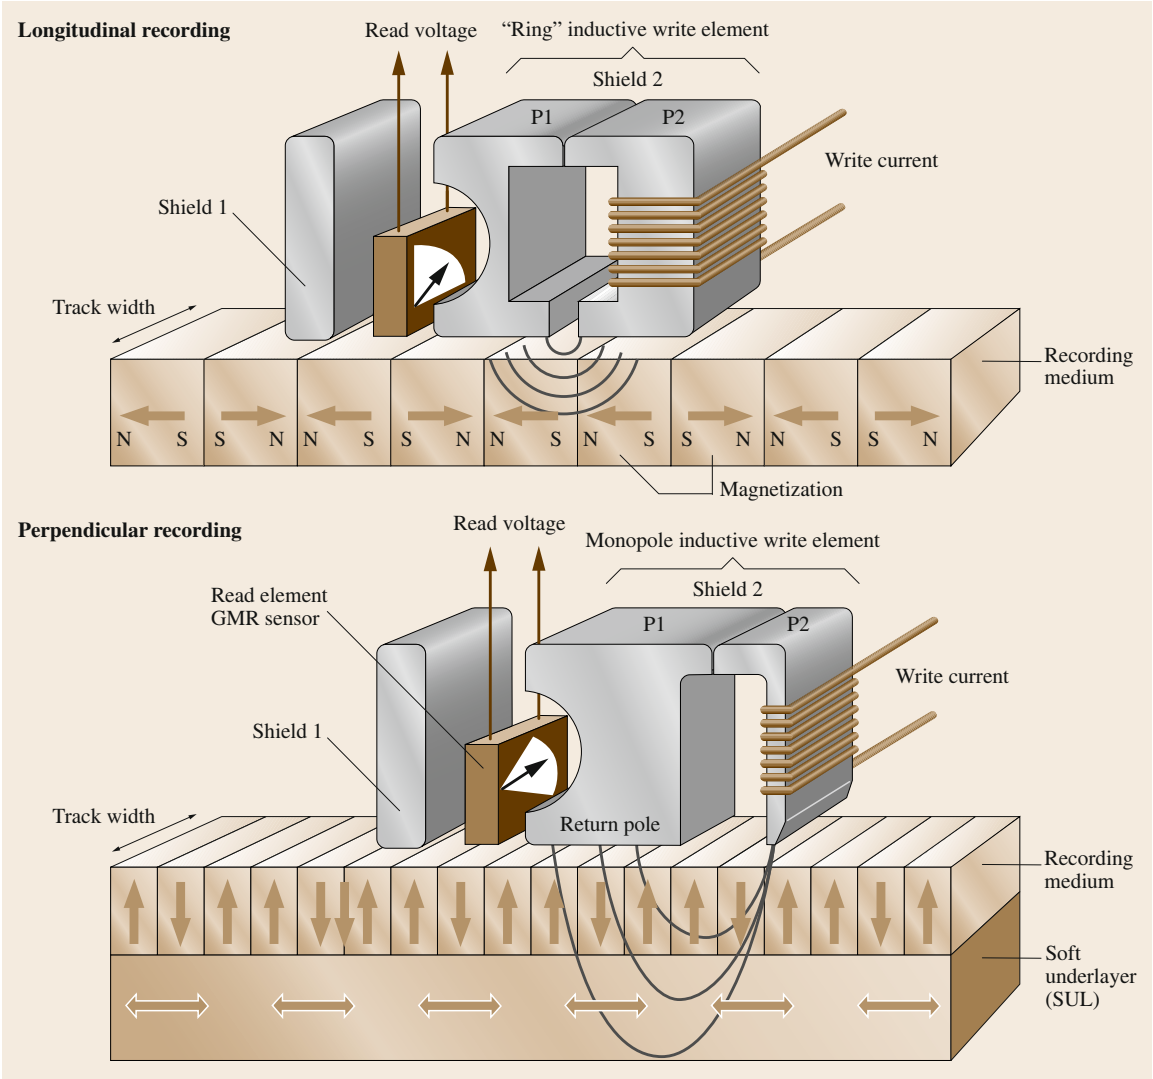

Fig. 49.27 Schematic of longitudinal and perpendicular recording systems. (After [49.1])

magnetic field and gradient of magnetic field from the write head can record media with a larger coercive field than for LMR, which results in a reduced transition length. Perpendicular-recording media can be made thicker than for longitudinal media for the same areal density. The media thermal stability factor ($K_u V/k_B T$) is increased both by an increase in K_u by virtue of the increased coercive field but also by the increase in the volume (V) with the thicker media. Reading of the magnetic transitions with perpendicular recording is done with a spin-valve head as with LMR – the difference being that with perpendicular recording the response is a step instead of a pulse (to be discussed).

A significant development for perpendicular write heads is the addition of a trailing-edge shield to the head that results in an improvement in the concentration of the writing flux and an increase in the gradient of the head field (dH_y/dx), which reduces the transition length [49.51, 52]. A schematic of a write head with a trailing-edge shield is shown in Fig. 49.28 [49.53]. The shield connects to the larger return structure for the head shown in Fig. 49.27.

The particular geometry and saturation magnetization of the main pole and the front yoke or trailing-edge shield were used in a two-dimensional finite element model to calculate the head fields and shape of the recorded transition [49.53]. Results of the simulation of transition shape are shown in Fig. 49.29, where it is seen that the recorded transition is considerably sharper with the head with the front yoke compared with the head

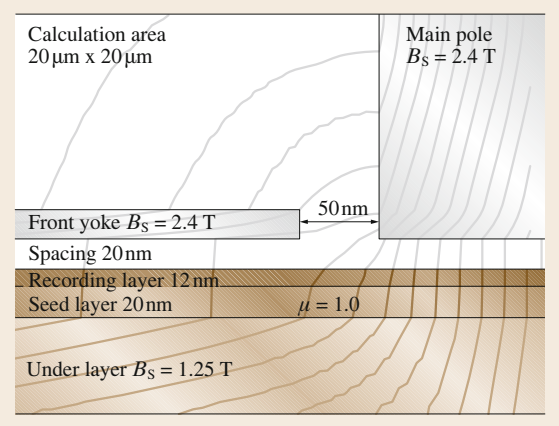

Fig. 49.28 Schematic of a perpendicular recording head including the main pole and the front yoke or trailing-edge shield. (After [49.53])

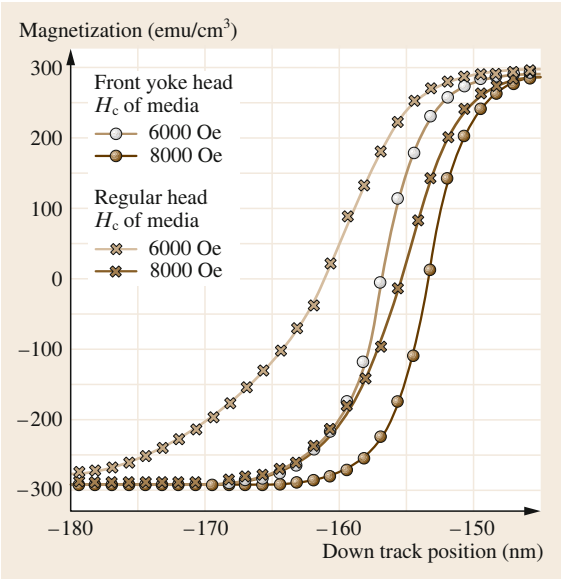

Fig. 49.29 Magnetic transitions in perpendicular recording with and without the front yoke or trailing-edge shield. (After [49.53])

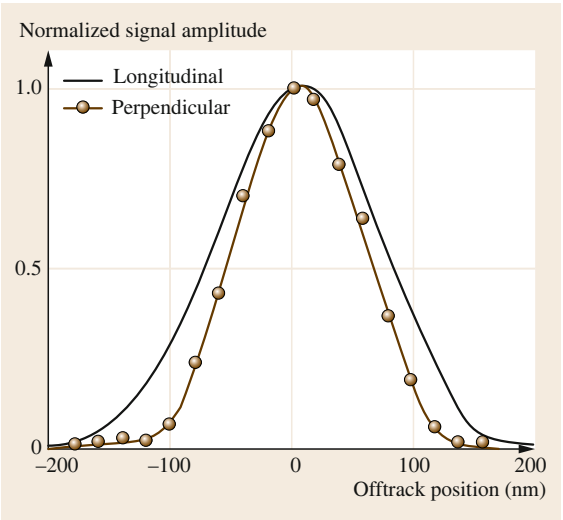

Fig. 49.30 Cross-track profile of the signal with perpendicular and longitudinal recording. (After [49.52])

without the shield, particularly with the higher coercivity media ($H_c = 8000$ Oe).

The perpendicular magnetic field has the amplitude reduced to one-half at a distance of $0.8d_0$ with the shield and $1.3d_0$ without the shield (assuming that the spacing of the shield is separated from the main pole by a distance d_0) [49.52]. The shield shunts some of the write flux, reducing the amplitude of the write field, so it is important to keep the height of the shield short. Another advantage of the trailing-edge shield is that a horizontal component of the field is added. This field reduces the field for switching since, if the angle of the field is θ, the switching field is

$$H_{\text{switch}} = \frac{H_k}{\left[(\cos\theta)^{\frac{2}{3}} + (\sin\theta)^{\frac{2}{3}}\right]^{\frac{3}{2}}},$$

where H_k is the anisotropy field of the perpendicular medium. The denominator of this equation is always larger than one and hence the switching field is reduced for angles θ larger than zero degrees. Note that this equation is the switching astroid equation used to explain the operation of the MRAM.

A significant advantage of PMR as compared with LMR is the narrower off-track read profile as shown in Fig. 49.30 [49.52]. This improvement in read profile leads directly to increased track density. There are limitations to the achievable track density in disk drives where there is significant skew of the head with respect to the track center line. Head skew results from the fact that disk drives use rotary actuators and the angle of the written transition with respect to the track center line varies as the actuator is rotated across the disk, being largest at the inside and outside diameters. With head skew it is possible for the write element of the head to be placed over the guard band or adjacent track of a selected track, resulting in unwanted recording in these areas. This problem is reduced by using trapezoidal poles [49.54]. Shields can be added to the side of the head to reduce this erasure of adjacent track information; however, the processing of such shields is complex.

Media for Perpendicular Recording

The magnetization and anisotropy in a perpendicular recording film is shown in Fig. 49.31. The energy of the magnetization in the presence of the demagnetizing, anisotropy and magnetostatic energies (Gaussian units) is

$$E = 2\pi M_s^2 \cos^2\theta + K_u \sin^2\theta - H_{ext} M_s \cos\theta \,, \tag{49.21}$$

where the demagnetizing factor for a thin film magnetized normal to the surface is 4π. The equilibrium angle is given by the solution to

$$\frac{dE}{d\theta} = -2\pi M_s^2 \sin 2\theta + K_u \sin 2\theta + H_{ext} M_s \sin\theta = 0 \,. \tag{49.22}$$

For stability

$$\frac{d^2E}{d\theta^2} = -4\pi M_s^2 \cos 2\theta + 2K_u \cos 2\theta + H_{ext} M_s \cos\theta > 0 \,. \tag{49.23}$$

The solution is $\sin\theta = 0$ ($\theta = 0°$ or $180°$) and the stability condition for $H_{ext} = 0$ results in $2K_u > 2\pi M_s^2$.

Alloys under consideration for perpendicular recording include those listed in Table 49.6 [49.55], and Tables 49.7 and 49.8. A review of work on perpendicular recording media was published [49.56]. It is observed from this table that these candidate materials satisfy the condition (49.22). The critical magnetic field below which the $\theta = 0°$ solution is no longer stable is given by the solution to (49.21) with $H_{ext} \neq 0$, resulting in

$$H_e^*(\theta = 0°) = -\frac{(2K_u - 4\pi M_s^2)}{M_s} \,,$$
$$H_e^*(\theta = 180°) = \frac{(2K_u - 4\pi M_s^2)}{M_s} \,. \tag{49.24}$$

The solution to (49.21) with $\sin\theta$ factored out is

$$-4\pi M_s^2 \cos\theta + 2K_u \cos\theta + H_{ext} M_s = 0 \,. \tag{49.25}$$

Thus

$$H_{ext} = \left(4\pi M_s - 2\frac{K_u}{M_s}\right)\cos\theta$$

and

$$\frac{M_\perp}{M_s} = \cos\theta = \frac{H_{ext}}{\left(4\pi M_s - 2\frac{K_u}{M_s}\right)} \,.$$

This solution applies when the magnetization curve is not saturated. Note that H_e^* is not the same as the coercive field where

$$M(H_{ext} = H_c) = 0 \,.$$

The coercive field is found from (49.24) by recognizing that the magnetic field

$$H_{ext} = -|H_e^*| - H' \,,$$

where H' is measured from $-|H_e^*|$. The coercive field is then

$$H_c = -2|H_e^*| \,.$$

The result for a Co-Cr-Pt alloy (Table 49.7) with the following parameters: $K_u = 1.45 \times 10^6$ erg/cm^3, $M_s = 280$ emu/cm^3 is as follows

$$H_e^*(\theta = 0°) = -\frac{(2K_u - 4\pi M_s^2)}{M_s}$$

thus

$$H_e^*(\theta = 0°) = -6.84\,\text{kOe} \quad \text{and}$$
$$H_e^*(\theta = 180°) = 6.84\,\text{kOe} \,,$$

whereas

$$\frac{M_\perp}{M_s} = \frac{(H_{ext} + 2|H_e^*|)}{|H_e^*|} \,,$$
$$H_c = -13.68\,\text{kOe} \,.$$

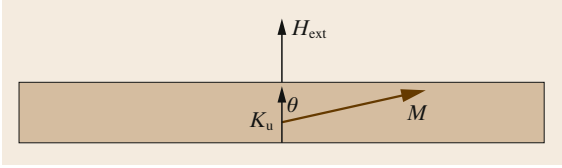

Fig. 49.31 Magnetization and perpendicular anisotropy for a perpendicular recording media. (After [49.5])

Table 49.6 Magnetic properties of selected materials for perpendicular recording. (After [49.55])

Material	H_k (kOe)	M_s (emu/cm^3)	K_u (erg/cm^3 10^6)	$2\pi M_s^2$ (emu/cm^3)^2
Co-Cr	7	270	0.95	0.46
Co-Cr-Pt	10	280	1.45	0.49
Co/Pd	17	350	2.98	0.77
Fe/Pt	28	750	10.5	3.53

Table 49.7 Properties of hard magnetic materials that might be used for PMR [49.57]. All these materials are considered as uniaxial and capable of sustaining $D_p \leq 10\,\text{nm}$ grain sizes over 10 year storage time. Physical parameters include anisotropy field: $H_k = 2K_u/M_s$, domain wall width: $\delta_w = \pi\sqrt{A/K_u}$, domain wall energy: $\gamma_w \approx 4\sqrt{AK_u}$, single particle domain size: $D_c = 1.4\gamma_w/M_s^2$, exchange coupling constant: $A = 10^{-6}\,\text{erg/cm}$, minimal stable grain size: $D_p = (60k_BT/K_u)^{1/3}$ ($\tau = 10$ years) are displayed

Alloy type	Material	K_u (10^7 erg/cm^3)	M_s (emu/cm^3)	H_k (kOe)	T_c (K)	δ_w (Å)	γ_w (erg/cm)	D_c (μm)	D_p (nm)

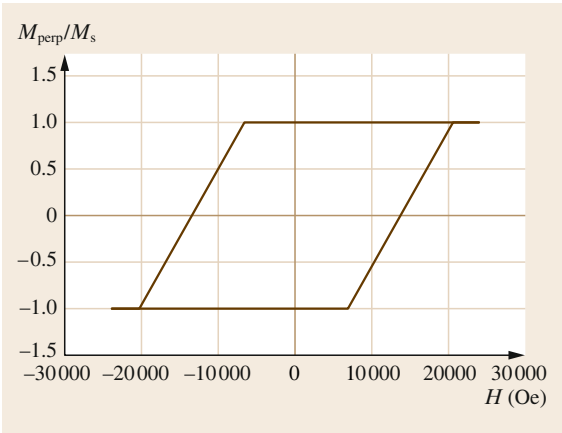

Fig. 49.32 Hysteresis curve for Co-Cr-Pt perpendicular recording media using the analysis in the text

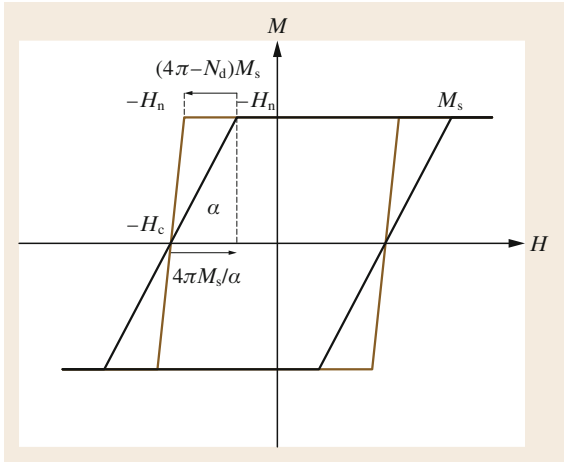

Fig. 49.33 Hysteresis curve with demagnetizing field $(4\pi M_s/\alpha)$ and a reduced demagnetizing factor N' for a perpendicular recording film with loop slope parameter α. (After [49.55])

The magnetization curve for the fourth quadrant is

$$\frac{M_\perp}{M_s} = \frac{(H_{ext} - H_e^*)}{|H_e^*|} - 1 \,.$$

The magnetization curve is shown in Fig. 49.32 and exhibits the desired large coercivity but the curve is sheared due to the large demagnetizing field. In general, the magnetic hysteresis curve (M versus H_{ext}) for the recording medium is as illustrated in Fig. 49.33 [49.55]. Here the slope parameter (α) characterizes the slope of the magnetization curve at $H = -H_c$

$$\alpha = 4\pi \left(\frac{dM}{dH}\right)_{H=-H_c} \,. \qquad (49.26)$$

Finite values of α result from variations in the direction of the perpendicular magnetization, dispersion in the perpendicular anisotropy and variations in the exchange coupling between grains and clusters in the media. The effective demagnetizing field is reduced from $4\pi M$ to $4\pi M/\alpha$. This reduction in demagnetizing field results from the formation of a rectangular checkerboard pattern of domains with high-density linear recording and high track densities [49.55].

The effective anisotropy energy, which assists in overcoming the thermal energy and the superparamagnetic limit, is given in terms of the nucleation field (H_n), at which field the magnetization just starts to reverse, by $K_{eff} = H_n M_s/2$. For high areal density, the reduced demagnetizing factor is $N_d = 0.5\,4\pi M_s$ while the nucleation field is increased to

$$H' = H_n + \frac{4\pi M_s}{2} \,.$$

For high-density recording, large values for α and H_c are required; however, the value of H_c is limited by the ability of the pole head to generate magnetic fields equal to or greater than approximately $1.5\,H_c$, the condition that ensures adequate overwrite. The transition parameter (a) for perpendicular recording can be estimated using the same write-slope criteria discussed for longitudinal recording [49.71]. Here,

$$\frac{dM}{dx} = \frac{dM}{dH}\left(\frac{dH_{head}}{dx} + \frac{dH_d}{dx}\right) \,. \qquad (49.27)$$

This equation is solved by assuming an arctangent transition shape and denoting the slope of the head field by

$$\frac{dH_{head}}{dx} = Q\frac{H_c}{s} \,,$$

where s is the total spacing of the write pole tip to the top of the SUL, consisting of the physical spacing (d), the thickness of the recording media (δ) and the spacing between the SUL and the magnetic recording film (u). H_d is the demagnetizing field. Using H_d for a perpendicular transition [49.72]

$$a = a_1 + \sqrt{\left(a_1^2 + \frac{(1-S^*)\delta s}{\pi Q}\right)} \,,$$

$$a_1 = \frac{4M_t s}{QH_c} + \frac{s(1-S^*)}{\pi Q} - \frac{\delta}{4} \,,$$

$$\alpha = \frac{\frac{4\pi M_t}{H_c}}{(1-S^*)} \,. \qquad (49.28)$$

A comparison between the transition parameters for longitudinal (a_L) and perpendicular (a_P) recording from (49.5) and (49.27) with the parameters listed in Table 49.9 is shown in Fig. 49.34 ((H_c) for longitudinal recording is the dark line and (H_c) for perpendicular

Table 49.9 Parameters for evaluating transition parameters for longitudinal and perpendicular recording

Parameter	a_L	a_P
d (nm)	26	26
t (nm)	–	50
u (nm)	–	0
S^*	0.95	0.98
M_r (emu/cm^3)	200	200
δ (nm)	14	–
Q	0.6	0.6
$H_{c,max}$ (Oe)	3500	8000

recording is dashed). It is seen that the transition parameter for perpendicular recording can be made smaller than that for longitudinal recording if the coercive field for perpendicular recording is larger than 6500 Oe. Note that the thickness of the recording media for perpendicular recording is larger than that for longitudinal recording. The magnetic squareness (M_r/M_s) for perpendicular recording media is larger than that for longitudinal recording.

Gao and *Bertram* have shown a significant advantage for perpendicular recording if the uniaxial anisotropy is not aligned perpendicular to the surface, but oriented at 45° to the perpendicular [49.73].

The geometry for this tilted perpendicular recording is shown in Fig. 49.35. The crystallites comprising the media are still aligned perpendicular but the crystalline anisotropy is assumed to be at 45°. No material system was disclosed that exhibits this tilted anisotropy. With tilted perpendicular recording the crystalline anisotropy field (H_k) can be made significantly larger than if the anisotropy is perpendicular. An example is 15 000 Oe for perpendicular recording and 28 000 Oe for tilted perpendicular recording [49.73]. Some of the advantages of tilted perpendicular recording are: reduced switching field and reduced average grain diameter, resulting in increased signal-to-noise ratio since the number of grains per bit is increased. The requirements for media for ultrahigh-density perpendicular recording have been analyzed [49.74]. Table 49.10 summarizes

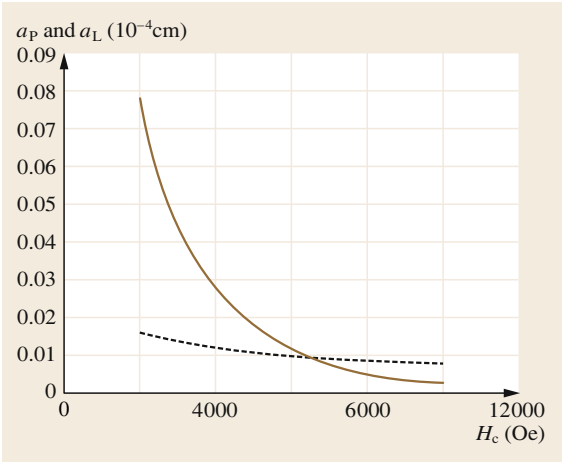

Fig. 49.34 Comparison of transition parameters versus the coercive field (H_c) for perpendicular (*solid line*) and longitudinal (*dashed line*) recording. (After [49.71])

the results for media parameters for areal densities of 100–1000 Gbit/in^2. Several key media parameters are the grains per bit and the coercivity (H_c). An estimate of the signal-to-noise ratio (SNR) using Poisson statistics of additive noise for the magnetic grains is SNR $= -10\log_{10}(N)$, where N is the number of magnetic grains per bit [49.74]. There are two possibilities to realize recording media with a large perpendicular anisotropy and that can approach Table 49.10 parameters: granular media typified by CoCr alloys and continuous multilayer media typified by [Co-Pd]$_n$ multilayers.

CoCr alloys exhibit good SNR but insufficient H_c for ultrahigh recording densities, while the multilayers do not exhibit a satisfying SNR.

Co/PdSi multilayers where the Pd layer is doped with silicon have shown an improvement in SNR [49.62]. The 50+ Gbit/in^2 technology uses a granular CoCr alloy. Tables 49.7 and 49.8 contain several metal alloy used in perpendicular recording. In general, Pt plays a significant role in determining the magnetic

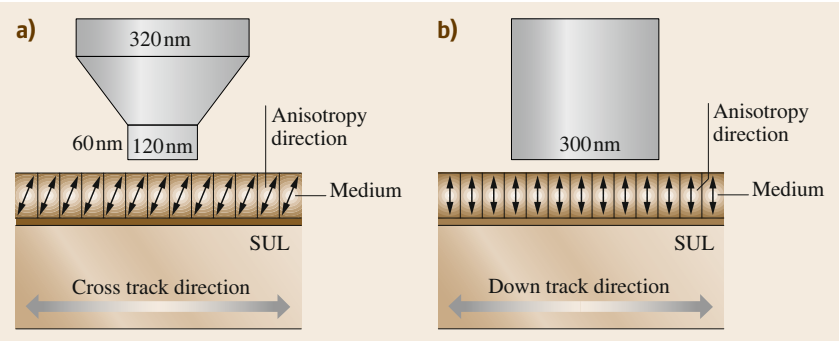

Fig. 49.35 Typical geometry of tilted perpendicular recording. The medium anisotropy directions and not the medium grains are tilted in the cross-track direction. (After [49.73])

Table 49.10 Requirements for perpendicular recording media for ultrahigh recording densities. (After [49.74])

Areal density (Gbit/in^2)	100	250	500	1000
Flying height d (nm)	8	7	6	5
Signal-to-noise ratio (RMS signal/RMS noise)	18	17	16	15
Grains per bit N	63	50	40	32
Average grain diameter D (nm)	9	7	5	4
S^*	1	1	1	1
Media thickness δ (nm)	18	20	22	24
Perpendicular anisotropy K_u (10^6 erg/cm^3)	2	3	4	6
Saturation magnetization M_s (emu/cm^3)	400	550	700	875
Coercivity H_c (kOe)	8.5	11.0	12.5	14.3

anisotropy and Cr, Ta, Nb and B reduce the exchange coupling, resulting in reduced noise.

Another alternative for perpendicular recording media is oxide media [49.66, 75, 76], for example CoCrPtO or CoCrPt-SiO_2.

Oxide media can have their coercivity improved and a negative nucleation field (H_n), a reduced pulse width and reduced signal decay with respect to CoCrPtB media [49.77]. An issue with oxide media is the nonuniformity of the coercivity and oxygen content in the disk surface due to the high gas pressure and oxygen-gas reactive sputtering [49.77]. The last two listings are for a *coupled granular/continuous* (CGC) medium that combines the best properties of the continuous media (high H_c and good thermal stability) and granular media (good SNR) [49.55, 66, 68].

A cross-section of the CGC media is shown in Fig. 49.36 [49.67]. The continuous layer causes an exchange coupling that stabilizes the granular medium; this exchange field is large (≈ 200 kOe) and can result in considerable improvement in thermal stability [49.78].

The initial results for CGC media were encouraging from the standpoint of thermal stability but the high-density SNR was 2 dB less than for the granular media alone. Further optimization of the CGC media using $[CoPt]_n$ multilayers coupled through a Pt buffer layer to a CoCrPt granular layer has shown an improvement in SNR over the granular media alone by 3–5 dB [49.78]. The improvement in SNR is believed to be due to the fact that magnetic recording transitions in the continuous layer are in the form of narrow domain walls and the magnetic interaction between the two layers may result in breaking up the magnetic clusters that form the transitions in the granular medium [49.78].

Magnetic materials used for the soft underlayer (SUL) for a perpendicular recording media must be

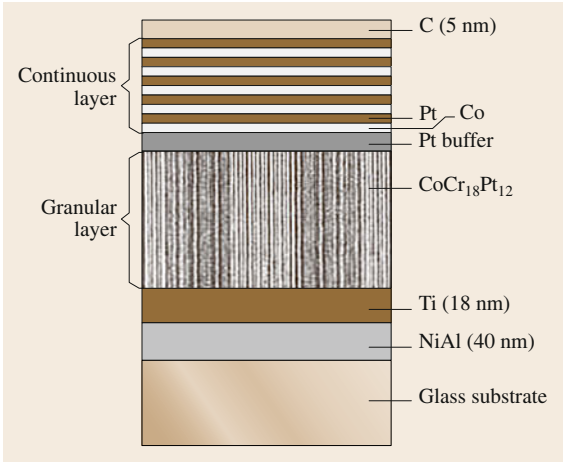

Fig. 49.36 Schematic representation for coupled granular/continuous (CGC) media. (After [49.67])

magnetically soft for low reluctance but also must not exhibit magnetic domains, which can contribute noise to the read signal. The SUL must have a magnetic moment that is larger than that for the pole tip of the write element so that the SUL saturates after the pole tip saturates. This condition assures that there is no excess reluctance directly under the pole tip. The SUL must also be thick enough that the reluctance of the path through which the flux travels allows the maximum magnetic field under the gap. Decreasing the reluctance of the flux path also increases the gradient of the magnetic field from the pole, which reduces the length of the transition parameter (49.20) [49.50]. A guide for selecting the SUL thickness (T_{SUL}) is

$$T_{SUL} \approx \frac{A_{\text{pole tip}}}{C_{\text{pole tip}}} \frac{M_{\text{pole tip}}}{M_{SUL}} , \qquad (49.29)$$

where $A_{\text{pole tip}}$ and $C_{\text{pole tip}}$ are the area and the circumference of the pole tip respectively, whereas $M_{\text{pole tip}}$ and M_{SUL} are the saturation magnetizations of the pole tip of the write head and soft underlayer respectively [49.50]. The effects of changing the thickness of the SUL on the recording parameters of a probe head are shown in Table 49.11 [49.50], where it is seen that the thickness

Table 49.11 Effect of the thickness of the FeAlN soft underlayer (SUL) on recording head parameters. (After [49.50])

Thickness of FeAlN SUL ($4\pi M_s = 20$ kG)	0.1 μm	0.3 μm
Maximum magnetic field (kOe) at recording layer at saturation current (mA) (in parentheses)	16.3 (90)	17.7 (70)
Maximum head field gradient (Oe/nm)	175	550

Table 49.12 Magnetic materials for soft underlayers (SUL). Permalloy has an insufficient magnetic moment for SUL with a field gradient that decreases at maximum field. Sendust also has an insufficient magnetic moment for SUL. FeAlN is sensitive to process conditions and believed to be less useful than FeCoB that must be annealed to reduce stress. CoZrNb has a lower magnetostriction than FeCoB. IrMn antiferromagnetic film is used along with CoZrNb to reduce spike noise due to domain walls

Material	B_s (kG) ($T \times 10^{-1}$)	Relative permeability	References
$Ni_{80}Fe_{20}$ (Permalloy)	10	1500–2000	[49.50]
Sendust (FeSiAl)	10	8000	[49.5]
FeAlN	20	2000	[49.55]
FeCoB	20–24	200–240	[49.83, 84]
CoZrNb	14		[49.84]
$NiFe_{17}Mo_4$			[49.85]
$(Ni\text{-}Fe/Si)_n$			[49.86]
IrMn/CoZrNb	14		[49.87]

and hence reluctance are key to head performance. Candidate materials for the SUL are listed in Table 49.12. A major issue with the soft underlayer is the motion of domain walls driven by the magnetic field from the write head, which can lead to *spike* noise. The last entry in Table 49.12 is for an antiferromagnetic pinning layer to prevent the motion of such domain walls.

Perpendicular Recording Developments

Perpendicular recording is presently used in commercial disk drives. The first was the Toshiba 40 GB, 1.8 in disk drive with an areal density of approximately 75 Gbit/in^2, while later the capacity was increased to 80 GB and the areal density to 133 Gbit/in^2 [49.79].

In 2006, Seagate provided 2.5 in notebook drives with a capacity of up to 160 GB and an areal density of 132 Gbit/in^2. An earlier technology with an areal density of 52.5 Gbit/in^2 was reported in 2001 [49.80] and one of approximately 100 Gbit/in^2 in 2003 [49.81]. Hitachi Global Storage Technologies reported later in 2005 an areal density of 240 Gbit/in^2 using perpendicular magnetic recording and a tunneling current-perpendicular-to-the-plane (CPP) GMR read head (see *Mueller* [49.82]).

We show in Table 49.13 the parameters used for the two areal density configurations.

In both cases a pole write head and a spin-valve read head were used. The parameters for the ≈ 100 Gbit/in^2 case are close to those required for the ultrahigh densities (> 100 Gbit/in^2) as described in Table 49.9, except that the coercivity is about one half that specified.

Table 49.13 Comparison of perpendicular recording parameters for two areal densities using CoCrPt. BER is bit error rate whereas CR is code rate, a measure of coding efficiency given by m/n where m is the number of initial bits and $n > m$ the number of code bits

Areal density	52.5 Gbit/in^2	≈ 100 Gbit/in^2
Type	CoCrPt	CoCrPt
M_s (emu/cm^3)	250	330
H_c (kOe)	2.6	4.94
K_u (erg/cm^3)	H_k = 10 kOe	1.82×10^6
S	0.98	0.92
D (nm)	–	11.9
Underlayer	FeTaC (16 kG) 400 nm	–
Head		
Turns	–	1

Material	FeNi (16 kG)	–
Width (nm)	250	105
Thickness (nm)	400	105
Write width (nm)	≈ 250	180
Shield-shield spacing (nm)	80	70
Read width (nm)	200	100
Component performance		
Sensitivity (mV/μm)	3	25
PW_{50}		70
Channel performance		
Channel type	Simulator (CR = 32/33)	Software (CR = 16/17)
Bit density (kb/in)	590	650
Track density (ktracks/in)	88.9	143
Areal density (user/channel) (Gbit/in^2)	52.5 (user)	84 (user) 93 (channel)
On-track BER	10^{-5}	6.7×10^{-5}

Note also that the superparamagnetic limit of PMR is formally set at 1 Tbit/in^2 as it was set previously at 100 Gbit/in^2 for LMR. A cross-section of the write and read elements for the perpendicular recording head used in the 52.5 Gbit/in^2 case is shown in Fig. 49.37 [49.80]. The pole of the write head is identified as the *main pole* and the thick return pole and upper shield of the GMR sensor are identified as the *auxiliary pole/upper shield*. The read signal versus density (roll-off curve) for the 52.5 Gbit/in^2 case is shown in Fig. 49.38 and results from the increasing interference of positive and negative step pulses in a long string of transitions. At low densities a step response is observed in perpendicular recording since the GMR sensor detects the vertical component of the stray magnetization that reverses at

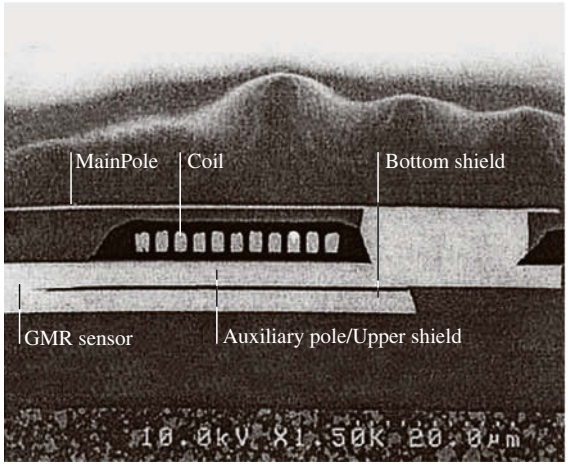

Fig. 49.37 Cross-sectional view of a perpendicular head with a GMR sensor including the bottom and upper shields. The upper shield also serves as the auxiliary pole. (After [49.80])

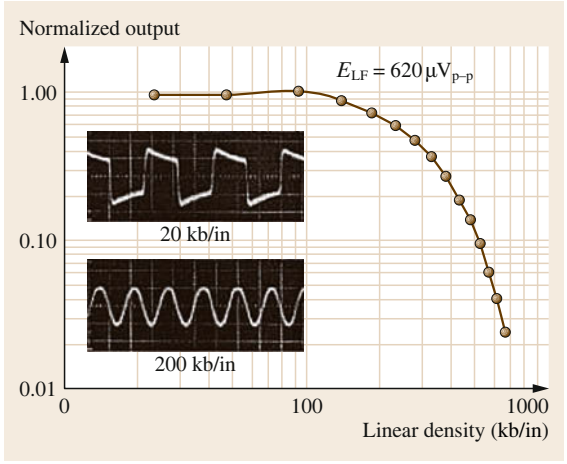

Fig. 49.38 Normalized voltage amplitude for a sequence of read signals from a perpendicular recording system versus linear density in kb/in. (After [49.80])

the transition and at higher densities the response appears as a sinusoid. The decay in the signal at the low-density response is due to the insufficient bandwidth of the preamplifier. The read signal for isolated transitions can be described by the response function

$$h(t) = A \tanh\left(\frac{\ln 3}{T_{50}} t\right), \qquad (49.30)$$

where A is one half of the signal amplitude and T_{50} is the time for the signal to rise from $-A/2$ to $A/2$. The step signals can be detected either by differentiating the signal to produce pulses, as with longitudinal recording, or with equalizer circuits that directly handle the step response. The channel performance as realized with simulator channels is listed in Table 49.12 and approximates the requirements of a practical system. Seagate technology reported an areal density of 100 Gbit/in^2 in November 2002 [49.89]. The linear density was 700 kb/in and the track density was 143 ktracks/in. In 2004 Seagate reported an areal density of 170 Gbit/in^2, crossing the 100 Gbit/in^2 barrier before *Mueller* [49.82] who reported 240 Gbit/in^2 in 2005.

Table 49.14 Progress of areal density as we change material type in PMR [49.88] through optimized selection of composite layers (thickness and material composition), magnetic cap layer (MCL) and granular recording layer (GRL). While grain size stays approximately constant, the number of grains per cluster decreases steadily in progressing from type 1 to 4, decreasing bit size and increasing areal density

Material type	Gains & Clusters	1	2	3	4
MCL + GRL	Grain size (nm)	8.8	8.6	8.8	8.1
	Distribution (%)	57.1	33.8	26.7	26.3
	Cluster size (nm)	38.8	30.0	27.1	18.9
	Distribution (%)	31.4	31.6	25.8	32.6
	Grains per cluster	19.4	12.2	9.5	5.4
GRL only	Grain size (nm)	8.7	8.5	8.8	8.1
	Distribution (%)	54.2	35.0	25.9	26.7
	Cluster size (nm)	24.1	15.6	10.1	10.4
	Distribution (%)	64.3	64.0	35.0	42.1
	Grains per cluster	7.7	3.4	1.3	1.6

Areal density can be further increased in PMR by the use of composite layers. A lower anisotropy layer called magnetic cap layer (MCL) provides continuous reversal and is deposited over a higher anisotropy granular recording layer (GRL). This results in an exchange-coupled-composite (ECC) with a continuous-granular-composite (CGC) that provides lateral exchange in the media [49.88]. In addition, CGC combines high H_c, good thermal stability and good SNR due to the granular nature, as previously discussed. The (ECC/CGC) combination paves the way for exploitation of even higher anisotropy GRL materials. Cluster size and distribution originating from lateral magnetic interaction can be optimized separately through the selection of GRL and MCL materials resulting in steady decrease of the number of grains per cluster, consequently improving areal density (Table 49.14).

Scaling Laws

Areal density controls scaling laws impacting several parameters of LMR and PMR. *Marchon* et al. [49.90] derived the following rules valid from 0.1 Gbit/in^2 to beyond 1000 Gbit/in^2:

- Bit size (in nm) $\approx 167.01\,x^{-0.3715}$, x in Gbit/in^2
- Track width (in nm) $\approx 3890.7\,x^{-0.6313}$, x in Gbit/in^2
- Bit aspect ratio (BAR) $\approx 23.296\,x^{-0.2598}$, x in Gbit/in^2
- Head media separation (HMS) (in nm) $\approx 71.5\,x^{-0.317}$, x in Gbit/in^2.

Additionally, we have the approximate relation [49.90] between HMS and bit size, expected to be valid even when the bit size is smaller (Table 49.14) than 10 nm: HMS $\approx$ (bit size)/2 as long as $10 <$ bit size (nm) < 1000.

49.2 Magnetic Random-Access Memory

The application of the giant-magnetoresistive effect to recording heads that we have discussed assumed that the sense current is in the plane of the recording film.

This is not the only possibility and devices with the current perpendicular to the plane (CPP) have been proposed both for magnetic-recording read heads but also for fast magnetic random-access memory (MRAM).

The performance of MRAM in comparison with other memory technologies is displayed in Table 49.15. SRAM, DRAM and FLASH are electronic memories, and FeRAM is ferroelectric memory similar to DRAM called 1C-1T technology (since a single bit requires a capacitor (C) and a transistor (T)) with the capacitor using a ferroelectric instead of an ordinary dielectric, also called 2C-2T technology because a single bit requires twice as much capacitors and transistors with respect to CMOS-DRAM technology.

The magnetic tunnel junction (MTJ) belongs to CPP technology and is important for both magnetic recording and MRAM developments. It involves a pinned and a free ferromagnetic film spaced by a thin insulating film, usually Al_2O_3 or MgO.

Figure 49.39 shows the schematic of an MTJ used for the MRAM application, including orthogonal bit and word or digit lines and the stack of films comprising a basic MTJ [49.93, 94].

Figure 49.40 shows a more detailed stack of films for an MTJ, including synthetic antiferromag-

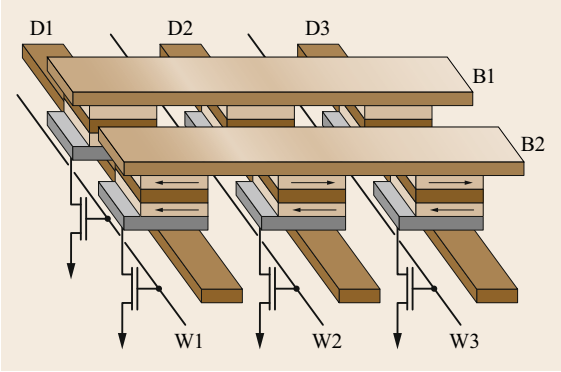

Fig. 49.39 Schematic of MRAM cross-point architecture with bits between orthogonal conductors and each cell defined by one MTJ and one transistor. The top lines in contact with the top electrode of the bits provides hard-axis fields, while the bottom lines are isolated and provide easy-axis fields. Turning on the transistor provides a current path so that the corresponding bit can be sensed. (After [49.93])

Table 49.15 Read and write times are given for the year 2007 and forecast for the year 2022. Cell surface is given in terms of parameter F the minimal feature length for the corresponding technology (current value $F = 14$ nm progressing toward 10 nm in 2017). FLASH memory has a poor endurance (program/erase cycle) of about only 10^5 because erasing uses Fowler–Nordheim tunneling that might leave electrons behind in the dielectric. FeRAM is ferroelectric RAM currently used in smartphones and electronic tablets because of its very low energy consumption, whereas STT-RAM is based on spin-transfer torque [49.91] as discussed in the text. Multilevel cell means that 1 to 3 bit might be stored in a single memory element. (After [49.92])

Memory type	SRAM	DRAM	NAND-FLASH	FeRAM	STT-MRAM
Read (2007)	0.3 ns	1–10 ns	50 ns	45 ns	< 20 ns
Read (2022)	70 ps	0.2–10 ns	10 ns	< 20 ns	< 0.5 ns
Write (2007)	0.3 ns	0.7ns	1 ns	10 ns	< 20 ns
Write (2022)	70 ps	0.2ns	1 ns	1 ns	< 0.5 ns
Retention time	Requires power	64 ms	> 10 years	> 10 years	> 10 years
Cell size	$140F^2$	$6–12F^2$	$5F^2$	$22F^2$	$6–8F^2$
Read voltage (V)	1.1	2	15	0.9–3.3	3

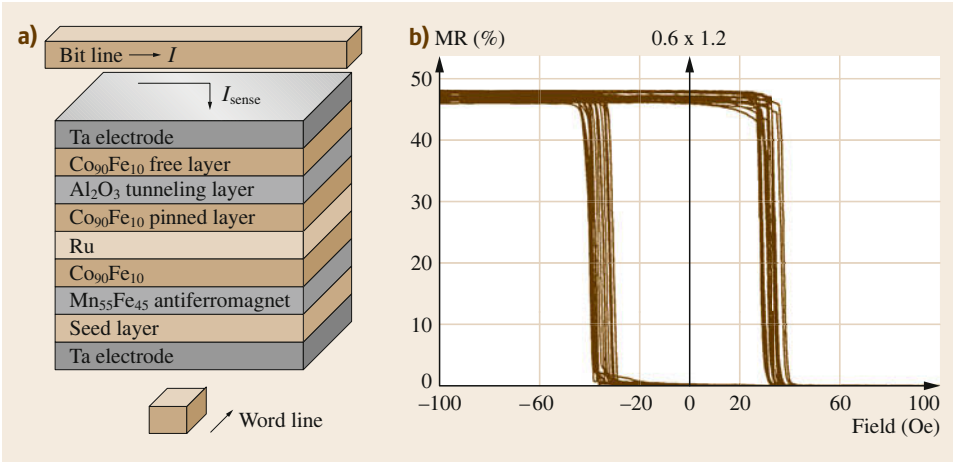

Fig. 49.40 **(a)** Stack of films comprising a typical MTJ. The *arrows* show the direction of the magnetizations in the two coupled films. **(b)** Hysteresis curves of $\Delta R/R$ versus magnetic field for $0.6 \times 1.2\,\mu m$ bits on a 6 in wafer. (After [49.94])

netic films, antiferromagnetic pinning films and the free film.

A typical MTJ has the following thickness values for the key films: antiferromagnet: 300 Å, $Co_{90}Fe_{10}$ ferromagnet: 20 Å, ruthenium: 8 Å, Al_2O_3: 10–15 Å, $Co_{90}Fe_{10}$ ferromagnet: 20 Å. As for the spin valve, the use of $Co_{90}Fe_{10}$ films for the free layer enhances $\Delta R/R$ [49.21]. Figure 49.41 also shows $\Delta R/R$ for a typical MTJ (for a bit area of $0.6 \times 1.2\,\mu m$) versus magnetic field with the multiple curves being taken over a 6 in wafer: the maximum change is greater than 48% [49.94].

The change in resistance (TMR) with orientation of the free layer relative to the pinned layer is significantly larger than for GMR technology (Table 49.15), but a thin insulating layer between the ferromagnetic films is required. The memory architecture that has evolved has a single MOS transistor coupled to the MTJ and the word line. The current in the word line supplies the magnetic field along the easy axis of the free film and is insulated from the MTJ (Fig. 49.39).

Switching of a soft-magnetic film with a magnetic field applied along the direction of an induced uniaxial anisotropy (the easy axis) and simultaneously along a direction orthogonal to the easy axis (the hard axis) has been discussed [49.5].

The switching is described by an astroid given by the following equation and shown in Fig. 49.41

$$(H_{easy})^{\frac{2}{3}} + (H_{hard})^{\frac{2}{3}} = (H_k)^{\frac{2}{3}}, \quad H_k = \frac{2K_u}{M_s}\,.$$

Note that the easy and hard magnetic fields are normalized with respect to the anisotropy field H_k in Fig. 49.41.

Switching of the state of the magnetization will occur whenever the combination of easy- and hard-axis fields is on the outside of the astroid.

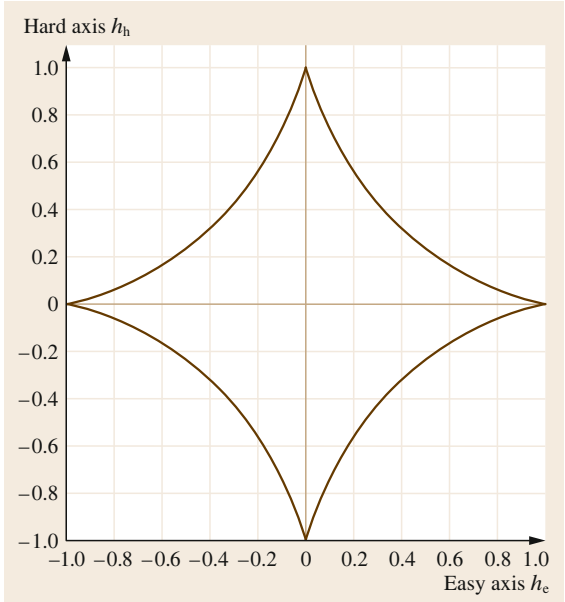

Fig. 49.41 Switching astroid plotted with magnetic fields normalized to the induced anisotropy field ($2K_u/M$). The ferromagnetic film will switch for any combination of easy- and hard-axis fields on the outside of the astroid

The switching field can be significantly reduced if magnetic fields are applied along both the easy- and hard-axis directions and an optimum is to have the fields equal. The bit line is used to supply the hard-axis magnetic field and the word line the easy-axis field. For writing a bit the sense transistor is turned off and current pulses are applied along both orthogonal conductors, generating a magnetic field at the free film sufficient in amplitude to switch the magnetization of the free film.

For reading a bit, the sense transistor is turned on by the word line and pulses of current are driven along the

bit line (with the amplitude of the magnetic field insufficient to switch the free film) and the current is either high when the ΔR is low, corresponding to say a 1 or the current amplitude is low when ΔR is high, corresponding to a 0. Without the sense transistor there would be many sneak paths for the current through other MTJs, reducing the available current for reading the selected bit.

MTJ memory cell technology shows considerable promise for replacing semiconductor SRAM and DRAM memories, primarily because of the nonvolatility of storage in MRAM technology.

The speed for reading data is comparable to that of SRAM and the density is comparable to that for DRAM. The physics of the MTJ is different from that for GMR [49.95]. Ferromagnetic films have two types of electrons: those polarized parallel to the magnetization (↑) and those polarized antiparallel to the magnetization (↓). A polarization ratio (P) for a ferromagnetic material can be defined as

$$P = \frac{D_\uparrow(E_\mathrm{F}) - D_\downarrow(E_\mathrm{F})}{D_\uparrow(E_\mathrm{F}) + D_\downarrow(E_\mathrm{F})} ,$$

where $D_\uparrow(E_\mathrm{F})$ and $D_\downarrow(E_\mathrm{F})$ are the densities of states for electrons at the Fermi energy for the spin-up and spin-down electrons respectively.

The magnetoresistance ratio of two films coupled by an insulator is [49.96]

$$\frac{\Delta R}{R} = \frac{R_\mathrm{a} - R_\mathrm{p}}{R_\mathrm{p}} = \frac{2P_1P_2}{1 - P_1P_2} , \qquad (49.31)$$

where R_a and R_p are the resistances of the coupled films in the antiparallel and parallel configurations respectively, and the spin polarizations are P_1 and P_2 for the two ferromagnetic films. Values of the spin polarization ratio are: $P_\mathrm{Co} \approx 0.35$, $P_\mathrm{Fe} \approx 0.44$ and $P_\mathrm{Permalloy} \approx 0.3$ [49.95]. With cobalt used as one electrode and Permalloy for the other electrode, the predicted value for $\Delta R/R$ is 24%. Conduction through the insulating film is by quantum mechanical tunneling, described by a transmission coefficient (T)

$$T = \frac{|\psi_\mathrm{transmitted}(x)|^2}{|\psi_\mathrm{incident}(x)|^2} ,$$

where $\psi(x)$ is the wavefunction for the electron plane wave and $|\psi(x)|^2$ is the probability of finding an electron at the position x.

The transmission coefficient is a measure of the barrier resistance. The transmission coefficient for electrons with energy E tunneling through an insulating film of thickness a with barrier height V_0, is given by

$$T = T_0 \mathrm{e}^{-2\alpha a} ,$$

where

$$T_0 = \frac{16E(V_0 - E)}{V_0^2} \text{ and } \alpha^2 = \frac{2m(V_0 - E)}{\hbar^2} .$$

This result applies when $\alpha a > 1$. A barrier height $V_0 = 10\,\mathrm{eV}$ applies for CoO.

The exponential dependence of the transmission coefficient on the thickness of the barrier shows the requirement for a thin barrier. A typical value of the thickness of an Al_2O_3 layer is 10 Å and the resistance changes by a factor of 100 million in changing the thickness from 0−10Å.

The reason that the MTJ is more attractive than a spin valve for the memory application is that the MTJ can be made with a resistance of many ohms, while the spin valve is nearly a short circuit. The use of the synthetic antiferromagnet for the MTJ also helps to avoid the superparamagnetic limit for this device, since the films comprising the synthetic antiferromagnet are thicker than the single antiferromagnetic film that was used to pin one of the ferromagnetic electrodes.

A significant problem with the MTJ is the different magnetic states that can be found depending on the size and shape of the bit. A review of an analysis of the states for a rectangular-shaped bit has been published [49.97] and we will quote some of their results to illustrate the problem. The analysis uses finite element analysis to solve the equation of motion for the magnetization (M) with Gilbert damping in the presence of an effective magnetic field ($\mathbf{H}_\mathrm{eff}$)

$$\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} = \gamma(\mathbf{M} \times \mathbf{H}_\mathrm{eff}) - \frac{\alpha}{M}(\mathbf{M} \times \dot{\mathbf{M}}) . \qquad (49.32)$$

The effective magnetic field $\mathbf{H}_\mathrm{eff} = -\delta G/\delta\mathbf{M}$ can be derived from the magnetic free-enthalpy density (or Gibbs potential) G per unit volume given by the sum of terms pertaining to exchange, anisotropy, demagnetization and external field

$$G = G_\mathrm{exchange} + G_\mathrm{anisotropy} + G_\mathrm{demag} + G_\mathrm{external} .$$

An example of this analysis is a rectangular film of thickness 20 nm, length 1 μm, width 1 μm with magnetic properties shown in Table 49.13. The exchange stiffness constant is $A = S^2a^2J_\mathrm{ex}N_\mathrm{v}/2$, where S is the spin of the atom, a the lattice constant and N_v is the number of nearest-neighbor atoms per unit volume.

The critical length determines the maximum size of the mesh used in the finite element analysis. Figure 49.42 shows three of the six states of the magnetization in the sample.

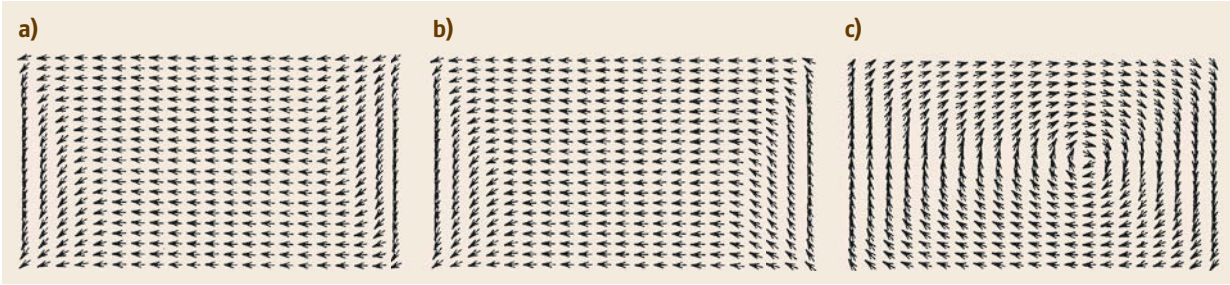

Fig. 49.42a–c Configurations for spins in a Permalloy sample described in Tables 49.16 and 49.17. Figure (a) is in S-state, (b) is in C-state and (c) is in shifted vortex state. (After [49.97])

The first two are high-remanence states referred to as S-state and C-state and can be formed if the starting conditions are a single-domain state. The last state shown is a low-remanence state with an shifted vortex. The last state is formed when the initial conditions are two domains along the long axis of the film. The total energies for the three states are shown in Table 49.17 using parameters of Table 49.16 and it is seen that the lowest energy is the low remanence state.

An issue with the MRAM is the possibility of exciting the different states in the storage cell that can then result in a different switching astroid. Thin films with low BAR bit shapes have been predicted to result in a reduced propensity to excite the vortex structures [49.98]. Changing the shape of the bit may also assist in minimizing the vortex structures. Software for analyzing these problems is the LLG Micromagnetics Simulator developed by M.R. Scheinfein.

One development in MRAM architecture is to pass the write current through the MTJ in order to heat the element and thus lower the writing threshold [49.99]. This is accomplished by turning on the selection transistor (Fig. 49.39) during the write operation. The advantages of this modification to the MRAM architecture are:

1. Since the selection at write is controlled by the temperature, selection errors are reduced.
2. The write threshold is reduced.
3. Thermal instability limits are increased by using materials with larger switching fields at the operating temperature [49.99].

Table 49.16 Parameters for Permalloy ($Ni_{80}Fe_{20}$)

M_s (T)	K_1 (J/m^3)	A (exchange stiffness) (10^{-12} J/m)	Critical length l_s (nm)
1.0	500	13	5.7

Table 49.17 Total energies for different spin configurations in the Permalloy film (described in the text and Table 49.16). (After [49.97])

Structure	G (10^{-18} J)
S-state	169.897
C-state	169.890
Shifted vortex state	88.733

Another important development in MRAM is the use of a spin current called spin-transfer torque (STT) [49.100]. Generally, spin currents [49.101] are either spin-polarized current (SPC) made of free (s-type) carriers or SWC (spin-wave current) carried by localized spins (d-type) undergoing oscillatory motion or STT originating from hybrid (s-d) exchange (called also double exchange) between free (s-type) and localized carriers (d-type) [49.91]. STT-MRAM are extremely fast (2 ns reading and writing speeds), completely electrically controlled with no moving parts and with unlimited endurance (number of program/erase cycles). In contrast, electronic FLASH memory has typically 10^5 endurance (Table 49.15).

49.2.1 Tunneling Magnetoresistive Heads

Tunneling magnetoresistance (TMR) can be used in a magnetic recording read-head application. These TMR heads use the CPP orientation of the sense current and, as with the MRAM, the tunneling is done through a thin insulating barrier. A schematic at the air-bearing surface in the simplest form of such a TMR head is shown in Fig. 49.43 [49.102]. The insulating barrier (again usually fabricated from Al_2O_3 films) is shown on edge and the current flow is in the plane of the paper.

Longitudinal bias to put the ferromagnetic TMR electrode films in a single-domain state and the top and bottom shields are shown. The GMR ratio with the TMR effect is large but the resistance × area (RA) product, which is the resistivity times the film thickness, may also be large, resulting in excessive shot noise. Shot noise is intrinsic to tunneling with the direct-current (DC) bias current required for GMR head operation and is the dominant noise source in the TMR head.

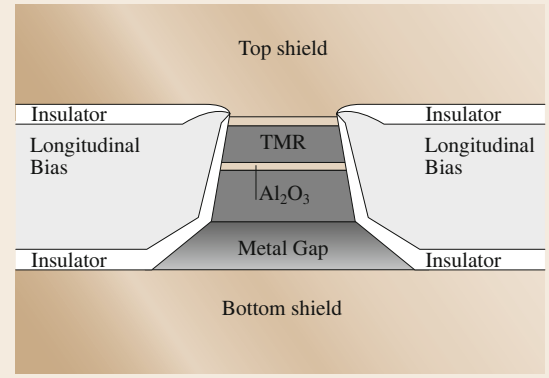

Fig. 49.43 Schematic drawing of the air-bearing surface view of a tunneling magnetoresistive (TMR) head. (After [49.102])

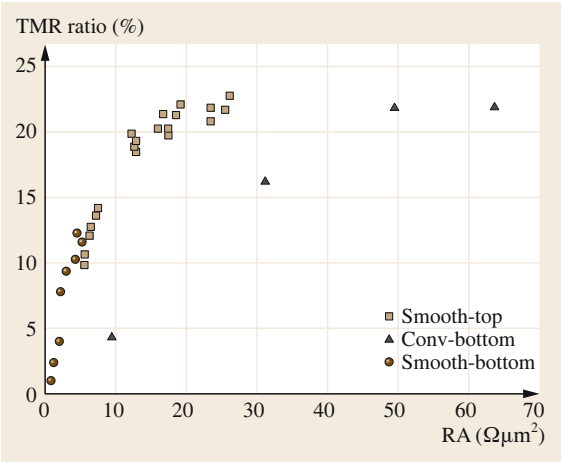

Fig. 49.44 Correlation between TMR ratio and resistance area product (RA) in three structures: *top*- and *bottom*-type MTJ with smoother interfaces and bottom-type MTJ with conventional stacking that has relatively rough interfaces. (After [49.102])

Figure 49.44 is a plot of the TMR ratio in % versus the RA product for three different TMR structures all made from the basic structure: buffer/PtMn/CoFe/Ru/CoFe/AlO_x/CoFe/NiFe/cap [49.102]. PtMn is an antiferromagnet, CoFe/Ru/CoFe is a synthetic antiferromagnet, AlO_x is the insulating barrier (prepared by in situ oxidation) and CoFe/NiFe is the second electrode. The data points for TMR versus RA for this structure are labeled *conv-bottom* (conventional bottom) and the data points for the *smooth-top* structure is for the PtMn layer on top instead of the bottom, while the *smooth-bottom* data points are for a head made with smoother interfaces. The TMR % remains constant at $\approx 20\%$ until a knee, below which the TMR % drops due to pinholes and incomplete insulation coverage.

Typically, room temperature TMR is about 1–70% when the insulating barrier is AlO_x and rises to almost 400% when the insulator is MgO (Table 49.18). At low temperature ($T = 4.2$ K) it can reach a value of 1800% in half-metallic compounds such as $La_{2/3}Sr_{1/3}MnO_3$ (LSMO)/$SrTiO_3$/LSMO, and 600% in Heusler alloys such as $Co_2MnSi/AlO_x/Co_2MnSi$ [49.103]. Perhaps the main issue is thermal stability, and that is why a system such as a perpendicular MTJ consisting of Ta/CoFeB/MgO/CoFeB/Ta possessing high thermal stability, a size as small as 40 nm diameter and a low switching current of 49 μA [49.104] is quite interesting in spite of a TMR ratio of only 120%. The thermal stability factor E_B/k_BT of the free layer should be larger than 40 to retain information (as previously seen), where E_B is the energy barrier. Because the volume V of the free layer decreases with junction size, the anisotropy energy density $M_sH_k/2$ needs to be large enough to ensure high thermal stability.

Table 49.18 TMR ratio increases strongly when AlO_x is replaced by MgO. Materials such as CoFeB/MgO/CoFeB and Co/MgO/Co reach about 400% at room temperature

Insulator	Junction	TMR (%)	Reference
AlO_x		1–70	*Zhu* et al. [49.105]
	CoFeB/AlO_x/CoFeB	70	*Wang* et al. [49.106]
MgO		5–400	*Ikeda* et al. [49.104]
	Fe/MgO (100)/Fe	220	*Parkin* et al. [49.107]

The stack of films is ion-milled and the stripe height is defined by lapping. Magnetic recording results showed the expected large signal (peak-to-peak $V_{pp} = 42$ mV/μm) with a biasing current of 1 mA with only 23.4 dB SNR deemed insufficient to demonstrate the required low error rate [49.102].

A significant problem with the TMR head is that there is a large resistance in parallel with the large capacitance resulting from the tunneling barrier. This combination results in a low-pass filter and care is required to limit the capacitance. In the example discussed here the cutoff linear density is near 580 kfc/in.

Because of the significantly larger value of ΔR for CPP as opposed to the CIP technology, CPP has become the dominant technology for read heads when areal density became much larger than 100 Gbit/in^2, whereas TMR was used when areal density was just around 100 Gbit/in^2 (see *Mueller* [49.82]).

49.3 Extraordinary Magnetoresistance (EMR)

An interesting development in read-head technology is the discovery that narrow band gap and hence high mobility semiconductors can be made to function as detectors of magnetic field [49.108]. The concept is based on the Lorentz force exerted on charge carriers by a magnetic field

$$F = q\mathbf{v} \times \mathbf{B} ,$$

where q is the charge, $\mathbf{v}$ is the velocity of the charge carrier and $\mathbf{B}$ is the magnetic flux density acting on the charge.

Electrons have the highest mobility as compared to holes and are the carriers used.

The electrons are driven by an external source similar to the sense current in GMR sensors in a high-mobility semiconductor, are deflected by the external magnetic field into a trajectory, and the voltage drop in the semiconductor at low locations is used to sense the magnetic field. The III–IV semiconductor InSb was chosen for the initial work on EMS because of the high mobility of electrons of $60\,000\,\mathrm{cm}^2/\mathrm{Vs}$.

However, a major limitation was the ability to maintain the high mobility in thin films ($< 100\,\mathrm{nm}$) required for read-head applications and this was addressed by forming a thin-film quantum well heterostructure [49.108]. An advantage of such sensors is the lack of any magnetic noise since there are no magnetic materials involved in the head structure. A review of EMR as magnetic field nanosensors has been reported by *Solin* [49.109].

49.4 Summary

It was the purpose of this chapter to review the current status of the technology of magnetic recording as used in disk drives. The emphasis was on the magnetic materials used in the application and on some of the technical problems that may limit areal density steady increase. MRAM technology, which has evolved from magnetic recording applications, was also reviewed. It was found that a wide range of magnetic materials is essential for the advance of magnetic recording and the MRAM technology, including high-magnetization soft-magnetic materials for write heads, antiferromagnetic alloys with high blocking temperatures and low propensity to corrosion for pinning films in giant-magnetoresistive sensors, and ferromagnetic alloys with large values of giant magnetoresistance. A significant limitation to magnetic recording was found to be the superparamagnetic effect and advances in multilayer ferromagnetic films to reduce the impact of the effect, but also to allow high-density recording, were discussed.

Perpendicular recording as an alternative to longitudinal recording was reviewed and it is projected by the ASTC (Advanced Storage Technology Consortium) that it will be replaced by HAMR [49.110] (heat assisted magnetic recording) and later by HDMR (heated dot magnetic recording) a combination of bit-patterned recording and HAMR. In the latter technology, large magnetic anisotropy materials are used, such as FePt (Tables 49.7 and 49.8) with $L1_0$ structure (FCT phase), which can provide grains as small as 2–3 nm in diameter yielding areal densities about as large as $100\,\mathrm{Tbit/in}^2$. The coercivity of these materials, being much larger than any magnetic field that can be generated by typical recording heads, can be reduced to zero by heating them above Curie temperature [49.110].

Magnetic quantum dot arrays that will be used in HDMR are individually addressable and adapted to scale integration since submicron ordered dot arrays possess properties such as moment, susceptibility, coercivity and remanence that are significantly enhanced with respect to their bulk counterparts. This originates from the fact they are closer to quantum atomic structures with augmented magnetic properties when fabricated on the nanometer scale. When the $100\,\mathrm{Tbit/in}^2$ level is reached, information storage by hard disks will be competing with human brain capacity, which is estimated to be on the order of several hundred terabytes.

50. High-Temperature Superconductors

Rainer Wesche

The discovery by J. G. Bednorz and K. A. Müller in 1986 that the superconducting state can exist in oxides at temperatures above 30 K stimulated research in the field of superconductivity and opened a new field of research. Within a few years a large number of cuprate superconductors with transition temperatures well above the boiling point of liquid nitrogen have been found. In this chapter, an overview of the major families of high-temperature superconductors and their physical properties is presented.

Starting from the well-known characteristics of conventional superconductors, described in Sect. 50.1, the new phenomena observed in high-temperature superconductors are considered. The complexity of the physical properties of the cuprate superconductors is closely related to the fact that these materials are close to a metal–insulator transition. In Sects. 50.2 and 50.3, the crystal structures, the general trends for the critical temperatures, the anisotropy of the physical properties, and the factors limiting the transport critical current density are discussed. Because of their importance in the field of electronics some features of thin films are presented in Sect. 50.4.

Strictly speaking, the binary compound MgB_2 is not a high-temperature superconductor. Nevertheless, an overview of the physical properties of this interesting metallic superconductor, characterized by a transition temperature as high as 39 K, has been included in the present chapter (Sect. 50.5).

In 2008, H. Hosono et al. discovered that the layered superconductor $La(O_{1-x}F_x)FeAs$ ($x = 0.11$) superconducts at a temperature as high as 26 K. A maximum critical temperature of 58 K has been reported for the iron-pnictide superconductor $Sm(O_{0.74}F_{0.26})FeAs$. The iron-based superconductors are therefore considered as a second class of high-temperature superconductors. Their properties are described in Sect. 50.6.

After the successful development of helium liquefaction techniques in the laboratory of Heike Kammerlingh Onnes at the University of Leiden, temperatures down to about 1 K became accessible for further research [50.1]. One of the first aspects to be studied was the electrical resistivity of pure metals at very low temperatures. The nearly temperature-independent residual resistivity of platinum and gold was found to decrease with increasing purity of the metals. In 1911, Kammerlingh Onnes found that, in contrast to the behavior of platinum and gold, the electrical resistivity of mercury drops to an unmeasurably small value at

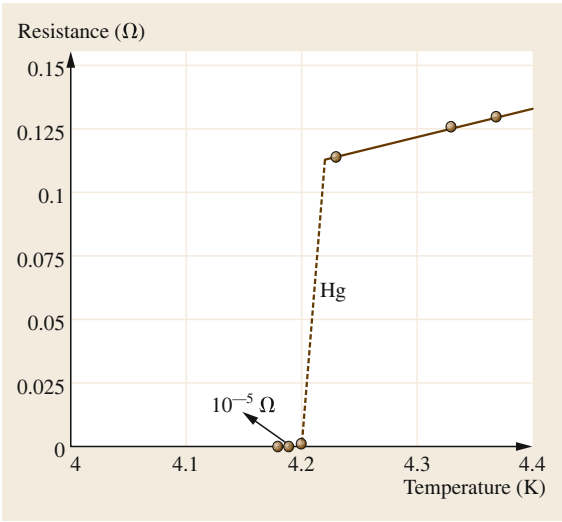

Fig. 50.1 Resistance–temperature plot for mercury obtained by Heike Kammerlingh Onnes

a temperature of 4.2 K, as shown in Fig. 50.1. The remarkable phenomenon of superconductivity had been discovered [50.1].

In addition to zero resistance, the superconducting state is characterized by perfect diamagnetism. *W. Meissner* and *R. Ochsenfeld* found in 1933 that, as soon as the superconducting state is reached, a magnetic field is expelled from the interior of a superconductor cooled in the presence of a static magnetic field [50.2]. In contrast to the shielding of a magnetic field applied to a material in the superconducting state, field expulsion cannot be explained by perfect conductivity. This Meissner effect is therefore indeed an additional characteristic property of superconductors.

The discoveries listed in Table 50.1 provide an overview of the history of superconductivity. The improvement in the highest known critical temperatures in metals, oxides, molecular (organic), and iron-based superconductors is shown in Fig. 50.2. Between 1911 and 1974, the critical temperatures T_c of metallic superconductors steadily increased from 4.2 K in mercury up to 23.2 K in sputtered Nb_3Ge films [50.17, 18]. Nb_3Ge held the record for the critical temperature in metallic superconductors until the unexpected discovery of superconductivity at 39 K in the intermetallic compound MgB_2 [50.15].

The first superconductingxoo oxide $SrTiO_3$ characterized by a transition temperature as low as 0.25 K was discovered in 1964 [50.19]. A remarkably higher critical temperature of 13 K was found for the perovskite $BaPb_{1-x}Bi_xO_3$ in 1975 [50.20]. These results stimulated J. G. Bednorz and K. A. Müller to search for higher critical temperatures in oxides. Their discovery of high-temperature superconductivity in the cuprate $(La, Ba)_2CuO_4$ ($T_c \approx 30$ K) opened up a new field of research [50.12]. Within less than a year a critical temperature well above the boiling point of liquid nitrogen could be achieved in $YBa_2Cu_3O_{7-\delta}$ [50.21]. So far, the highest transition temperature of 135 K at ambient pressure has been found in $HgBa_2Ca_2Cu_3O_{8+\delta}$ [50.13, 14].

It should be mentioned that the phenomenon of superconductivity has also been observed in organic materials [50.22–24] and fullerenes [50.25–27]. Remarkably, high transition temperatures of 19, 33 and 40 K have been found in the fullerenes K_3C_{60}, $RbCs_2C_{60}$, and Cs_3C_{60} respectively.

Since *H. Hosono* and collaborators discovered in 2008 [50.16] that the iron-pnictide $La(O_{0.89}F_{0.11})FeAs$ superconducts at a temperature of 26 K, the cuprates are no longer the only known class of complex high-temperature superconductors. The highest reported critical temperatures of iron-based superconductors are in the range of 56−58 K.

An important advantage of high-temperature superconductors is the possibility of operating devices at

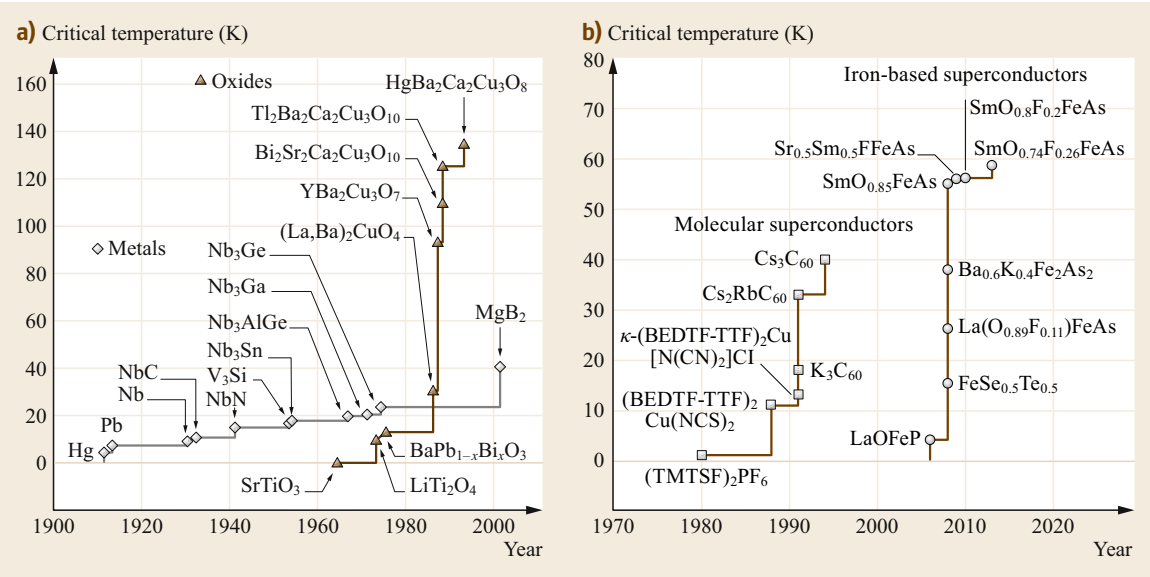

Fig. 50.2a,b Highest known critical temperatures of metallic, oxide, molecular (TMTSF and BEDTF-TTF) and iron-based superconductors. Between 1911 and 1974, the critical temperature of metallic superconductors increased steadily from 4.2 K (Hg) to 23.2 K (Nb_3Ge). In 2001, the unexpected discovery of superconductivity in MgB_2 raised the maximum known T_c of metallic superconductors to 39 K. After the discovery of high-T_c superconductivity in $(La, Ba)_2CuO_4$, in 1986, the maximum T_c of oxides rapidly exceeded 77 K the boiling point of liquid nitrogen **(a)**. In 1980, a first molecular superconductor was discovered. In the fullerene Cs_3C_{60}, a remarkably high T_c of 40 K was found. Between 2006 and 2013, the maximum known T_c of iron-based superconductors increased from around 4 K (LaOFeP) to 58 K ($SmO_{0.74}F_{0.26}FeAs$) **(b)**. (After [50.12–34])

temperatures well above 20 K, leading to a considerable reduction in the required refrigerator input power. In contrast to power applications, the use of liquid nitrogen as a coolant is of less importance for superconducting electronics, which are typically cooled by closed cycle coolers. The economics of closed cycle coolers depends strongly on the operating temperature. Considering an ideal, reversible cooling cycle, the input power necessary to remove a heat load dQ/dt is

$$P_{in} = \frac{1}{\eta_C}\frac{dQ}{dt}\,, \qquad (50.1)$$

where

$$\eta_C = \frac{T_{op}}{300\,K - T_{op}} \qquad (50.2)$$

is the Carnot efficiency. To remove a heat input of 1 W an ideal, reversible refrigerator consumes at room temperature a power of 70 W for $T_{op} = 4.2$ K, whereas this power is only 9 and 2.9 W for operation at 30 and 77 K, respectively. The efficiency η_r of real refrigerators is much smaller than the Carnot efficiency, and depends strongly on the refrigerator size, as illustrated in Fig. 50.3. For small refrigerators able to remove a power of 1 W, the refrigerator efficiency is only a few

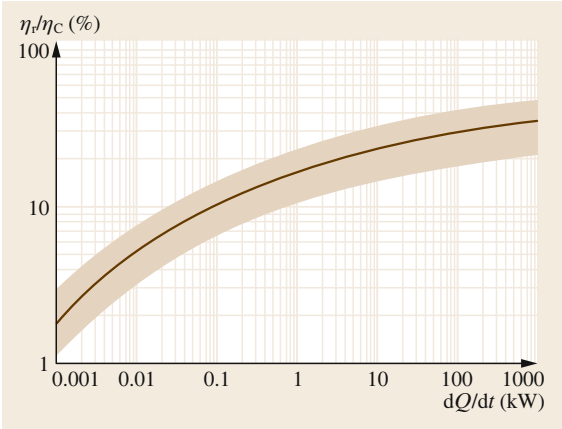

Fig. 50.3 The efficiency of real refrigerators normalized to the Carnot efficiency is typically in the *highlighted area*. The ratio of η_r/η_C increases with increasing refrigeration capacity. (After [50.35])

percent of the Carnot efficiency. On the other hand, large refrigerators with a cooling capacity well above 10 kW may reach 30% of the Carnot efficiency. The ratio η_r/η_C has been found to depend only weakly on the operating temperature.

50.1 The Superconducting State

50.1.1 Characteristic Properties of Superconductors

The discussion of the physical properties of high-temperature superconductors has to be based on the knowledge of the behavior of conventional, metallic superconductors. In this section the superconducting state is therefore described in more detail, starting from the properties of simple, metallic superconductors.

Below a certain temperature, T_c the electrical resistance of a superconducting material vanishes. The critical temperature T_c is characteristic of the superconductor in question. In pure metals, the zero resistance state can be reached within a few mK (Fig. 50.1). In the chemically complex cuprate, high-T_c superconductors the transition to the superconducting state is less sharp than in metallic low-T_c superconductors. The transition width ΔT_c for single-phase cuprate superconductors is typically 1 K. Thus the critical temperature depends slightly on the criterion used to define T_c. Several criteria are illustrated in Fig. 50.4.

At the transition temperature, a resistance drop of several orders of magnitude is typically observed. However, it is in principle not possible to prove experimentally that the resistance in the superconducting state is in fact zero. The most efficient way to determine an upper limit of the resistance is to detect the decay of the magnetic fields generated by currents induced in a superconducting loop. Upper resistivity limits between 2×10^{-18} [50.36] and $7\times10^{-23}\,\Omega$ cm [50.37] have been reported for the high-T_c superconductor $YBa_2Cu_3O_7$, while a value of $3.6\times10^{-23}\,\Omega$ cm has been found for type I low-T_c superconductors [50.38]. These upper resistivity limits are orders of magnitude smaller than the resistivity of $10^{-10}\,\Omega$ cm at 4.2 K achievable in annealed, very pure metals. It is therefore justified to assume zero resistance below T_c for all practical purposes.

The second outstanding feature of the superconducting state is perfect diamagnetism. To understand the magnetic behavior of a superconductor, the two different situations illustrated in Fig. 50.5 have to be considered. In the first case, the superconductor is cooled below T_c without an applied magnetic field (zero field-cooled). In the second case the superconductor is cooled below T_c while a magnetic field is applied (field-cooled). In both cases, the magnetic flux is excluded from the interior of the superconductor. Screening currents flowing in the surface layer of the superconductor generate a flux opposite to that of the applied magnetic field. The magnetic flux density is therefore zero everywhere inside the superconductor. On the other hand, outside the superconducting sphere the magnetic field is enhanced because of the superposition of the flux

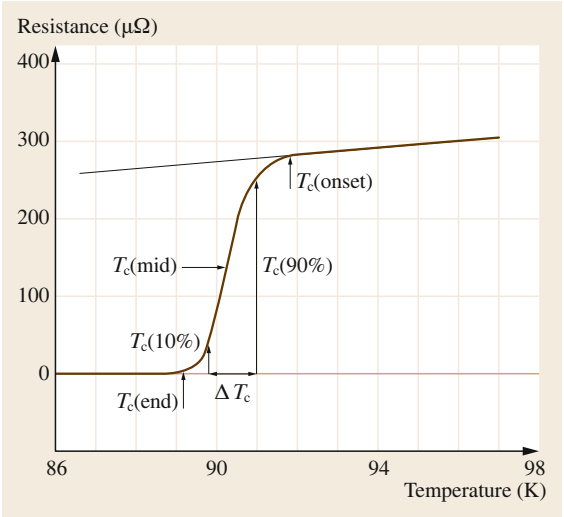

Fig. 50.4 Resistance versus temperature for a $Bi_2Sr_2CaCu_2O_8$/Ag multicore wire. The transition temperatures resulting from different definitions of T_c are indicated. The width of the transition $\Delta T_c = T_c(90\%) - T_c(10\%)$ is ≈ 1.2 K

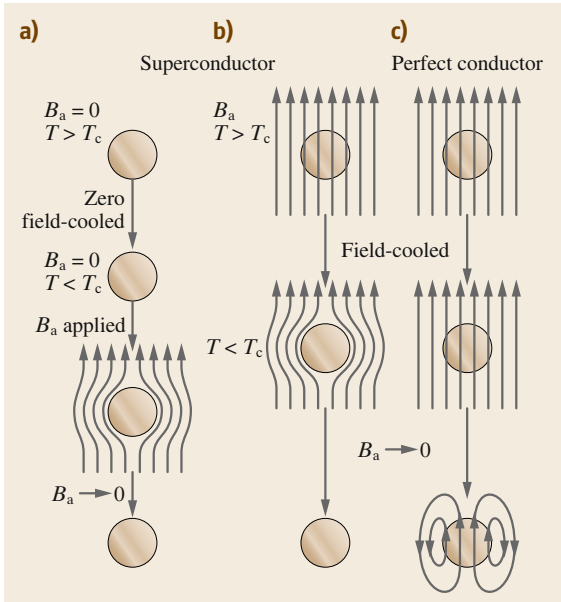

Fig. 50.5a–c The magnetic flux is excluded from the interior of a superconductor **(a)** without field-cooling as well as **(b)** with it. In contrast to this behavior, a magnetic flux would exist in the interior of a field-cooled perfect conductor **(c)**. (After [50.39, p. 20])

of the applied magnetic field and that of the screening currents. In both situations, the superconductor is unmagnetized when the magnetic field is removed. The behavior of a zero field-cooled superconductor may be considered simply as a screening effect caused by perfect conductivity. In contrast to screening, the expulsion of the magnetic flux from a field-cooled superconductor (the Meissner effect) cannot be explained by perfect conductivity. The different behavior of a field-cooled perfect conductor is also shown in Fig. 50.5. The values of the relative magnetic permeability for nonferromagnetic metals are close to unity. Thus the magnetic flux inside the metal is nearly the same as that of the applied magnetic field. Because $dB/dt = 0$, no screening currents are induced, and hence the magnetic flux is not removed from the interior of the perfect conductor at low temperatures. Finally, the removing of the magnetic field ($dB/dt \neq 0$) leads to the magnetization of the perfect conductor.

The superconducting state can be destroyed by a sufficiently large applied magnetic field. The transition from the superconducting to the normal state occurs at a certain critical magnetic field $\boldsymbol{B}_c$, which is a characteristic property of the superconductor considered. The dependence of the critical field on the temperature is typically well described by

$$\boldsymbol{B}_c(T) = \boldsymbol{B}_{c0}\left[1 - \left(\frac{T}{T_c}\right)^2\right], \tag{50.3}$$

where T_c is the critical temperature and $\boldsymbol{B}_{c0}$ is the critical field at zero temperature. The critical field as a function of temperature is shown in Fig. 50.6 for selected metallic superconductors. The $\boldsymbol{B}_c(T)$ curves

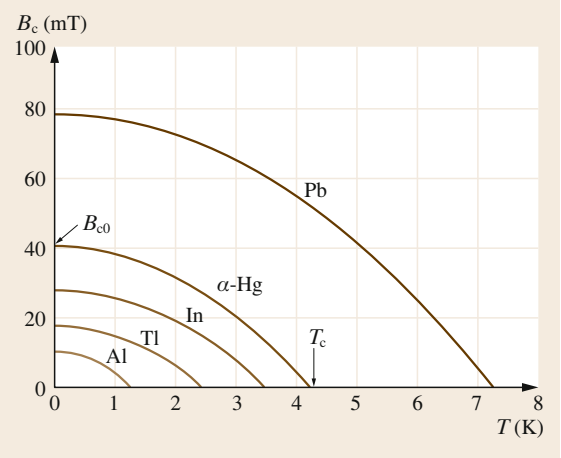

Fig. 50.6 Critical field versus temperature curves for selected metallic superconductors. The B_{c0} values vary from ≈ 10 to ≈ 80 mT. (After [50.39, p. 24])

separate the superconducting from the normal state. The Meissner effect ensures that the properties at any point in the superconducting state are independent of the order in which the final conditions of the applied magnetic field and temperature are reached.

50.1.2 Superconductor Electrodynamics

The electrodynamics of superconductors can be described by the two London equations. As a consequence of the infinite conductivity in the superconducting state, Ohm's law must be replaced by the first London equation

$$\frac{d\boldsymbol{j}}{dt} = \frac{1}{\mu_0 \lambda_L^2}\boldsymbol{E}, \tag{50.4}$$

where $\boldsymbol{j}$ is the current density, $\boldsymbol{E}$ is the electric field, μ_0 is the permeability of free space, and λ_L a constant. The electric field in the superconductor is zero for constant current density. The current density and the magnetic field are related by the second London equation

$$\mathrm{curl}\,\boldsymbol{j} = -\frac{1}{\mu_0 \lambda_L^2}\boldsymbol{B}. \tag{50.5}$$

Using the Maxwell equation $\mathrm{curl}\,\boldsymbol{B} = \mu_0 \boldsymbol{j}$ the following differential equation results for the magnetic field

$$\nabla^2 \boldsymbol{B} = \frac{1}{\lambda_L^2}\boldsymbol{B}. \tag{50.6}$$

For a semi-infinite superconductor with the magnetic field applied along the z-direction, an exponential decay of the magnetic field $\boldsymbol{B}(x) = \boldsymbol{B}_0 \exp(-x/\lambda_L)$ results, as illustrated in Fig. 50.7. The London penetration depth λ_L is therefore the characteristic length for the decay of the magnetic field in the surface layer of the superconductor. Typical values of the penetration depth are 10^{-5}–10^{-6} cm at $T = 0$. The penetration depth is closely related to the number density of the Cooper pairs (Sect. 50.1.3)

$$\lambda_L = \sqrt{\frac{m_C}{\mu_0 n_C q_C^2}}, \tag{50.7}$$

where n_C, q_C, and m_C are the number density, the charge and the mass of the Cooper pairs. Because of the decreasing Cooper pair density, the penetration depth increases rapidly for temperatures close to T_c (see the inset of Fig. 50.7). The temperature dependence is given by

$$\lambda_L(T) = \lambda_{L0}\left[1 - \left(\frac{T}{T_c}\right)^4\right]^{-1/2}, \tag{50.8}$$

where λ_{L0} is the penetration depth at $T = 0$.

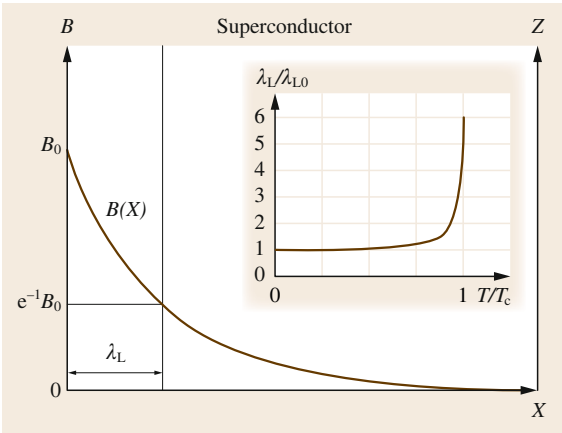

Fig. 50.7 Exponential decay of an applied magnetic field in the surface layer of a semi-infinite superconductor. The normalized penetration depth λ_L/λ_{L0} versus reduced temperature is shown in the *inset*

50.1.3 Superconductivity: A Macroscopic Quantum Phenomenon

Bardeen–Cooper–Schrieffer (BCS) Theory

Next, the microscopic causes of superconductivity in conventional superconductors are briefly described. *J. Bardeen* et al. proposed a microscopic theory of superconductivity [50.4, 5], which is now well known as the BCS theory. At the moment, it seems to be unlikely that the mechanism of superconductivity in the cuprates, which is still not yet understood, can be explained by the BCS theory. The recently discovered iron-based superconductors seem to be a second class of high-temperature superconductors, which show unconventional superconductivity [50.16]. In this chapter, only some fundamental ideas and results of the BCS theory are presented.

Independent of each other, two researchers [50.40, 41] found theoretically that lattice vibrations (phonons) can provide an attractive interaction between two electrons. This can be understood as a consequence of the polarization of the lattice by the electrons. The concentration of positive charges produced by the first electron reduces the potential energy of the second electron. Because of this attractive interaction, electrons with opposite momenta and spins form electron (Cooper) pairs. The Cooper pairs, characterized by zero spin and momentum, have to be considered as new particles. Because their spin is zero, they do not obey Pauli's exclusion principle. The probability that a state is occupied increases with the number of particles populating the same quantum state. Therefore, all Cooper pairs occupy the same quantum state with a single value of the momentum in the presence of an applied electric field. A change of momentum results only for scattering processes that break up some Cooper pairs. Resistance occurs as soon as the energy taken from the electric field exceeds the binding energy of the Cooper pairs. This behavior explains the existence of a critical current.

The electron–phonon interaction leads to an energy gap 2Δ in the density of states for the single electrons. The width of the energy gap at zero temperature is

$$2\Delta(0) = 3.5 k_B T_c \,, \tag{50.9}$$

where k_B is the Boltzmann constant and T_c is the critical temperature. For superconducting elements the measured ratios of $2\Delta(0)/k_B T_c$ are typically 3.2–4.6 [50.42], which is in reasonably good agreement with the value of 3.5 predicted by the BCS theory. The single-electron density of states close to the Fermi energy is

$$D_s(E - E_F) = D_n(E_F) \frac{|E - E_F|}{\sqrt{(E - E_F)^2 - \Delta^2}} \,, \tag{50.10}$$

where Δ is the half-width of the energy gap and $|E - E_F| > \Delta$. The variation of the normal state density of states $D_n(E)$ can be neglected because $E_F \gg 2\Delta$. The single-electron density of states shown in Fig. 50.8 reflects that the energy states present in the normal state within the energy gap are shifted to the edges. The inset of Fig. 50.8 shows the temperature dependence of the energy gap predicted by the BCS theory. The critical temperature is [50.5]

$$T_c = 1.14 \frac{\hbar \omega_D}{k_B} \exp\left(-\frac{1}{D_n(E_F) V_p}\right) , \tag{50.11}$$

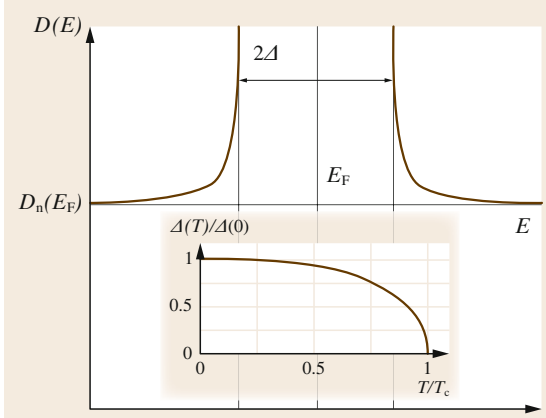

Fig. 50.8 Energy gap and density of states for unpaired electrons in the superconducting state in the vicinity of the Fermi energy E_F. The temperature dependence of the energy gap predicted by the BCS theory is shown in the *inset*

where the electron–phonon interaction is described by the constant V_p. The Debye frequency ω_D is the cut-off frequency of the phonon spectrum in a solid. Considering the atoms in a solid as harmonic oscillators of frequency $\omega = (k_e/M)^{1/2}$, where k_e is the elastic constant resulting from the binding forces, both ω_D and T_c are expected to be proportional to $M^{-1/2}$ for different isotopes of the same element. In many metallic superconductors, this isotope effect has been observed [50.43–46].

All Cooper pairs populate the same quantum state, resulting in a collective wave function

$$\psi = n_C^{1/2} \exp[i\varphi(r)] , \qquad (50.12)$$

where $n_C = \psi^*\psi$ (ψ^*: conjugate complex of ψ) is their concentration. Because the phase coherence of the Cooper pairs is effective at large distances, the phase $\varphi(r)$ is a macroscopically observable quantity. As a consequence, the magnetic flux in a superconducting hollow cylinder of the cross-sectional area F is quantized

$$\phi = \int_F B\mathrm{d}F = \frac{h}{2e} N_\phi = \phi_0 N_\phi . \qquad (50.13)$$

In the above equation, N_ϕ is an integer, e is the electron charge and $\phi_0 = 2.068 \times 10^{-15}$ V s is the flux quantum. The magnetic flux generated by the screening currents flowing in the surface layer of the superconductor is typically small, and has therefore been neglected.

Tunneling Effects

First, single-electron tunneling in a normal–insulator–superconductor (N-I-S) junction will be considered. The two conductors are separated by an insulating oxide layer typically less than 2 nm thick. Tunneling can take place only when empty target energy states are available, otherwise the process is forbidden by the Pauli principle (Fig. 50.9). For a voltage of $U = \Delta/e$ ($-e > 0$), the empty energy states of the superconductor above the energy gap reach the same level as the Fermi energy of the normal conductor, and strong tunneling sets in. On the other hand, for a voltage $U = -\Delta/e$, pair breaking becomes possible. One of the electrons tunnels into the normal conductor and gains an energy Δ available for the excitation of the second electron to an empty state above the energy gap. The resulting N-I-S current–voltage characteristic and the Bose condensation representation of the tunneling process are shown in Fig. 50.9.

In the case of two identical superconductors (S-I-S junction), strong single-electron tunneling sets in at an applied voltage $|U| \geq |2\Delta/e|$. This voltage is high

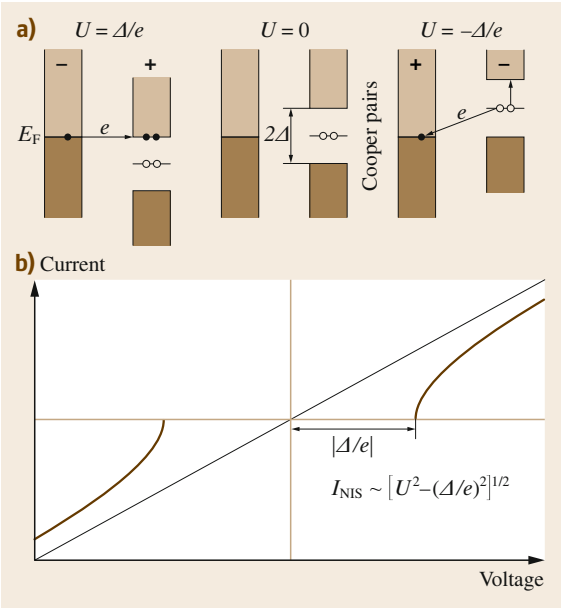

Fig. 50.9a,b Bose condensation representation of N-I-S tunneling **(a)** and the corresponding current voltage characteristic at $T = 0$ **(b)**

enough to allow the empty energy states above the gap of the first superconductor, and the filled energy states below the gap of the second superconductor, to overlap; pair breaking becomes possible. Figure 50.10 shows the semiconductor representation of the tunneling process and the resulting S-I-S current–voltage characteristic. The weak tunneling currents for $|U| < |2\Delta/e|$ are a consequence of a few quasi-particles being thermally excited above the energy gap for $T > 0$ (Fig. 50.10).

So far, only single-electron tunneling has been considered. In 1962, *B. D. Josephson* predicted that Cooper pair tunneling through a very thin insulating layer is possible [50.10]. Even for zero voltage across the insulating layer of an S-I-S junction, Cooper pairs can tunnel through the barrier. This process has to be considered as the tunneling of the wave function collectively describing the Cooper pairs. The DC current through the contact is

$$I = I_c \sin\delta , \qquad (50.14)$$

where I_c is the critical current of the Josephson junction. The Josephson DC current through the contact is between $-I_c$ and I_c, depending on the phase difference δ of the two Cooper pair wave functions. This phase difference is time independent for zero voltage across the insulating layer. Applying a DC voltage U across the insulating layer of the Josephson contact causes a time-

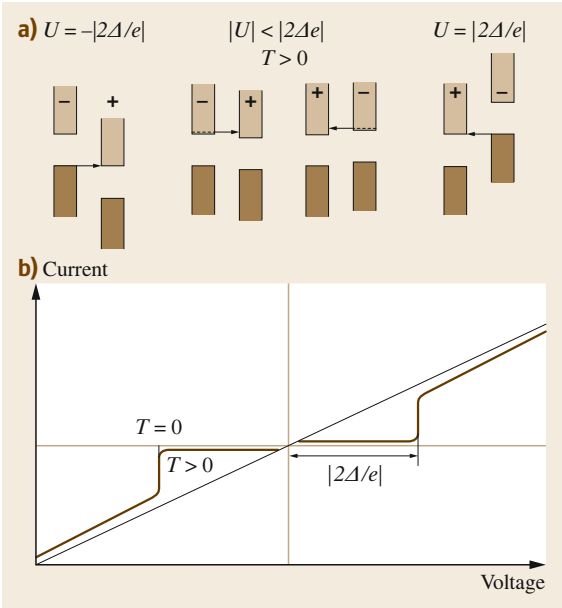

Fig. 50.10a,b S-I-S tunneling. The semiconductor representation of the process **(a)** shows that strong tunneling sets in for $U = |2\Delta/e|$. A few electrons (quasi particles) are thermally excited into states above the gap at $T > 0$. The corresponding current–voltage characteristic **(b)** shows that these electrons are responsible for the weak tunneling current at low voltages. (After [50.39, p. 42])

dependent phase difference between the two Cooper pair wave functions. As a consequence, there flows an AC current

$$I_{AC} = I_c \sin\left[2\pi\nu_J t + \delta(0)\right], \tag{50.15}$$

where

$$\nu_J = \frac{2\,|e|\,U}{h} = \frac{U}{\phi_0}\,. \tag{50.16}$$

The AC Josephson current I_{AC} oscillates with a frequency of 483.6 MHz/μV. The tunneling of the Cooper pair through the barrier is connected to the emission or absorption of a photon with energy $E = h\nu_J$. The AC Josephson current flows in addition to the current resulting from single-electron tunneling. A more detailed description of the AC Josephson effect can be found in [50.42].

Finally, macroscopic quantum interference effects in Josephson junctions will be briefly considered. These interference effects are closely connected to the phase shifts of the Cooper pair wave functions caused by a magnetic field applied transversely to the current direction. The applied magnetic field gives rise to a spatial variation of the phase difference of the two Cooper

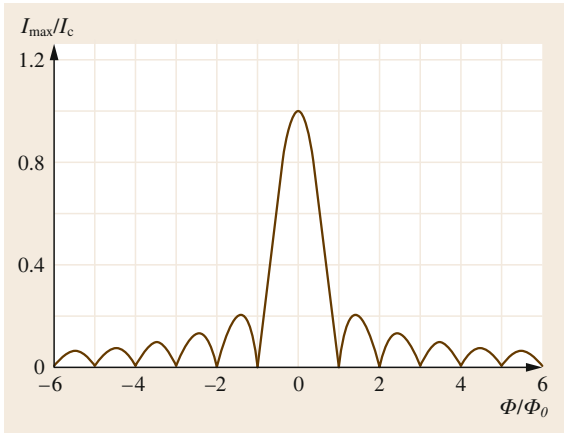

Fig. 50.11 Josephson–Fraunhofer diffraction pattern for the normalized maximum Josephson DC current I_{max}/I_c. Minima of the current occur for Φ/Φ_0 values of 1, 2, 3 etc. (After [50.39, p. 49])

wave functions within the contact area. The resulting Josephson DC current for a rectangular barrier is

$$I = I_c \sin\delta_0 \frac{\sin \pi\phi/\phi_0}{\pi\phi/\phi_0}\,, \tag{50.17}$$

where I_c is the critical current of the Josephson junction, ϕ is the total flux enclosed by the barrier, and ϕ_0 the flux quantum. The phase shift δ_0 is unknown. The maximum Josephson DC current

$$I_{max} = I_c \left| \frac{\sin \pi\phi/\phi_0}{\pi\phi/\phi_0} \right| \tag{50.18}$$

is reached for $\sin\delta_0 = 1$, corresponding to a phase difference of $\pi/2$. In Fig. 50.11, the resulting interference pattern for the Josephson DC current is shown. The Josephson–Fraunhofer interference of the two Cooper pair wave functions indicates that superconductivity is a macroscopic quantum phenomenon (for more details see [50.39]).

50.1.4 Type II Superconductors

A quantitative description of the behavior of type II superconductors is provided by the Ginzburg–Landau theory (see for example [50.42]). In the London theory, the Cooper pair density is assumed to be constant. The only characteristic length scale is the penetration depth λ_L describing the decay of a magnetic field inside a superconductor. Taking into consideration, a variation of the Cooper pair density leads to a second characteristic length scale, namely the coherence length ξ, the shortest distance within which a considerable change

Table 50.2 Coherence length ξ and Ginzburg–Landau parameter κ for selected superconductors at $T = 0$. (After [50.39, p. 70])

Material	T_c (K)	ξ (nm)	$\kappa = \lambda_L/\xi$	Reference

$YBa_2Cu_3O_{7-\delta}$	93	2	95	[50.42]

of the Cooper pair density can occur. At the interface of a normal and a superconductor, the Cooper pair density increases continuously from zero to the value n_C deep inside the superconductor. The ratio of the coherence length and the penetration depth is the Ginzburg–Landau parameter κ

$$\kappa = \frac{\lambda_L}{\xi} . \qquad (50.19)$$

Depending on whether the parameter κ is smaller or larger than $1/\sqrt{2}$, the superconductor in question is of type I or II, respectively. Values of the coherence length and the Ginzburg–Landau parameter of selected metallic superconductors are listed in Table 50.2. The cuprate high-T_c superconductors are extreme type II superconductors with κ values of ≈ 100.

In Fig. 50.12, the phase diagrams of both types of superconductors are compared. In type I superconductors, there exist two different phases, namely the

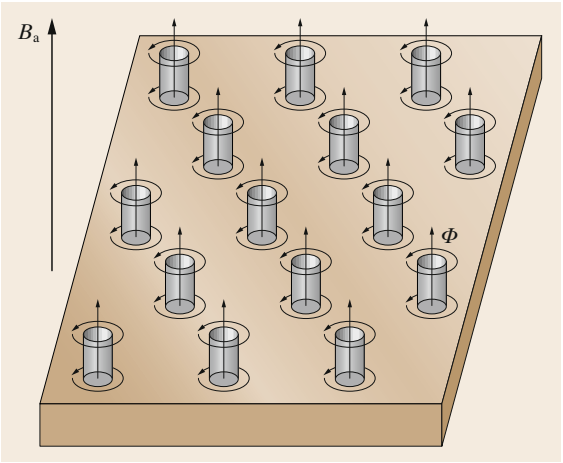

Fig. 50.13 Type II superconductor in the mixed state. Each vortex contains just a single fluxoid $\Phi_0 = h/2|e|$. (After [50.39, p. 74])

superconducting and the normal, which cannot coexist. On the other hand, three different phases can exist in type II superconductors. Below the lower critical field $B_{c1}(T)$, the type II superconductor is in the superconducting phase characterized by perfect diamagnetism, where it behaves like a type I superconductor. Above the upper critical field $B_{c2}(T)$, the material is in the normal state. In the mixed state between the lower and upper critical fields superconducting and normal regions can coexist in a type II superconductor. The mixed state shown in Fig. 50.13 is characterized by an array of normal cores within the superconductor, which allows magnetic flux to enter into the superconductor. The supercurrents encircling the normal cores (vortices) cause a repulsive vortex–vortex interaction.

In the mixed state of a type II superconductor, the transport currents can flow throughout the conductor. In the presence of a magnetic field perpendicular to

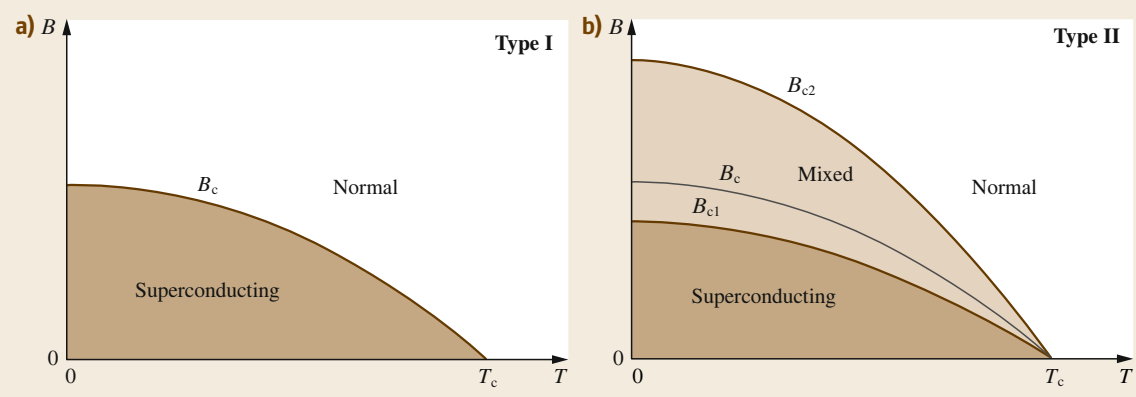

Fig. 50.12a,b Comparison of the phase diagrams for type I **(a)** and II superconductors **(b)**. (After [50.39, p. 74])

the current direction, a Lorentz force $F_L = j\phi_0$ acts on the vortices, which leads to a motion of the vortices perpendicular to the current and the field direction. The variation of the magnetic flux leads to a flux flow resistance, and hence the critical current would be zero. However, in a real type II superconductor defects are always present, which act as pinning centers. As long as the Lorentz force is smaller than the pinning force, flux motion is suppressed, resulting in zero resistance.

50.2 Cuprate High-T_c Superconductors: An Overview

50.2.1 Major Families of Cuprate Superconductors

At present, around 100 cuprate superconductors are known. The major families of cuprate superconductors are listed in Table 50.3. Common features of the cuprate superconductors are layered crystal structures. In the cuprates, conducting copper oxide blocks and insulating charge-carrier reservoirs alternate with each other along the crystallographic c direction. As a consequence of the layered structures, the physical properties of the cuprates are highly anisotropic. The electrical resistivity along the crystallographic a- and b-directions within the conductive CuO_2 planes is much lower than along the c-direction, where the current has to cross the insulating charge-carrier reservoirs. Figure 50.14 shows as an example the layering scheme of Tl-22$(n-1)n$ superconductors. The three thallium-based compounds are distinguished by the different number n of CuO_2 planes in the copper oxide blocks. In the compounds with $n \geq 2$, adjacent CuO_2 planes are separated by Ca layers. In the Bi-22$(n-1)n$ counterparts, Tl and Ba are replaced by Bi and Sr, respectively. In both families of cuprate superconductors the copper oxide blocks are embedded between TlO or BiO double layers. An analogous layering scheme results for the Tl-12$(n-1)n$ compounds. However, the copper oxide blocks of these compounds are separated only by single TlO layers. The highest critical temperature is typically reached in the compounds with three CuO_2 layers ($n = 3$) in the copper oxide blocks.

The physical properties of the cuprate superconductors depend strongly on their chemical composition and the resulting carrier concentration. As in semiconductors, the carrier concentration in the cuprates can be changed by doping. For example, let us consider the superconductor $La_{2-x}Sr_xCuO_4$. The possible oxidation states of copper are +1, +2, and +3. In the insulating parent compound La_2CuO_4, the oxidation state of copper is +2. The valence of La is +3 and that of Sr +2. Substitution of Sr^{2+} for La^{3+} leads to the formation of Cu^{3+} or O^- defects (holes), which are expected to be mobile. Thus, an increasing number of holes is created in the CuO_2 planes with increasing Sr concentration x.

The cuprates are complex nonstoichiometric oxides. Heat treatments in reducing or oxidizing atmosphere

Table 50.3 Major families of superconducting cuprates. (After [50.39, p. 79])

Family	Symbol	Maximum T_c (K)

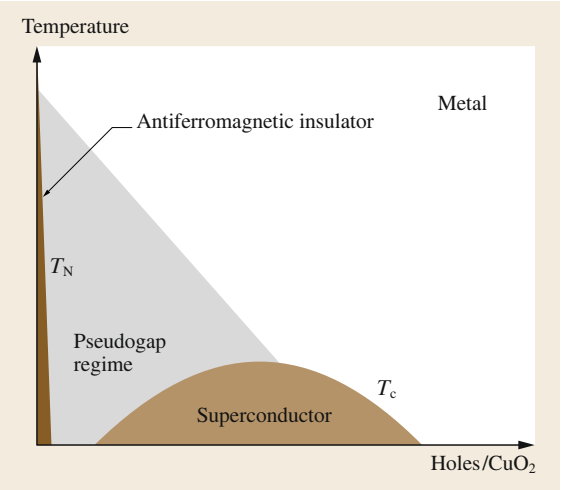

Fig. 50.15 Generic phase diagram for cuprate superconductors indicating that these materials are close to a metal–insulator transition. The physical properties of the cuprates vary considerably with increasing hole concentration ◄

therefore lead to considerable changes in the oxygen content. Incorporation of excess oxygen is a further way to enhance the hole concentration in the CuO_2 planes of the cuprates.

Finally, it should be noted that, in addition to the major families of cuprate superconductors listed in Table 50.3, there exist a large number of high-temperature superconductors which can be synthesized only under high pressure (see for example [50.39]).

50.2.2 Generic Phase Diagram of Cuprate Superconductors

It is beyond the scope of this chapter to discuss all the new physical phenomena related to cuprate superconductors. To give an impression of the complexity of these materials, the generic phase diagram is briefly described. The one shown in Fig. 50.15 indicates that the cuprate superconductors are close to a metal–insulator transition. Their parent compounds are antiferromagnetic Mott insulators, of which La_2CuO_4 and $YBa_2Cu_3O_6$ are examples. The Néel temperature T_N, at which magnetic ordering sets in, reaches values of 250–400 K in the parent compounds. The Néel temperature decreases rapidly with increasing hole concentration. A transition from an insulating to a superconducting phase is observed for further enhanced doping levels. The critical temperature increases with increasing number of holes and reaches a maximum at ≈ 0.18 holes per CuO_2 unit before decreasing again. At doping levels well above 0.3 holes/CuO_2, the material behaves as a nonsuperconducting metal.

In the last few years it could be clarified that the energy gap in cuprate superconductors is of d-wave symmetry, whereas it is of s-wave symmetry in conventional superconductors. The two different symmetries are illustrated in Fig. 50.16. For s-wave symmetry, the superconducting energy gap is constant irrespective of the direction of the wave vector $\boldsymbol{k}$. In the case of d-wave symmetry, there exist positions on the Fermi surface for which the energy gap is zero. At these positions, the sign of the order parameter changes from + to − or vice versa. As a consequence, a finite tunnel conductivity $[\mathrm{d}I/\mathrm{d}V \propto D(E)]$ is observed within the energy gap (Fig. 50.16).

Next, let us consider the temperature dependence of the energy gap. The tunneling conductance of under-

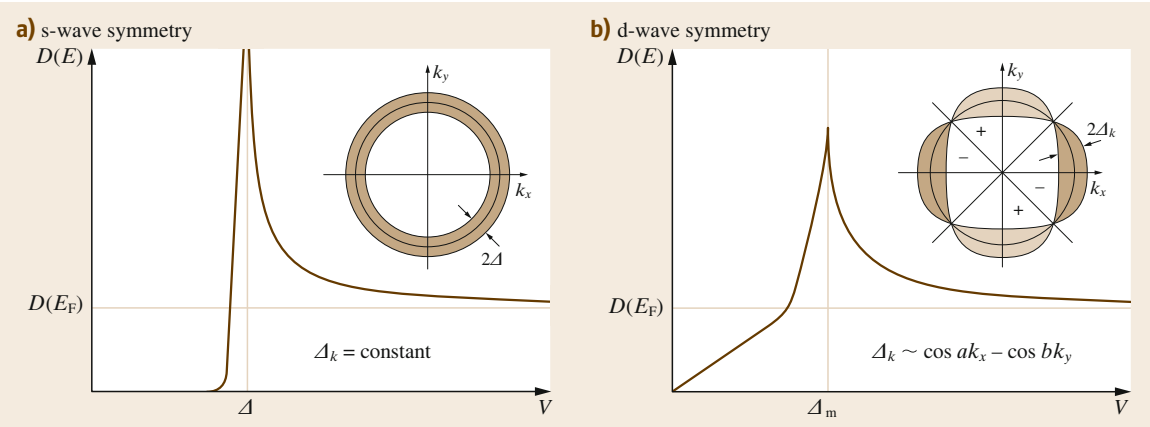

Fig. 50.16a,b The two different symmetries of the energy gap and the corresponding density of states. For s-wave symmetry **(a)**, the width of the energy gap is independent of the wave vector $\boldsymbol{k}$. In the case of the d-wave symmetry **(b)**, the energy gap depends on the wave vector. At four positions on the Fermi surface, the energy gap is zero. (After [50.50])

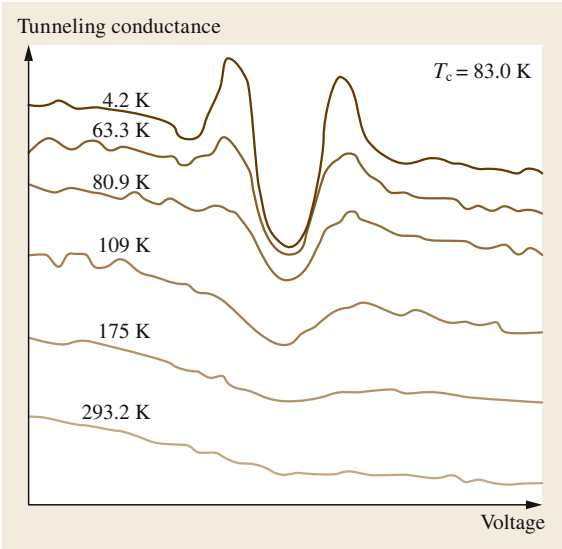

Fig. 50.17 Schematic illustration of the tunneling conductance of under-doped Bi-2212 providing the density of states in the vicinity of the energy gap. For clarity the spectra are offset vertically. A gap-like feature (pseudogap) can be observed even at a temperature as high as 175 K, well above T_c. (After [50.51])

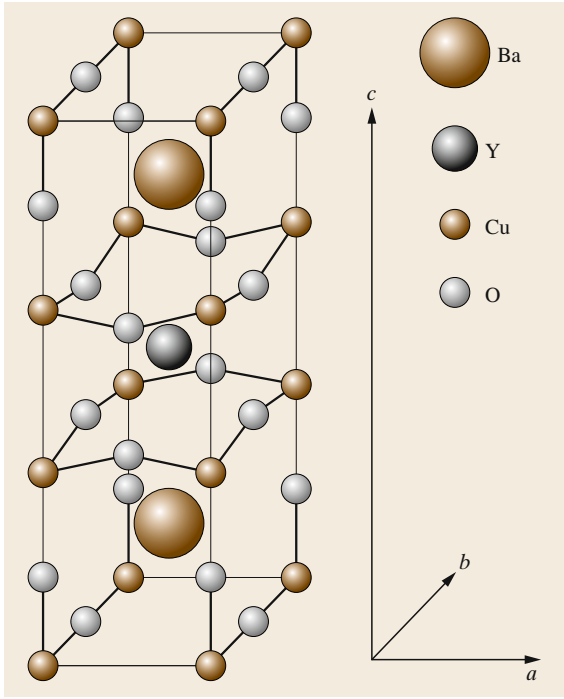

Fig. 50.18 Orthorhombic unit cell of $YBa_2Cu_3O_{7-\delta}$. A special feature of this cuprate are CuO chains in the *b*-direction. (After [50.39, p. 100])

doped Bi-2212 as shown in Fig. 50.17 indicates that the energy gap of cuprate superconductors is independent of temperature. This behavior is in contrast to the predictions of the BCS theory. In under-doped cuprate superconductors, the energy gap has been found to increase for decreasing number of charge carriers in spite of a reduced critical temperature. On the other hand, both the energy gap and the critical temperature of over-doped cuprates decrease with increasing carrier concentration. An outstanding feature of cuprate superconductors is the existence of an energy gap even at temperatures well above T_c. This pseudogap is found in the region of the phase diagram where a transition from an antiferromagnetic insulator to a superconductor occurs.

A potential explanation for the existence of the pseudogap is the formation of Cooper pairs at temperatures well above T_c. However, because of the low Cooper pair density, they are not macroscopically correlated. As a consequence, the material is not able to carry a supercurrent above T_c.

The Nernst effect is a thermo-magnetic phenomenon, in which a transverse voltage originates from a transverse magnetic field and a thermal gradient along the sample. In the presence of vortices, the Nernst effect is strongly enhanced. Measurements of the Nernst effect [50.52, 53] provided evidence for pairing well above the critical temperature in under-doped cuprate superconductors. However, the maximum temperature for the existence of vortices seems to be well below the temperature at which the pseudogap vanishes.

Newer results seem to favor the hypothesis that the pseudogap phenomenon competes with the gaps associated with superconductivity. A combined scanning tunneling microscopy and angle-resolved photoemission study of $Bi_2Sr_{2-x}La_xCu_{6+\delta}$ showed two distinct energy gaps. In the nodal direction, a small gap was found, which vanished at the critical temperature, while in the anti-nodal direction a large one was observed to exist well above the critical temperature. The two gaps seem to coexist in the antinodal direction [50.54]. In the nodal direction the energy gap of a d-wave superconductor vanishes.

New theories have predicted competing orders in the pseudogap regime of under-doped cuprate superconductors. As an example, let us consider charge stripes. Spin and charge are separated, resulting in antiferromagnetic domains and charge stripes located at the antiphase boundaries [50.55]. Experimental evidence for this scenario has been found from neutron scattering [50.56].

50.2.3 Crystal Structures

Next, let us consider the crystal structures of the cuprates in more detail. For $YBa_2Cu_3O_{7-\delta}$ (Y-123)

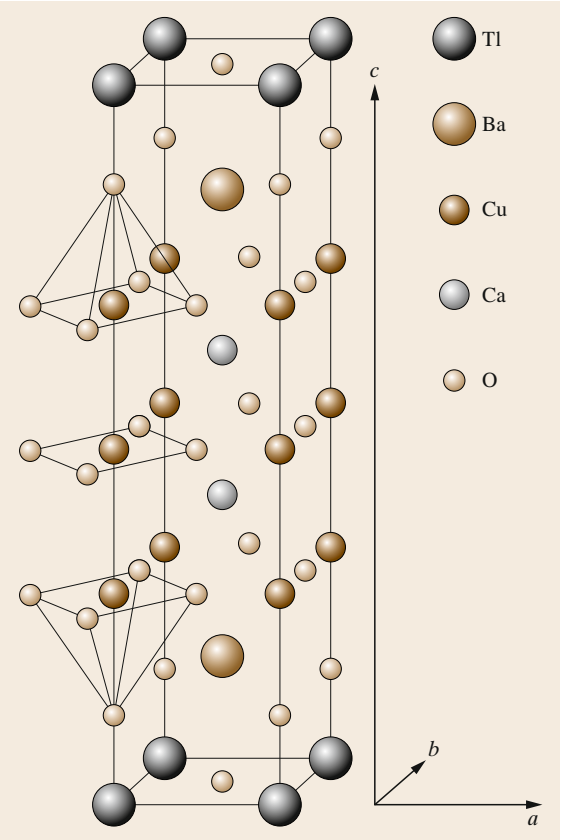

Fig. 50.19 Primitive tetragonal unit cell of $TlBa_2Ca_2Cu_3O_9$. (After [50.39, p. 108])

an orthorhombic structure with lattice parameters $a = 0.38\,\text{nm}$, $b = 0.39\,\text{nm}$ and $c = 1.17\,\text{nm}$ has been deduced from x-ray powder diffraction data [50.57, 58]. Figure 50.18 shows the orthorhombic unit cell of Y-123. The unit cell of $YBa_2Cu_3O_{7-\delta}$ contains double CuO_2 layers with embedded yttrium ions (Fig. 50.18). Slightly different z positions of the Cu and O atoms lead to buckling in the CuO_2 planes. The oxygen atoms occupy perovskite-like anion positions halfway between the copper atoms. These square-coordinated CuO_2 layers are a characteristic feature of all cuprate superconductors. Because metallic conductivity has been found in these layers, they are also called conduction planes. Along the crystallographic c-axis perpendicular to these planes, insulating or semiconducting behavior is frequently observed. Neighboring CuO_2 blocks are separated by two BaO layers. The CuO chains between the two BaO layers in the b-direction are a special feature of the Y-123 compound.

The crystal structures of Tl-12$(n-1)n$ and the analogous Hg-12$(n-1)n$ superconductors are primitive tetragonal. Because of the common CuO_2 planes, the a and b lattice parameters of cuprate superconductors are generally close to 0.39 nm. In both cuprate superconductor families, the c lattice parameter is given approximately by $c \cong (0.63 + 0.32n)\,\text{nm}$. As an example of these crystal structures the primitive tetragonal unit cell of $TlBa_2Ca_2Cu_3O_9$ is shown in Fig. 50.19. The copper oxide blocks of the Tl-1223 compound are formed of three CuO_2 layers. The CuO_2 layers within the copper oxide blocks are separated by

Ca ions. In contrast to the Tl-22$(n-1)n$ compounds (Fig. 50.14) adjacent CuO_2 blocks are separated by only a single TlO layer. Like the TlO double layers of the 22$(n-1)n$ compounds, the single TlO layers of the 12$(n-1)n$ compounds are embedded between two BaO layers. The reduced distance of neighboring copper oxide blocks leads to an enhanced coupling of the conduction planes. This improved coupling is reflected in less anisotropic superconducting properties (Sect. 50.3). Defects in the BaO/TlO/BaO layers forming the charge-carrier reservoirs provide holes for the doping of the CuO_2 planes. In the Tl-12$(n-1)n$ compounds, the BaO layers can be replaced by SrO layers. The substitution of Tl by Hg leads to the structurally analogous Hg-12$(n-1)n$ counterparts. The lattice parameters of selected cuprate superconductors are listed in Table 50.4.

50.2.4 Critical Temperatures

Next, some of the factors determining the critical temperature of cuprate superconductors will be discussed. As shown in the generic phase diagram for cuprate superconductors (Fig. 50.15), the critical temperatures of these materials are closely connected to the hole concentration p in the CuO_2 planes, which is determined by the formal valence $2+p$ of the copper atoms in the conduction planes. Generally, an inverse parabolic dependence of the critical temperature on the number of holes per CuO_2 has been found. The maximum T_c is typically reached for a hole concentration p of 0.15–0.2 holes per CuO_2. For hole concentrations above 0.2 holes per CuO_2 the critical temperature decreases with increasing carrier concentration, leading to a nonsuperconducting metal for $p > 0.3$ holes per CuO_2. As an example of this behavior, the critical temperature of $HgBa_2CuO_{4+\delta}$ as function of the hole concentration is shown in Fig. 50.20.

In addition to the carrier concentration, the number of CuO_2 planes in the perovskite blocks is of importance for the critical temperature. The maximum critical temperatures of selected cuprate superconductors listed in Table 50.5 clearly indicate that the critical temperature increases with increasing number n of CuO_2 planes in the copper oxide blocks, at least up to the compound with $n = 3$. For compounds with four or more CuO_2 planes in the perovskite blocks, the critical tem-

perature decreases with increasing n. In Fig. 50.21, this behavior is illustrated for the Hg-12$(n-1)n$ compounds. A possible explanation for the observed behavior is the fact that in cuprates with $n \geq 3$, the hole concentrations in the central and outer CuO_2 layers may be considerably different. It may therefore be impossible to reach simultaneously the optimum carrier concentration in all the CuO_2 layers for compounds with $n \geq 4$.

Finally, it should be mentioned that the critical temperature of cuprate superconductors has been found to be connected with the lattice parameters. Consequently, the critical temperature depends on applied pressure. Application of a hydrostatic pressure typically enhances the critical temperature of cuprate superconductors. In Hg-1223, superconductivity was observed at temperatures as high as 164 K at a pressure of 31 GPa [50.65]. A more complex situation results for the application of uniaxial pressure. In the case of pressure along the crystallographic a- or b-axis the critical temperature is enhanced, whereas for uniaxial pressure along the c-direction T_c is reduced [50.66, 67].

50.3 Physical Properties of Cuprate Superconductors

50.3.1 Anisotropic Superconductors

As a consequence of the layered crystal structures of the cuprates, the penetration depth depends on the direction of the screening currents. Assuming that the screening currents in the a- and b-directions are equal, two different penetration depths λ_{ab} and λ_c result. The indices give the direction of the screening currents. Thus, two different Ginzburg–Landau parameters $\kappa_{ab}(B||ab)$ and $\kappa_c(B||c)$ can be defined

$$\kappa_{ab} = \left(\frac{\lambda_{ab}\lambda_c}{\xi_{ab}\xi_c}\right)^{1/2} ,$$
$$\kappa_c = \frac{\lambda_{ab}}{\xi_{ab}} , \qquad (50.20)$$

where ξ_{ab} and ξ_c are the coherence lengths in the ab-plane and along the c-direction, respectively. The dimensionless anisotropy parameter is given by [50.68]

$$\gamma_a = \left(\frac{m_c}{m_{ab}}\right)^{1/2} = \frac{\lambda_c}{\lambda_{ab}} = \frac{\xi_{ab}}{\xi_c} = \frac{B_{c2,ab}}{B_{c2,c}} = \frac{B_{c1,c}}{B_{c1,ab}} , \qquad (50.21)$$

where m_{ab} and m_c are the effective masses of the charge carriers for in-plane and out-of-plane currents, respectively. The expressions for the upper critical fields are [50.48, 68]

$$B_{c2,c} = \frac{\phi_0}{2\pi\xi_{ab}^2} ,$$
$$B_{c2,ab} = \frac{\phi_0}{2\pi\xi_c\xi_{ab}} . \qquad (50.22)$$

The upper and lower critical fields of various cuprate superconductors are listed in Table 50.6. The lower critical fields are typically between 10 and 500 mT for magnetic fields applied along the c-direction. The upper critical fields of cuprate superconductors can exceed 100 T even for the unfavorable field direction $B||c$. The data for Tl-2201, Hg-1201, and Hg, Cu-1201 given in Table 50.6 clearly indicate that the critical fields, like the critical temperatures, depend on the actual doping level.

For the characteristic length scales in cuprate superconductors, the following relation has been found

$$\xi_c < \xi_{ab} \ll \lambda_{ab} < \lambda_c . \qquad (50.23)$$

Table 50.7 lists for various cuprate superconductors the penetration depths and the coherence lengths. The in-plane coherence length ξ_{ab} is typically 1–4 nm. The considerably smaller values found for the out-of-plane coherence length ξ_c are comparable to interatomic distances. The small values of ξ_c are responsible for the insulating character of the charge-carrier reservoirs (Fig. 50.14) separating adjacent CuO_2 blocks. The cuprates are therefore nearly two-dimensional superconductors with intrinsic Josephson junctions along the c-direction. Moreover, the cuprates are extreme type II superconductors with κ_c values around 100.

50.3.2 Irreversibility Line

The magnetic phase diagram of cuprate superconductors is much more complicated than that of metallic superconductors. It is beyond the scope of this chapter to describe the details of the magnetic phase diagram of cuprate superconductors. A simplified magnetic phase diagram is shown in Fig. 50.22. An outstanding feature of high-temperature superconductors is the existence of an irreversibility line well below the upper critical field. Above this line, the vortices are movable, and hence the critical current density is zero. The irreversibility line

[a] Different doping levels

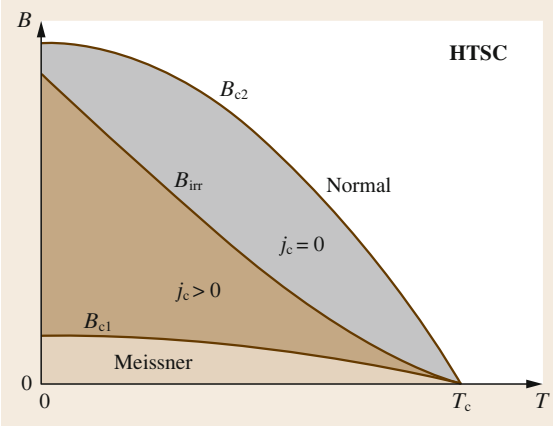

Fig. 50.22 Simplified magnetic phase diagram of cuprate superconductors. Above the irreversibility line, the vortices are movable, and hence the critical current density is zero. (After [50.39, p. 138])

can be described by the expression

$$B_{irr} = B_0 \left(1 - \frac{T_{irr}}{T_c}\right)^{\alpha}, \qquad (50.24)$$

where B_{irr} is the irreversibility field, T_{irr} is the irreversibility temperature, B_0 is a fitting parameter, and the exponent α is characteristic of the superconductor in question. In the case of Y-123, the exponent α is close to 1.5 for magnetic fields perpendicular to the crystallographic c-direction, while values around 1.3 have been found for $B||c$ [50.73].

The existence of the irreversibility line is reflected in the broadening of the resistive transition in the pres-

ence of an applied magnetic field. Figure 50.23 shows the resistive transition of a Bi-2212 single crystal for magnetic fields of 2, 5, and 12 T parallel to the *c*-direction. The data for zero applied field are also shown in Fig. 50.23. The end point of the resistive transition corresponds to the irreversibility temperature for the magnetic field applied. On the other hand, the onset of the resistivity drop may be used to determine the upper critical field.

The existence of an irreversibility line can be explained in two different ways. In the more conventional picture, the occurrence of resistance above the irreversibility line is caused by thermally activated depinning. Within this picture, it can be easily understood that the irreversibility line of cuprate superconductors is shifted to higher fields and temperatures by heavy-ion irradiation [50.90–92]. The irradiation generates amorphous tracks, which are efficient pinning centers. An alternative scenario is the melting of the flux-line lattice. Evidence for this possibility is the latent heat measured at the phase transition [50.93, 94].

The maximum operating field of cuprate superconductors is limited by the irreversibility line for the unfavorable field direction $B||c$. In any comparison of the behavior of different cuprates the irreversibility field as a function of the reduced temperature T/T_c should be considered. The highest irreversibility fields result for Y-123, while the lowest values of B_{irr} have been found for Bi- and Tl-22$(n-1)n$ compounds. Intermediate irreversibility fields result for Tl- and Hg-12$(n-1)n$ compounds [50.39, 95]. The observed order in the irreversibility fields indicates that flux pinning is more efficient in cuprates with less anisotropic physical properties. The largest anisotropy of the physical properties has been observed in Bi- and Tl-22$(n-1)n$ compounds with the largest distance of adjacent CuO_2 blocks. The relatively small anisotropy of Y-123 seems to be the consequence of the short-circuiting of the insulating charge-carrier reservoirs by the CuO chains (Fig. 50.18).

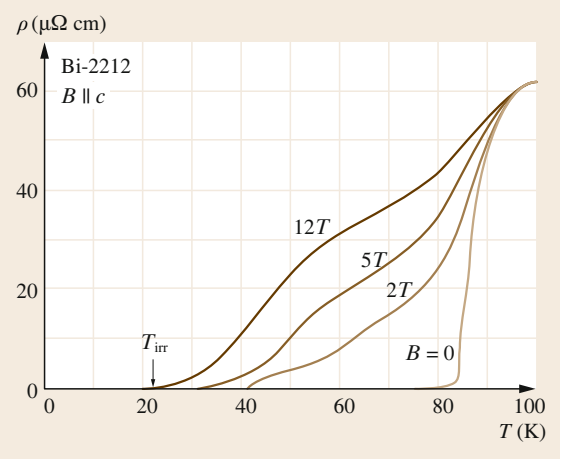

Fig. 50.23 Resistivity versus temperature curves of a Bi-2212 single crystal for magnetic fields parallel to the *c*-direction. (After [50.39, p. 139], results from [50.89])

50.3.3 Limitations of the Transport Critical Current

The electric field generated in a superconductor at the transition to the normal conducting state is typically well described by a power law $E = E_c(I/I_c)^n$, where I is the current, n is the index of resistive transition, and E_c the electric field used to define the critical current I_c. Typically E_c values of 0.1 or 1 μV/cm are used to determine the critical current.

It should be recognized that, unlike the critical temperature and the upper critical field, the critical current density is not an intrinsic material property. The achievable j_c values are determined mainly by the microstructure of the superconductor in question. Grain boundaries can act as weak links, leading to small critical current densities in polycrystalline cuprate superconductors. In the absence of grain-boundary weak links, the transport j_c is mainly determined by flux pinning. Before these effects are discussed, the anisotropy of j_c in individual grains and epitaxial thin films is considered.

Anisotropy of the Critical Current Density

In cuprate superconductors, conductive copper oxide blocks and insulating charge-carrier reservoirs alternate along the crystallographic *c*-direction. The currents can easily flow in the conductive CuO_2 planes, whereas currents along the *c*-direction have to cross the insulating or semiconducting charge-carrier reservoirs (tunneling). In spite of j_c values as high as 10^8 A/cm^2 in the CuO_2 planes of Hg-1212 films, the estimated j_c along the *c*-direction is as low as 5000 A/cm^2 [50.96].

A further anisotropy of the critical current density is related to the direction of the applied magnetic field. Figure 50.24 shows the critical current density of an epitaxial Bi -2212 film as a function of the applied magnetic field for selected temperatures. The critical current density declines rapidly with increasing applied field for $B||c$, while the field dependence of j_c is much less pronounced for $B||ab$. This behavior reflects the considerably different upper critical fields for these two field directions. The angle dependence of j_c in epitaxial Bi-2212 and Bi-2223 films can be described by the expression

$$j_c(B,\theta) = j_{c,c}(B\sin\theta)\,, \qquad (50.25)$$

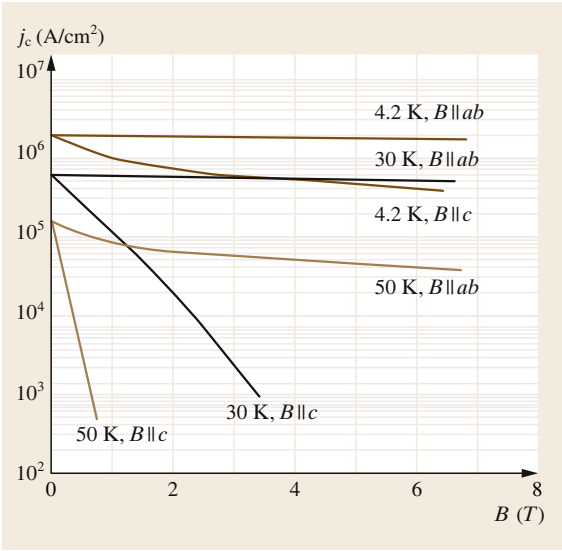

Fig. 50.24 Critical current densities in epitaxial Bi-2212 films as a function of applied magnetic field for B along the ab-planes and parallel to the crystallographic c-direction. (After [50.97])

where θ is the angle between the ab-planes and the field direction, and $j_{c,c}$ is the critical current density for $B||c$. The above expression states that the reduction of the critical current by an applied magnetic field is determined exclusively by the field component parallel to the c-direction.

Grain-Boundary Weak Links

Soon after the discovery of superconductivity above 77 K in Y-123, it was noticed that the transport j_c in sintered samples is typically well below 1000 A/cm^2. In addition, magnetic fields of a few mT are sufficient to reduce the j_c by an order of magnitude. On the other hand, critical current densities well above 10^6 A/cm^2 could be achieved in epitaxial Y-123 films. These experimental results suggest that the grain boundaries present in polycrystalline material can act as barriers for the transport current. Due to extremely short coherence lengths, $\xi_c < 1$ nm, the Cooper pair density can be considerably reduced within the width of a grain boundary. Two grains separated by a grain boundary can therefore be considered as a Josephson junction.

The high j_c values achieved in highly textured films suggest that low-angle grain boundaries are strongly coupled. To clarify this aspect, the transport properties of artificial grain boundaries have been studied [50.98, 99]. In epitaxial growth the crystallography prescribed by the substrate can be transmitted to the Y-123 film. Using $SrTiO_3$ bicrystals, two Y-123 grains connected by an artificial grain boundary with a well-defined mis-

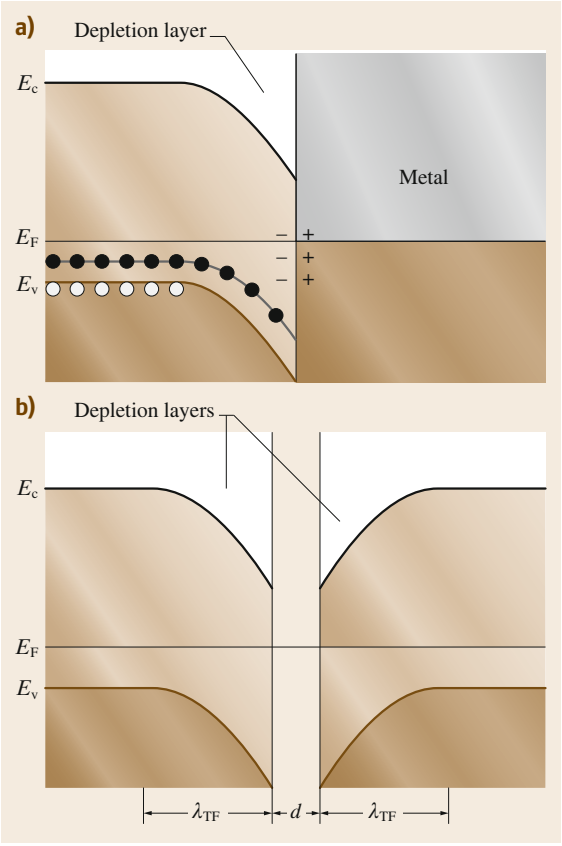

Fig. 50.25a,b Space-charge effects and band bending at a semiconductor–metal interface **(a)** and at a grain boundary in a cuprate superconductor **(b)**. (After [50.102])

orientation angle θ can be prepared. The critical current density across the grain boundaries has been found to decrease rapidly with increasing misalignment angle. For [001]-tilt boundaries (rotation of the second grain around the common c-axis) in Y-123 films, the grain boundary j_c depends exponentially on the misalignment angle θ

$$j_c = j_{c0} \exp\left(-\frac{\theta}{\theta_0}\right), \qquad (50.26)$$

where $\theta_0 \cong 6.3°$ and $j_{c0} \cong 2 \times 10^7$ A/cm^2 at 4.2 K [50.100]. The corresponding values for Bi-2223 [001]-tilt grain boundaries are $j_{c0} = 6 \times 10^6$ A/cm^2 and $\theta_0 = 5°$ at 26 K [50.101].

The weak-link behavior is closely related to the strong reduction of the Cooper pair density in the grain boundaries caused by the extremely short coherence lengths and the low carrier concentrations in cuprate superconductors. The carrier concentration in optimally doped cuprate superconductors is around 5×10^{21} cm^{-3},

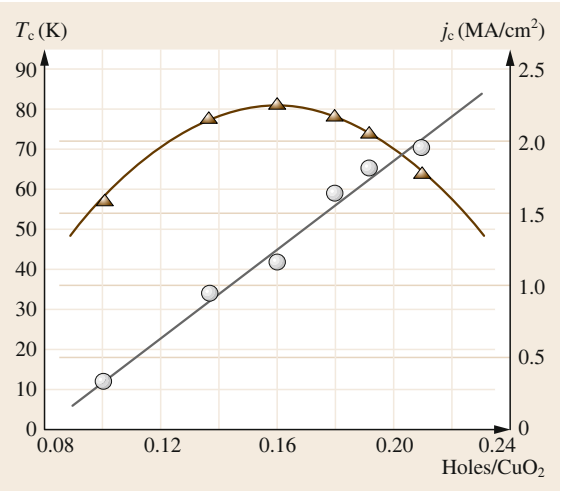

Fig. 50.26 Critical temperature (*triangles*) and current density (*circles*) of a symmetric 24° [001]-tilt boundary as a function of the hole concentration. The charge-carrier concentration in the bicrystalline $Y_{0.7}Ca_{0.3}Ba_2Cu_3O_{7-\delta}$ films has been modified by annealing at different oxygen pressures. (After [50.100])

whereas the carrier concentration in copper is as high as $85\times10^{21}\,\mathrm{cm}^{-3}$. Furthermore, the behavior of grain boundaries in cuprate superconductors is similar to that of semiconductor–metal interfaces [50.102, 103]. In the case of a p-type semiconductor in contact with a metal characterized by a smaller work function, electrons flow from the metal into the semiconductor. As a consequence, both the valence and the conduction band are bent downward (Fig. 50.25a). There an excess of negatively charged acceptor ions and a depletion of holes in the valence band result. Currents from the metal to the semiconductor would further enlarge the space-charge region and are therefore negligible (Schottky contact). Because of low carrier concentrations and large dielectric constants ($\varepsilon\approx10$), band-bending effects can occur in cuprate superconductors. The grain boundaries of cuprate superconductors may be considered as double Schottky barriers (Fig. 50.25b). The resulting Thomas–Fermi screening length is in the range of 0.5−1 nm, which is comparable to the coherence length. The width of the insulating layer at the grain boundary is $t=d+2l_\mathrm{d}$, where d is the structural width of the boundary and l_d the thickness of the depletion layer. The structural width of typical grain boundaries is ≈0.4 nm. On the other hand, the thickness of the depletion layer is 0.16 nm for $\varepsilon=10$, an in-built voltage of 0.1 V, and a carrier concentration of $4.5\times10^{21}\,\mathrm{cm}^3$ [50.102]. Consequently, the total thickness of the insulating layer is considerably enhanced by the space-charge region.

In such a scenario it should be possible to modify the electronic properties of the interface by increasing the carrier concentration. In Y-123 this can be done by Ca doping. Figure 50.26 shows for symmetric 24° [001]-tilt boundaries the critical temperature and current density as a function of the hole concentration. As expected the j_c values at 4.2 K increase with increasing hole concentration even in the over-doped region, where T_c decreases.

Flux Pinning

Transport currents without losses can only flow in a type II superconductor when the flux lines are effectively pinned. The screening currents circulating around each flux line are responsible for a repulsive vortex–vortex interaction, which prevents flux motion as soon as a sufficiently large fraction of the flux lines is pinned. The effectiveness of this collective pinning depends on the stiffness of the flux-line lattice.

The energy required to create a flux line can be estimated from the lower critical field B_{c1} [50.47]. At the lower critical field, flux lines start to enter the superconductor. The formation energy for each flux line is therefore

$$E_\mathrm{fl}=\int_0^{B_{c1}} m\mathrm{d}B \quad\text{with}\quad m=\frac{\phi_0}{\mu_0}l_\mathrm{fl}\,, \tag{50.27}$$

where m is the magnetic moment of a flux line of length l_fl containing a single flux quantum. The required energy per unit length is

$$\frac{E_\mathrm{fl}}{l_\mathrm{fl}}=\frac{\phi_0}{\mu_0}B_{c1}\,. \tag{50.28}$$

Using $\kappa=\lambda_\mathrm{L}/\xi$ the lower critical field can be written as [50.42]

$$B_{c1}=\frac{\phi_0\ln\kappa}{4\pi\lambda_\mathrm{L}^2}\,. \tag{50.29}$$

When the flux line is in a normal region, no energy is required to form the normal vortex core, and the resulting pinning energy per unit length is

$$\frac{E_\mathrm{fl}}{l_\mathrm{fl}}=\frac{1}{4\pi\mu_0}\left(\frac{\phi_0}{\lambda_\mathrm{L}}\right)^2\ln\left(\frac{\lambda_\mathrm{L}}{\xi}\right). \tag{50.30}$$

Generally, regions with reduced Cooper pair densities due to defects can act as pinning centers.

The pinning properties of the cuprate superconductors are highly anisotropic. Relatively strong pinning has been found for magnetic fields transverse to the current direction applied in the *ab* plane. For the resulting

Lorentz force along the *c*-direction, strong intrinsic pinning may be provided by the insulating charge-carrier reservoirs of the layered structure along the *c*-direction. On the other hand, the pinning is weak for magnetic fields transverse to the current direction applied along the *c*-direction, leading to a Lorentz force parallel to the *ab*-planes. Flux lines along the *c*-direction experience strong pinning only within the CuO_2 blocks. As a consequence of the layered structure, the vortices may be cut into vortex segments or even pancake vortices which exist only within the conductive CuO_2 blocks. These pancake vortices could easily move in the direction of the Lorentz force.

The positions of the irreversibility lines in the different cuprate superconductors reflect the anisotropy of the pinning properties. Typically, the pinning efficiency for magnetic fields along the *c*-direction decreases as one progresses from Y-123 via the Hg- and Tl-$12(n-1)n$ compounds to the highly anisotropic Bi- and Tl-$22(n-1)n$ cuprates.

50.4 Superconducting Films

Because of the weakly coupled large-angle grain boundaries present in polycrystalline bulk material, the transport critical current density is much smaller than the j_c of the individual grains. In contrast to polycrystalline bulk material, adjacent grains of epitaxial films are connected by low-angle grain boundaries. As a consequence, the critical current densities measured in epitaxial films are close to the j_c values of individual grains. At low temperatures and zero applied field, the critical current densities in epitaxial Y-123, Bi-2212, Bi-2223 and Hg-1223 films exceed 10^7 A/cm^2 [50.97, 104–106]. Even at 77 K j_c-values well above 10^7 A/cm^2 have been measured in Y-123 films [50.107].

The physical properties of ultrathin films can be considerably different from those of bulk single crystals. First, let us consider the effect of the film thickness on the critical temperature. For the growth of epitaxial ultrathin films, a substrate with good lattice matching is required. $YBa_2Cu_3O_7$ films of thickness equal to the height of a single unit cell in the *c*-direction can be grown onto $SrTiO_3$ single crystals covered by a six-unit-cell-thick nonsuperconducting $PrBa_2Cu_3O_7$ (Pr-123) buffer layer [50.108]. The lattice mismatch of Y-123 and Pr-123 is less than 1.5%. The layer growth can be checked by the observation of the strong intensity oscillations of reflection high-energy electron diffraction. The period of these oscillations has been found to correspond to the height of a single unit cell. Y-123 films with a thickness of 1−10 unit cell heights were grown by coevaporation of the metals under oxygen atmosphere. To provide hole doping the ultrathin Y-123 films are covered by a six-unit-cell-thick Pr-123 layer. The offset critical temperature of these Y-123 films is considerably lower than that of a 100-nm-thick film (Fig. 50.27). On the other hand, the onset critical temperature has been found to be much less affected. The reduction of the offset critical temperature has been attributed to the more pronounced critical fluctuations in the thinner films. Critical fluctuations are variations of the superconducting order parameter $\psi = n_C^{1/2}\exp(i\varphi)$ (n_C is the Cooper pair density) around the thermal equilibrium values.

The critical temperature of ultrathin Y-123 layers in Y-123/Pr-123 multilayers has been found to depend on the thicknesses of the insulating Pr-123 layers [50.109]. The thickness of 1.2 nm of the embedded Y-123 layers corresponds to the height of a single unit cell in the *c*-direction. The critical temperature of the Y-123/Pr-123 multilayer decreases from ≈ 50 K (10% of normal-state resistance) to ≈ 13 K for Pr-123 interlayer thicknesses of 1.2 and 7.2 nm, respectively. Because of the Josephson coupling of adjacent Y-123 layers in the multilayer the critical fluctuations are expected to be less pronounced than in a single Y-123 film

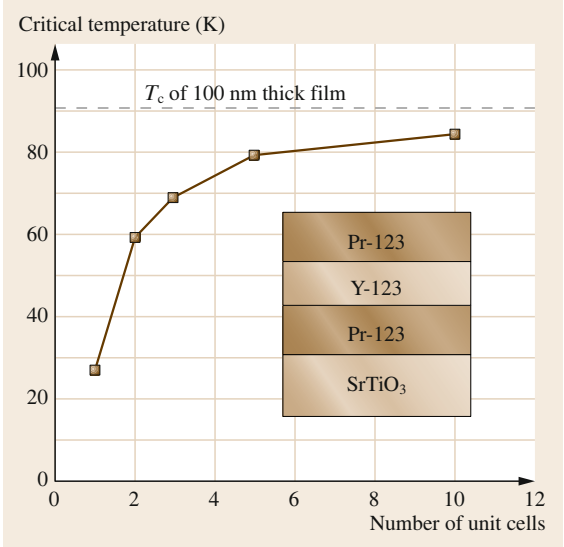

Fig. 50.27 Offset critical temperature of ultrathin Y-123 films as a function of the layer thickness normalized to the *c* lattice parameter. (After [50.108])

of the same thickness. Thus, the T_c of the Y-123 layers in the Y-123/Pr-123 multilayer with a Pr-123 thickness of 1.2 nm is higher than that of a single Y-123 layer of the same thickness (Fig. 50.27).

Finally, let us consider the effects of epitaxial strain on the critical temperature of (La, Sr)$_2$CuO$_4$ films [50.67, 110, 111]. In epitaxial growth, the crystallography prescribed by the substrate is transmitted to the film. For a sufficiently small film thickness, the lattice constant of the film is equal to that of the substrate. As a consequence of the lattice mismatch a considerable epitaxial strain can be induced in the film. Under epitaxial growth conditions, a compressive strain in the CuO_2 planes of (La, Sr)$_2$CuO$_4$ is accompanied by a tensile strain in the *c*-direction. Typically, in-plane compressive and out-of-plane tensile strains enhance the T_c of cuprate superconductors. Thus, the critical temperature of cuprate superconductors should be much more sensitive to epitaxial strain effects than to hydrostatic pressure, where the opposite in-plane and out-of-plane effects partly cancel each other. Because of film deposition at temperatures above 750 °C, differences in the thermal expansion coefficients provide an additional contribution to the strain in the films. In thick films the epitaxial strain is released by the appearance of misfit dislocations. The expected change in the critical temperature of the films is given by

$$T_c = T_c(0) + 2\frac{dT_c}{d\varepsilon_{ab}}\varepsilon_{ab} + \frac{dT_c}{d\varepsilon_c}\varepsilon_c \,, \qquad (50.31)$$

where $\varepsilon = (d_{bulk} - d_{strained})/d_{bulk}$, with d being a lattice parameter.

To study the epitaxial strain effects, *Locquet* et al. [50.67] deposited $La_{1.9}Sr_{0.1}CuO_4$ films ($a = 0.3784$ nm, $\alpha = 8.5\times10^{-6}\,K^{-1}$) of 10–15 nm thickness on $SrTiO_3$ ($a = 0.3905$ nm, $\alpha = 9\times10^{-6}\,K^{-1}$) and $SrLaAlO_4$ ($a = 0.3754$ nm, $\alpha = 10.5\times10^{-6}\,K^{-1}$) substrates. Using x-ray diffraction, strain values of $\varepsilon_{ab} = 0.63\%$ and $\varepsilon_c = -0.76\%$ have been determined for the La-214 film on $SrTiO_3$. The corresponding strain values for the La-214 film deposited onto $SrLaAlO_4$ are $\varepsilon_{ab} = -0.54\%$ and $\varepsilon_c = 0.35\%$. The results of *Locquet* et al. [50.67] are shown in Fig. 50.28. The critical temperatures of the La-214 films of 10 ($SrTiO_3$) and 49 K ($SrLaAlO_4$) are, as expected, considerably different from the bulk value of 25 K. In addition, the temperature dependencies of the normal state resistivities of the two films are remarkably different. The film experiencing a tensile in-plane strain shows an upturn of the normal state resistance at temperatures below 100 K, which is an effect also found in under-doped cuprate superconductors.

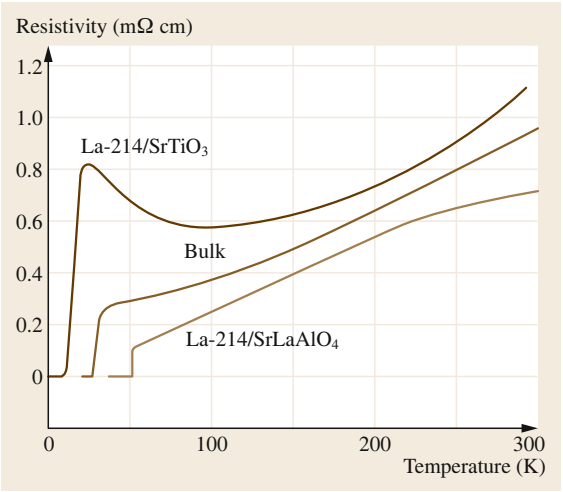

Fig. 50.28 Resistivity versus temperature for La-214 films on $SrTiO_3$ and $SrLaAlO_4$ substrates. The different epitaxial strains lead to considerably different critical temperatures of 10 and 49 K. For comparison the resistivity of La-214 bulk material ($T_c = 25$ K) is also shown. (After [50.67])

50.5 The Special Case of MgB_2

In spite of the fact that MgB_2 has been known since the early 1950s, it was unknown until 2001 that it is a superconductor with a remarkably high transition temperature. Figure 50.29 shows the hexagonal crystal structure of MgB_2, consisting of alternating layers of boron and magnesium. As a consequence of the layered structure, anisotropic physical properties result. The arrangement of the boron atoms is the same as that of the carbon atoms in graphite. Each of the boron atoms is surrounded by three other boron atoms at the same distance.

To study the role of phonons in the superconductivity of MgB_2, the critical temperatures of isotopically pure $Mg^{10}B_2$ and $Mg^{11}B_2$ specimens have been studied [50.117]. The transition temperatures of $Mg^{11}B_2$ and $Mg^{10}B_2$ defined by a 2% onset criterion are 39.2 and 40.2 K, respectively. Defining a partial boron isotope-effect exponent $\beta_B = \Delta \ln T_c / \Delta \ln M_B$, where M_B is the atomic mass of boron, a value of $\beta_B = 0.26 \pm 0.03$ results from the experimental data. On the other hand, the isotope effect for $^{26}MgB_2$ and $^{24}MgB_2$ is much less pronounced [50.118]. The shift of

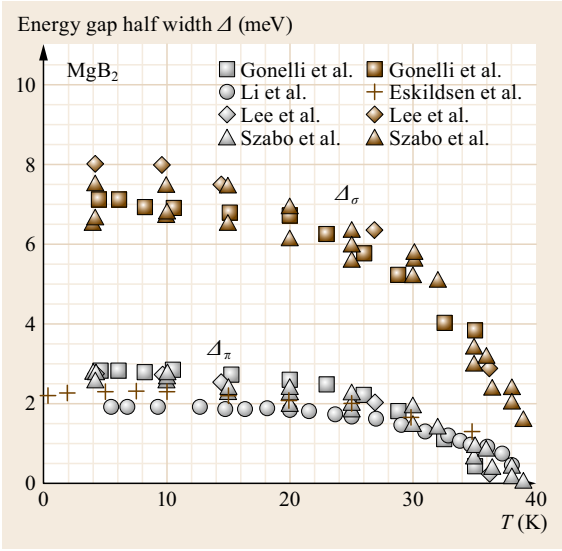

Fig. 50.30 Half-widths of the σ- and π-band gaps of MgB_2. (After [50.112–116])

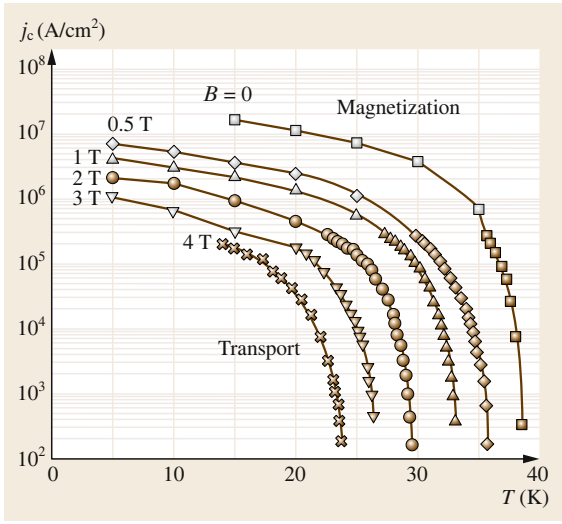

Fig. 50.31 Critical current density of a c-axis-oriented MgB_2 film as a function of temperature for magnetic fields up to 4 T. (After [50.133])

0.1 K in T_c corresponds to a partial Mg isotope-effect exponent β_{Mg} of 0.02. The strong boron isotope effect suggests that the pairing of the electrons is caused by the boron phonons. Thus, MgB_2 seems to be a conventional metallic superconductor with an extremely high transition temperature. The high transition temperature seems to be caused by the small atomic mass of boron, leading to high phonon frequencies.

The currently known physical properties of MgB_2 are summarized in Table 50.8. As in cuprate superconductors, the operation range of MgB_2 is limited by the irreversibility field. In polycrystalline bulk samples, the irreversibility field typically reaches 50% of B_{c2}. In nanocrystalline MgB_2 bulk material the irreversibility field is shifted to 80% of B_{c2}. The enhancement of the irreversibility field in the nanocrystalline material has been attributed to the improved pinning provided by the large number of grain boundaries [50.119]. Maximum irreversibility fields of more than 14 T at 4.2 K have been reported for MgB_2 bulk material annealed in Mg vapor [50.120]. MgB_2 is an extreme type II superconductor with a Ginzburg–Landau parameter κ of 38. The coherence length of $\xi_c \approx 2.5$ nm is considerably larger than the values of ≈ 0.2 nm measured for cuprate superconductors (Table 50.7). The anisotropy of the upper critical fields reported for c-axis-oriented films [50.121] and single crystals [50.122] is typically close to $B_{c2,ab}/B_{c2,c} \approx 3$.

A special feature of MgB_2 is the existence of two energy gaps. In MgB_2, layers of Mg^{2+} ions and metallic boron alternate along the crystallographic c direction (Fig. 50.29). The electronic structure of MgB_2 is similar to that of graphite. The highest occupied electronic states are σ- and π-bonding boron orbitals [50.134–136]. The incompletely filled σ-bands are confined to the boron planes, while the nonbonding π-electrons fill two three-dimensional metallic bands. Band structure calculations indicate that σ-electrons are transferred to the π-bands [50.134]. The superconductivity of MgB_2 is dominated by the σ-band holes, which are strongly coupled to the in-plane vibrations of boron atoms,

Table 50.8 Physical properties of MgB_2

Parameter	Value	Comments	Reference
T_c (K)	40.2	$Mg^{10}B_2$	[50.117]
Lattice parameters		Crystal structure	[50.15]

$\kappa_{ab} = (\lambda_{ab}\lambda_c/\xi_{ab}\xi_c)^{0.5}$	37.1	Single crystal, $T = 0$	[50.125]
$\kappa_c = \lambda_{ab}/\xi_{ab}$	8.1	Single crystal, $T = 0$	[50.125]
Δ (meV)	8.5–9.5[a]	$T = 4.2$ K	[50.131]
Δ_σ (meV)	6.5–8		[50.112–116]
Δ_π (meV)	1.9–2.8		[50.113, 115, 116]

[a] MgB_2 is a double gap superconductor (see for example [50.132])

leading to strong pairing and an energy gap with half-width $\Delta_\sigma \approx 7$ meV [50.135]. In addition, weaker pairs ($\Delta_\pi \approx 2$ meV) are formed by the π-electrons [50.135]. The measured values of the half-widths of the two energy gaps are presented in Fig. 50.30.

Immediately after the discovery of superconductivity in MgB_2, the current transport across grain boundaries was studied [50.137, 138]. The results of these investigations indicate that the grain boundaries in MgB_2 do not act as weak links. This behavior reflects the fact that the coherence length of MgB_2 is considerably larger than that of cuprate superconductors.

To give an impression of the current-carrying capacity of MgB_2, the critical current density of c-axis-oriented films as a function of temperature is shown in Fig. 50.31 for selected applied magnetic fields ($B||c$). The critical current density at 15 K and zero applied field is as high as 16 MA/cm^2 [50.133, 139], which is comparable to the j_c values of cuprate superconductors.

Finally, let us briefly consider the synthesis of MgB_2. Polycrystalline MgB_2 can be synthesized by the reaction of boron powder with magnesium vapor. Stoichiometric quantities of boron and magnesium are sealed into a tantalum tube under an argon atmosphere. In addition, the tantalum tube containing the B/Mg mixture is sealed into a quartz ampoule. To form the desired MgB_2 intermetallic compound, the mixture is heat treated at 950 °C for 2 h [50.140]. In a similar way boron precursor films can be converted to MgB_2 in the presence of Mg vapor. The annealing temperature for the formation of MgB_2 films is typically in the 850 °C range. Very recently c-axis-oriented epitaxial MgB_2 films were grown onto Al_2O_3 substrates [50.121]. For applications in electronics, it is desirable to grow the MgB_2 films in situ in a single step on a suitable substrate. The substrate and electronic materials ZrO_2, MgO, TiN, TaN, AlN, and SiC show no reaction with MgB_2 up to an annealing temperature of 800 °C [50.141].

50.6 Iron-Based Superconductors

In 2008, *Hosono* and collaborators discovered that $LaO_{1-x}F_xFeAs$ is a superconductor with a critical temperature of 26 K [50.16]. Very recently a critical temperature, as high as 58.1 K, was reported for $SmO_{0.74}F_{0.26}FeAs$ [50.142]. Because of these high critical temperatures, the iron-based superconductors are considered as a second class of complex high-temperature superconductors. There exist four main families of iron-based superconductors, which, like the cuprates, are characterized by layered crystal structures. The (1111)-family can be represented by the chemical formula REOFeAs, where RE is a rare earth element. Layers of REO and FeAs alternate along the crystallographic c direction. Figure 50.32 shows a sketch of the tetragonal crystal structure of the undoped LaOFeAs (La-1111) at room temperature.

In a second family of iron-pnictide superconductors, layers of earth alkaline ions alternate with Fe_2As_2 layers. These (122) compounds crystallize with a tetragonal crystal structure (space group I4/mmm) [50.145, 146]. Figure 50.33 shows as an example the tetragonal crystal structure of $CaFe_2As_2$ (Ca-122) [50.146].

In the (111)-family of iron-pnictide superconductors, FeAs layers alternate with layers of alkali ions (Li, Na) along the crystallographic c direction [50.147, 148].

In the cuprate superconductors, the current flows mainly along the conductive CuO_2 planes, which are separated by the insulating layers of the charge-carrier reservoirs (Fig. 50.14). The iron-pnictide superconductors are characterized by layered crystal structures similar to the cuprates. In the iron pnictides, the FeAs layers are conductive, while the layers of REO ((1111)-family), alkaline earth ions ((122)-family) and alkali ions ((111)-family) act as charge-carrier reservoirs. A further analogy to the cuprate superconductors is the fact that the nondoped parent compounds are not superconducting. However, the parent compounds of the iron-pnictide superconductors are metals showing an antiferromagnetic order, whereas the parent compounds of the cuprate superconductors are antiferromagnetic Mott insulators. Doping suppresses the antiferromagnetic ordering and the low-temperature

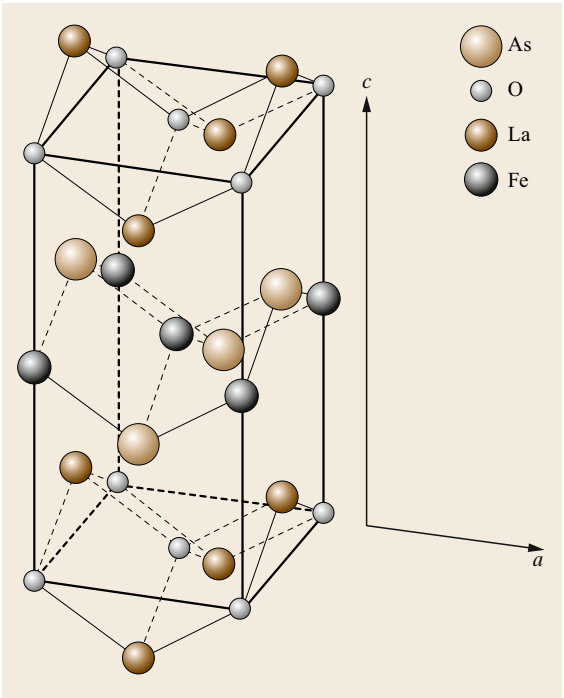

Fig. 50.32 Sketch of the tetragonal crystal structure of LaOFeAs (space group P4/nmm). The lattice parameters of the non-fluorine-doped compound are $a = 0.4033$ nm and $c = 0.8741$ nm [50.143]. The z positions of the atoms are $z = 0$ and $z = c$ for oxygen, $z = 0.141c$ and $z = 0.859c$ for La, $z = 0.5c$ for Fe and $z = 0.348c$ and $z = 0.652c$ for As [50.143]. (After [50.144, 145])

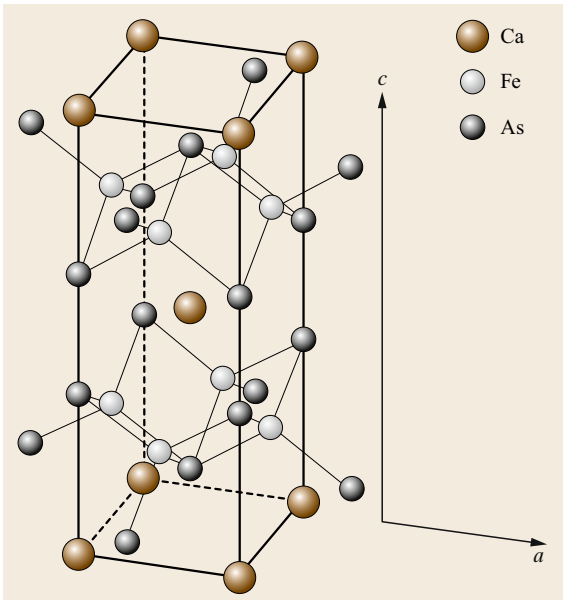

Fig. 50.33 Sketch of the tetragonal crystal structure of $CaFe_2As_2$ (space group I4/mmm). The lattice parameters of the nondoped compound are $a = 0.3872$ nm and $c = 1.1730$ nm at room temperature [50.146]. The z positions of the atoms are $z = 0$, $z = 0.5c$ and $z = c$ for Ca, $z = 0.25c$ and $z = 0.75c$ for Fe, and $z = 0.133c$, $z = 0.367c$, $0.633c$ and $z = 0.867c$ for As. (After [50.145, 146])

transition from a tetragonal to an orthorhombic crystal structure (Fig. 50.34).

The critical temperature of iron-pnictide superconductors depends on the doping level. In LaOFeAs, superconductivity can be established by fluorine doping. The charges per formula unit of LaOFeAs are +1 in the LaO layer and −1 in the FeAs layer. The charges of La, O, and F are +3, −2 and −1 respectively. Substitution of 10% of the oxygen atoms by fluorine (leading to $LaO_{0.9}F_{0.1}FeAs$) increases the charge of the LaOF layer to +1.1. For charge neutrality, the negative charge of the FeAs layer must be increased to −1.1, i. e., the FeAs layer is doped with electrons. In a similar way, replacement of Ba by K leads to hole doping in $Ba_{1-x}K_xFe_2As_2$.

In contrast to cuprate superconductors, in which doping in the CuO_2 planes is detrimental for superconductivity, cobalt doping for iron can establish superconductivity in $Ba(Fe, Co)_2As_2$ [50.148]. Furthermore, phosphorous doping leads to superconductivity in $BaFe_2(As, P)_2$ without the introduction of additional charge carriers to the FeAs planes [50.150]. In the iron-pnictide superconductors, not only the addition of charge carriers but also the effect of doping on the crystal structure are of importance.

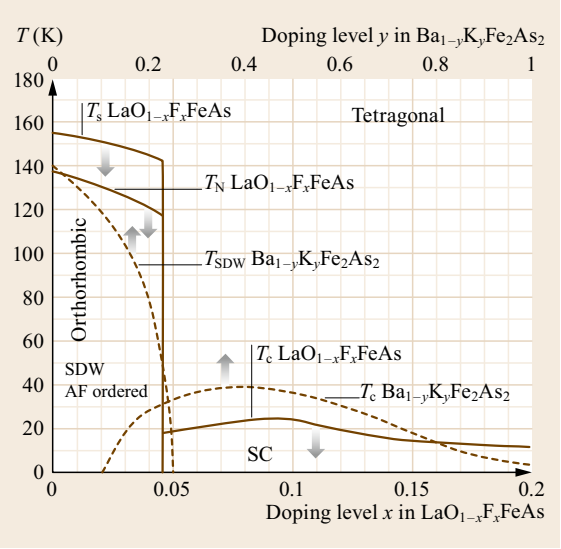

Fig. 50.34 Phase diagrams of La-1111 (*solid lines*) [50.148] and Ba-122 (*dotted lines*) [50.149]. In the case of La-1111, the T_s line indicates the temperature of the structural transformation from a tetragonal to an orthorhombic structure. At a slightly lower temperature T_N, a transition to an antiferromagnetic state occurs. Above 4.5% fluorine doping, superconductivity is observed, while the transition to an orthorhombic crystal structure and antiferromagnetic ordering is suppressed. For Ba-122, the transition to an orthorhombic crystal structure and SDW ordering occurs at the same temperature T_{SDW}. Again, doping suppresses of the structural transition and the antiferromagnetic SDW ordering. A maximum critical temperature of ≈ 38 K is reached for $y = 0.4$

In addition to the iron pnictides, there exists a fourth family of iron-based superconductors without FeAs layers. In this (11)-family with the chemical formula FeCh, where Ch represents Se, Te, or S, the FeAs layers are replaced by iron chalcogenide layers. Moreover, there are no layers to act as charge-carrier reservoirs [50.148].

The next aspect to be considered are the phase diagrams of $LaO_{1-x}F_xFeAs$ (La-1111) [50.148] and $Ba_{1-y}K_yFe_2As_2$ (Ba-122) [50.149] (Fig. 50.34). The La-1111 parent compound without fluorine doping shows a transition from a tetragonal to an orthorhombic structure at a temperature $T_s \approx 155$ K. Slightly below 140 K, antiferromagnetic ordering has been observed. Doping with fluorine suppresses both the structural instability and the antiferromagnetic order. Above 4.5% fluorine doping, superconductivity is observed, and a maximum critical temperature of 26 K is reached at around 10%. In the case of the Ba-122, the establishment of an antiferromagnetic spin density wave (SDW) order is accompanied by a structural change from a tetragonal to an orthorhombic structure. In the nondoped parent compound, the transition to the orthorhombic crystal structure and the SDW order occurs around 140 K. Doping suppresses the structural instability and the antiferromagnetic SDW order. Superconductivity can exist above 10% potassium doping. For doping levels between 10 and 25% superconductivity and SDW order can coexist in Ba-122 in the orthorhombic crystal structure. The maximum critical temperature of around 38 K is reached when around 40% of the barium atoms are replaced by potassium.

The known physical properties of various iron-based superconductors are listed in Table 50.9. The maximum critical temperatures of (1111) compounds exceed 50 K. For Ba-122 and Sr-122, maximum critical temperatures of 38 K have been reported. The (1111) compounds crystallize in a tetragonal crystal structure with the space group P4/nmm. The lattice parameters of the fluorine-doped compounds are slightly shorter than those of the parent compounds. For the compounds considered, the a lattice parameters are in the range of 0.3932 and 0.4039 nm, while the c lattice parameters are between 0.8490 and 0.8742 nm. The crystal structures of the (122) compounds are body-centered tetragonal (space group I4/mmm). The lattice parameters of the nondoped Ba-122 are $a = 0.3964$ nm and $c = 1.3022$ nm. In some of the iron-pnictide superconductors, evidence for the existence of two gaps has been found. The ratio of $2\Delta/T_c$ is between 3 and 4

for the smaller gap, and above 7 for the larger. A characteristic feature of the iron-based superconductors is an extremely high upper critical field of the order of 100 T. Because of the layered crystal structures, the physical properties of iron-based superconductors are anisotropic. The coherence length along the FeAs (*ab*) planes varies between 1.2 and 5 nm, while along the *c* direction it is in the range of 0.35 to 1.2 nm. The penetration depth for screening currents flowing in the *ab* planes is of the order of 200 nm.

The last aspect to be considered is the critical current density in iron-based superconducting films. The critical current densities of Fe(Te,Se) [50.177], $Ba(Fe,Co)_2As_2$ [50.178], $BaFe_2(As,P)_2$ [50.179], and IBAD-MgO/$Ba(Fe,Co)_2As_2$ films [50.180] are presented in Fig. 50.35. The critical current densities at 4.2 K and zero applied field reach values between 0.4 (Fe(Te,Se)) and 3.5 MA/cm^2 ($BaFe_2(As,P)_2$). For the $Ba(Fe,Co)_2As_2$ film, critical current densities for fields applied parallel and perpendicular to the crystallographic *c*-direction are shown. The critical current densities at 4.2 K and an applied magnetic field of 9 T parallel and perpendicular to the *c*-direction are 0.12 and 0.2 MA/cm^2, respectively. This anisotropy with respect to the direction of the applied magnetic field is less pronounced than in conductors coated with $REBa_2Cu_3O_7$ (RE: rare earth element). The j_c data of the $BaFe_2(As,P)_2$ film at temperatures of 4.2, 10, and 20 K indicate that the dependence on the applied magnetic field at 20 K is much more pronounced than at 10 or 4.2 K. The high critical current densities and the weak field dependence at low temperatures suggest that the iron-based superconductors show promise in the generation of extremely high magnetic fields. Because of the very short coherence length along the crystallographic *c*-direction, they may show a weak-link behavior of the grain boundaries similar to the cuprates. Several research groups [50.170, 181–186] have studied the intergrain and the intragrain critical current densities in iron-based superconductors. Evidence for intergrain critical current densities much smaller than the intragrain j_c has been found. However, the large difference between the two is caused partly by the wetting of the grain boundaries with FeAs. The extent to which the observed reduction of the intergrain j_c is caused by an intrinsic weak-link problem needs to be clarified.

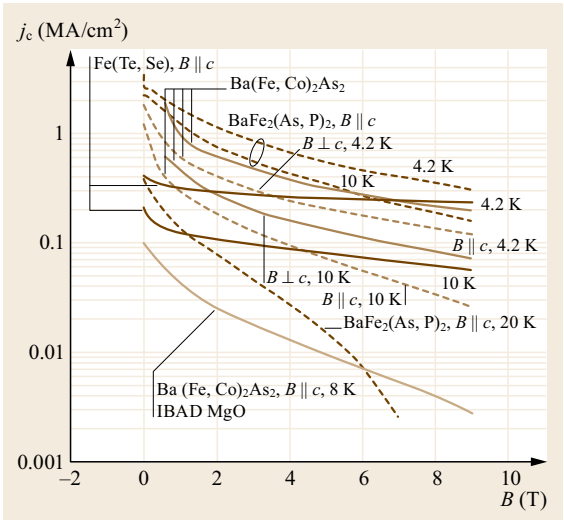

Fig. 50.35 Critical current density versus field in Fe(Te,Se) [50.177], $Ba(Fe,Co)_2As_2$ [50.178], $BaFe_2(As,P)_2$ [50.179], and IBAD-MgO/$Ba(Fe,Co)_2As_2$ films [50.180]

50.7 Summary

The cuprate high-temperature superconductors are characterized by layered crystal structures. Conductive CuO_2 layers in the crystallographic *ab*-planes are a common feature of all cuprate superconductors. Along the *c*-direction, conducting copper oxide blocks and insulating charge-carrier reservoirs alternate. As a consequence, the physical properties of cuprate superconductors are strongly anisotropic.

The critical temperature as well as the other physical properties depends considerably on the charge-carrier concentration. The maximum critical temperature is typically reached for a carrier concentration of 0.18 holes per CuO_2. Furthermore, the highest T_c of optimally doped cuprate superconductors is typically reached in compounds with three or four CuO_2 layers in the CuO_2 blocks. The highest known critical temperature of 135 K at ambient pressure was achieved in Hg-1223.

The cuprate superconductors are close to a metal–insulator transition. The d-wave symmetry of the energy gap and the existence of a pseudogap above T_c, especially in under-doped cuprate superconductors, suggest that the pairing mechanism of the electrons is different from that in metallic superconductors. Furthermore, only a weak isotope effect has been observed in the cuprates, which again suggests that the electron pairing is not phonon mediated.

Extremely short coherence lengths and low carrier concentrations seem to be responsible for the weak-link

behavior of large-angle grain boundaries in the cuprate superconductors. To achieve transport critical current densities comparable to the intra-grain j_c, a biaxial texture is required.

Since the discovery of superconductivity above 50 K in the iron pnictides, the cuprates are no longer the only class of high-temperature superconductors. In the iron pnictides, layers of FeAs alternate with layers of REO, alkaline earth or alkali ions, which act as charge-carrier reservoirs resembling those in the cuprate superconductors. As in the cuprates, the superconducting state is close to an antiferromagnetic state. However, the parent compounds of the iron-pnictide superconductors are metals and not Mott insulators as in the case of the cuprates. Because of their very high upper critical fields, the iron-based superconductors are potential high field superconductors.

The metallic intermediate-temperature superconductor MgB_2 may have applications in spite of its moderate critical temperature of 39 K, because of its simpler chemistry and the fact that its grain boundaries do not act as weak links. The observation of a pronounced boron isotope effect suggests that MgB_2 is a conventional BCS superconductor. The anisotropy of the physical properties of MgB_2 is less pronounced than that of the cuprate superconductors.

The maximum operation fields of MgB_2, cuprate and iron-based superconductors are limited by the irreversibility line, which is well below the upper critical field. The existence of an irreversibility line may be caused by thermally activated depinning or flux-line lattice melting.

Acknowledgments. The author wishes to thank P. Bruzzone for his support and encouragement. The careful reviewing and many constructive suggestions on the manuscript by J. F. Crawford are especially appreciated.

51. Molecular Electronics

Michael C. Petty, Takashi Nagase, Hitoshi Suzuki, Hiroyoshi Naito

The prospects of using organic materials in electronics and optoelectronics applications have attracted scientists and technologists since the 1970s. This field has become known as *molecular electronics*. Some successes have already been achieved, for example, the liquid-crystal display, organic light-emitting displays, and photoreceptors in electrophotography. Other products such as organic photovoltaic devices, chemical sensors and plastic transistors are developing fast. There is also a keen interest in exploiting technologies at the molecular scale that might eventually replace silicon devices. This chapter provides some of the background physics and chemistry to the interdisciplinary subject of molecular electronics. A review of some of the possible application areas for organic materials is presented and some speculation is provided regarding future directions.

Molecular electronics is concerned with the exploitation of organic and biological materials in electronics and optoelectronics [51.1–3]. The subject, as it has matured over the last 40 years, can broadly be divided into two themes. The first area, *molecular materials for electronics*, has its origins in materials science and concerns the development of devices that utilize the unique macroscopic properties of organic compounds. The most successful commercial product to date is the liquid-crystal display (LCD). However, following many years of research, devices such as organic light-emitting displays, organic photovoltaic (PV) devices, organic transistors, pyroelectric detectors for infrared imaging, and chemical and biochemical sensors are beginning to make a technological impact. The Nobel prize in chemistry for 2000 was awarded to three scientists working in this area: Alan Heeger, Alan MacDiarmid, and Hideki Shirakawa, who have made significant contributions to the development of electrically conductive polymers. More challenging is *molecular-scale electronics*. Here, the focus is on the behavior of individual organic molecules or groups of molecules. Topics such as molecular switches [51.3–9], molecular memories [51.10–13], molecular rectifiers [51.14], negative differential-resistance junctions [51.15], deoxyribonucleic acid (DNA) electronics [51.16], and molecular manufacturing [51.17, 18] have all been described in the literature. It is much too early to say which, if any, of these could find their way into the commercial arena.

This chapter provides an introduction to the interdisciplinary world of molecular electronics. In the first instance, the physics background to semiconductive organic compounds is outlined. A review of the available materials is presented and some of the possible device applications are described. There are currently a limited number of ways in which organic molecules can be deposited and manipulated on surfaces to form solid films, which can then be used in device structures. The most popular methods are outlined, and methods to pattern the films are described. The prospects for molecular-scale electronics are contrasted with the progress of the inorganic semiconductor industry. Finally, a selection of the ongoing work on molecular-scale devices is described and some speculation about future developments is given.

51.1 Electrically Conductive Organic Compounds

Metallic and semiconductive behavior is not restricted to inorganic materials. Figure 51.1 shows that the room-temperature conductivity values for organic polymers can extend over much of the spectrum of electrical conductivity, from insulating to semiconducting, and even metallic, behavior [51.19]. The physical explanation can be found in the nature of the chemical bonds that hold solids together.

51.1.1 Orbitals and Chemical Bonding

Carbon-based materials are unique in many respects. This is due to the many possible configurations of the electronic states of a carbon atom. Carbon has an atomic number of six and a valency of four. Its electron configuration is $1s^2$, $2s^2$, $2p^2$, that is, the inner 1s shell is filled and the four valence electrons available for bonding are distributed two each in the 2s orbital and the 2p orbitals. As the 2s orbital is spherically symmetrical (Fig. 51.2) it can form a bond in any direction. In contrast, the 2p orbitals are directed along mutually orthogonal axes and will tend to form bonds in these directions. When two or more of the valence electrons of carbon are involved in bonding with other atoms, the bonding can be explained by the construction of *hybrid* orbitals by mathematically combining the 2s and 2p orbitals. In the simplest case, the carbon 2s orbital hybridizes with a single p orbital. Taking the sum and difference of the two orbitals gives two sp *hybrids*; two p orbitals then remain. The sp orbitals are constructed from equal amounts of s and p orbitals; they are linear and 180° apart.

Other combinations of orbitals lead to different hybrids. For example, from the 2s orbital and two 2p orbitals (e.g., a $2p_x$ and a $2p_y$), three equivalent sp^2 hybrids may be constructed. Each orbital is 33.3% s and 66.7% p. The three hybrids lie in the *xy* plane (the same plane defined by the two p orbitals), directed 120° from each other, and the remaining p orbital is perpendicular to the sp^2 plane. Four sp^3 hybrids may be derived from an s orbital and three p orbitals. These are directed to the corners of a tetrahedron with an angle of 109.5° between the bonds; each orbital is 25% s and 75% p.

A chemical bond can also be formed from a mixture of the above hybrid orbitals, for example, it is possible to have a hybridized orbital that is 23% s and 77% p. Thus, sp, sp^2 and sp^3 hybrids must be considered as limiting cases. Electrons in s orbitals have a lower energy than electrons in p orbitals. Therefore, bonds with more s character tend to be stronger.

Carbon forms four bonds in most compounds, resulting from its four valence electrons. In ethane, C_2H_6, the C–H bonds are all approximately $C(sp^3)$–H(s), while the C–C bond is approximately $C(sp^3)$–$C(sp^3)$. However, in the ethylene molecule, C_2H_4, each of the two carbons is attached to just three atoms while in acetylene, C_2H_2, each carbon atom is only attached to one carbon. In these compounds, the two carbon atoms are bound together by double ($CH_2{=}CH_2$) or triple ($CH{\equiv}CH$) bonds, which involve sp^2 and sp hybrids, respectively. These bonds can be considered to have two distinct components. For example, in ethylene, two sp^2 hybrids on each carbon bond with the hydrogens. A third sp^2 hybrid on each carbon forms a $C(sp^2)$–$C(sp^2)$ single bond, leaving a p orbital *left-over* on each carbon. This orbital lies perpendicular to the plane of the six atoms. The two p orbitals are parallel to each other and have regions of overlap above and below the

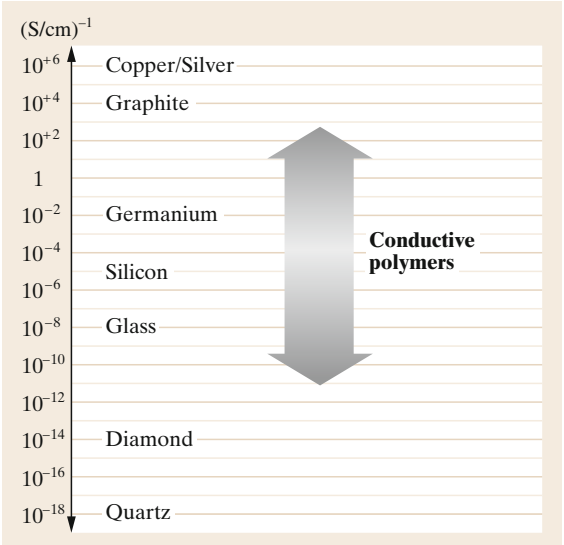

Fig. 51.1 Room-temperature conductivity values of conductive polymers compared to other materials. (After [51.19], with permission from Wiley)

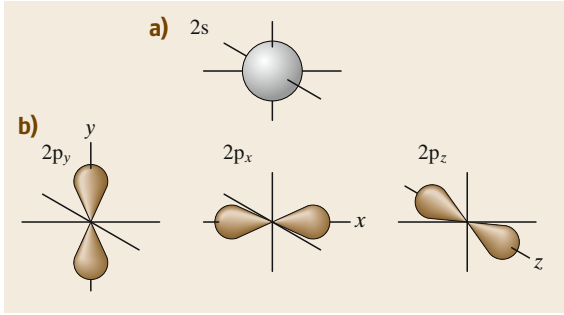

Fig. 51.2 **(a)** 2s orbital. **(b)** $2p_y$, $2p_x$, and $2p_z$ orbitals

molecular plane. This type of bond, consisting of two separate sausage-like electron clouds lying above and below the planes of the carbon nuclei, is called a pi (π) bond. In contrast, the bond formed by the head-on overlap of the two carbon sp^2 orbitals is known as a sigma (σ) bond and the electron cloud is densest at the midpoint between the carbon nuclei. The π bond has little electron density in the region between the carbon atoms and is much weaker than the σ bond. Figure 51.3 illustrates sigma and pi bonding. Carbon compounds that contain π bonds are said to be unsaturated, meaning that the carbon atoms, while having formed the requisite number of bonds, are not fully saturated in terms of their number of potential neighbors. Saturated carbon molecules, on the other hand, contain only single bonds.

51.1.2 Band Theory

The application of quantum mechanics to the electrons in the bonds of inorganic semiconductors led to the development of band theory, one of the great success stories of modern physics. Whenever two identical atoms are brought close together, the electron orbitals overlap and the energy level associated with each electron in the separated atoms is split into two new levels, with one above and one below the original level. A rigorous, quantum-mechanical description of the bonding reveals that the total number of orbitals must be conserved, that is, the total number of molecular orbitals must be the same as the number of atomic orbitals that went into their formation. Consider, for example, the formation of a hydrogen molecule from two separated atoms. When the two atoms approach each other so that their 1s orbitals overlap, two new orbitals (σ bonds) are formed around the atoms, symmetric with respect to the interatomic axis. In one orbital, the bonding orbital, the electron has a lower energy than that in the isolated atomic orbital and in the other, the antibonding orbital, an electron has a higher energy. In the hydrogen molecule, the electron pair normally resides in the bonding orbital. The energy of the electrons in this orbital is lowered relative to that in the atomic orbitals, which is why the atoms remain bound together.

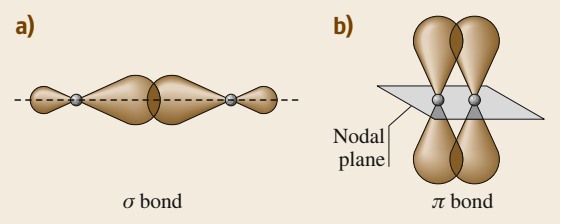

Fig. 51.3 **(a)** Sigma (σ) and **(b)** pi (π) bonding

In an extended solid, many atoms can interact and many similar splittings of energy levels occur. For a solid containing approximately 10^{26} atoms (Avogadro's number) each energy level splits, but the energies between these split levels are very small and continuous ranges or bands of energy are formed. Two such important bands are the valence band and the conduction band, analogous to the bonding and antibonding levels of the two-atom model. The energy gap, or band gap, between them is a forbidden energy range for electrons. Electrical conduction takes place by electrons moving under the influence of an applied electric field in the conduction band and/or holes moving in the valence band. Holes are really vacancies in a band but, for convenience, they may be regarded as positively charged carriers. For an electron, or hole, to gain energy from an applied electric field, and therefore for conductivity to occur, the charge carrier must be able to move into an unoccupied higher energy state. If the carrier cannot be accelerated by the field, then it cannot contribute to the electrical conduction. In a metal, the various energy bands overlap to provide a single energy band that is only partly full of electrons. An insulator has a full valence band and a relatively large energy separation ($> 5\,\text{eV}$) to the higher conduction band. Most semiconductors possess the band structure of an insulator, but a forbidden energy gap of only $0.1-3\,\text{eV}$, so that carriers may be produced in the conduction and/or valence bands by optical or thermal means, or by doping with impurities.

An important feature of the band model is that the electrons are delocalized or spread over the lattice. The strength of the interaction between the overlapping orbitals determines the extent of delocalization that is possible for a given system. For many polymeric organic materials, the molecular orbitals responsible for bonding the carbon atoms of the chain together are the sp^3 hybridized σ bonds, which do not give rise to extensive overlapping. The resulting band gap is large, as the electrons involved in the bonding are strongly localized on the carbon atoms and cannot contribute to the conduction process. This is why a simple saturated polymer such as polyethylene, $(CH_2)_n$, is an electrical insulator.

A significant increase in the degree of electron delocalization may be found in unsaturated polymers, that is, those containing double and triple carbon–carbon bonds. If each carbon atom along the chain has only one other atom, for example, hydrogen, attached to it, the spare electron in a p_z-orbital of the carbon atom overlaps with those of carbon atoms on either side forming delocalized molecular orbitals of π-symmetry. For a simple lattice of length $L = Na$, where N is the total

number of atoms and a is the spacing between them, it can be shown that the total number of electron states in the lowest energy band is equal to N. This result is true for every energy band in the system and applies to three-dimensional (3-D) lattices. Allowing for the two spin orientations of an electron, the Pauli exclusion principle requires that there will be room for two electrons per cell of the lattice in an energy band. If each atom contributes one bonding electron, the valence band will be only half filled.

It might therefore be expected that a linear polymer backbone consisting of many strongly interacting coplanar p_z orbitals, each of which contributes one electron to the resultant continuous π electron system, would behave as a one-dimensional (1-D) metal with a half-filled band. In chemical terms, this is a conjugated chain and may be represented by a system of alternating single and double bonds. It turns out that, for 1-D systems, such a chain can more efficiently lower its energy by introducing bond alternation (alternating short and long bonds). This limits the extent of electronic delocalization that can take place along the backbone. The effect is to open an energy gap in the electronic structure of the polymer. All conjugated polymers are semiconductors, with band gaps more than about 1.5 eV, rather than metals (N.B. the band gap in silicon is 1.1 eV at room temperature). Figure 51.4 shows the chemical π bonding and the electronic band structure of polyacetylene.

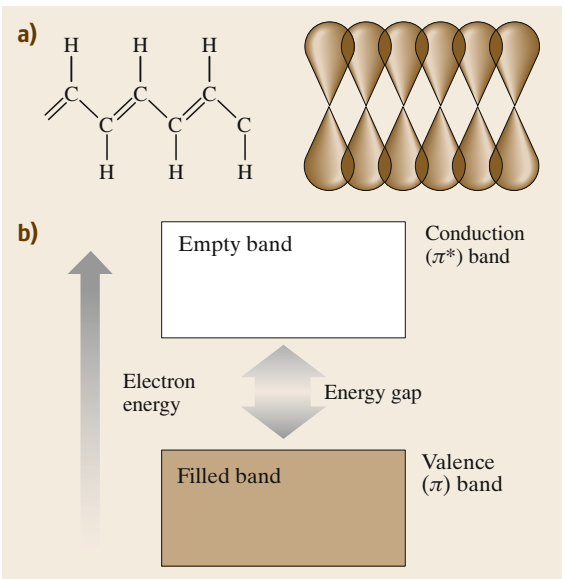

Fig. 51.4 (a) Chemical π bonding in polyacetylene. **(b)** Electronic band structure showing the normally empty π^* band (conduction band) and the normally filled π band (valence band)

51.1.3 Electrical Conductivity

In polyacetylene, the valence band, or π band, is normally filled with electrons while the conduction band, or π^* band is normally empty. Like silicon, the conductivity of polyacetylene can be changed by the addition of impurity atoms. However, the term *doping* is a misnomer as it tends to imply the use of minute quantities, parts per million or less, of impurities introduced into a crystal lattice. In the case of conductive polymers, typically 1–50% by weight of chemically oxidizing (electron withdrawing) or reducing (electron donating) agents are used to alter physically the number of π-electrons on the polymer backbone, leaving oppositely charged counterions alongside the polymer chain. These processes are redox chemistry. For example, the halogen-doping process that transforms polyacetylene to a good conductor is oxidation (or p-doping)

$$[\mathrm{CH}]_n + \frac{3x}{2}\mathrm{I}_2 \rightarrow [\mathrm{CH}]_n^{x+} + x\mathrm{I}_3^- \,.$$

Reductive doping (n-doping) is also possible, for example, using an alkali metal

$$[\mathrm{CH}]_n + x\mathrm{Na} \rightarrow [\mathrm{CH}]_n^{x-} + x\mathrm{Na}^+ \,.$$

In both cases, the doped polymer is a salt. The counterions, I_3^- or Na^+, are fixed in position while the charges on the polymer backbone are mobile and contribute to the conductivity. The doping effect can be achieved because a π electron can be removed (or added) without destroying the σ backbone of the polymer so that the charged polymer remains intact. The increase in conductivity can be as much as 11 orders of magnitude.

The electrical properties of semiconductive organic polymers are not directly comparable to those of silicon. An important material parameter is the mobility of the charge carriers μ. This determines the (additional) velocity that a charge carrier (an electron or hole) acquires because of an applied electric field, and is defined by

$$\mu = \frac{v_\mathrm{d}}{E} \,,$$

where v_d is the drift velocity of the carrier and E is the electric field. The mobility may be further related to the electrical conductivity σ by the expression

$$\sigma = |q| n \mu \,,$$

where n is the density of charge carriers and $|q|$ is the magnitude of their charge (charge on an electron $= 1.6 \times 10^{-19}$ C). The carrier mobility provides an indication of how quickly the carriers react to the field (i. e.,

the frequency response of the material). The greater the degree of electron delocalization, the larger the width of the bands (in energy terms) and the higher the mobility of the carriers within the band. For inorganic semiconductors such as silicon or gallium arsenide, the 3-D crystallographic structure provides for extensive carrier delocalization throughout the solid, resulting in a relatively high mobility μ.

Electrical conduction in polymers not only requires carrier transport along the polymer chains but also some kind of transfer, or *hopping*, between these chains, which tend to lie tangled up like a plate of spaghetti. The charge-carrier mobilities in organic polymers are therefore quite low, making it difficult to produce very high-speed electronic computational devices that are competitive with those based on silicon and gallium arsenide. However, some improvement in the carrier mobility can be achieved by both increasing the degree of order of the polymer chains [51.20, 21] and by improving the purity of the material. Table 51.1 contrasts the room-temperature carrier mobility values for Si, GaAs, and a number of different conductive organic compounds [51.20–26]. The exceptionally high value for graphene ($2\times10^5\,\mathrm{cm^2/Vs}$) should be noted. However, this two-dimensional (2-D) material has a zero band gap, which is an obstacle to its use in certain electronic devices, such as field effect transistors. The values of the other organic materials are low in comparison with those of the inorganic semiconductors, but the field-effect mobilities of $>10\,\mathrm{cm^2/Vs}$ achieved recently make such conjugated small molecules and polymers useful for industrial application. In addition, other features make them more attractive for certain types of electronic devices, as indicated in the later sections.

Table 51.1 Room-temperature field-effect carrier mobilities for field-effect transistors based on organic semiconductors. (After [51.20–26]). The electron mobilities in single-crystal silicon and gallium arsenide are also given

Material	Mobility ($\mathrm{cm^2/Vs}$)
Si single crystal (electrons)	1500
GaAs single crystal (electrons)	8500
Region-regular polythiophene	0.47
Polyacetylene	10^{-4}
Phthalocyanine	10^{-4}–10^{-2}
Thiophene oligomers	10^{-4}–10^{-1}
Organometallic dmit complex	0.2
Pentacene	10^{-3}–1
Bis[1]benzothieno[2,3-d;2′,3′-d′]naphtho[2,3-b;6,7-b′]dithiophene	7
2,7-Dioctylbenzothienobenzothiophene	31
Regioregular poly[4-(4,4-dihexadecyl-4H-cyclopenta[1,2-b:5,4-b']dithiophen-2-yl)-alt-[1,2,5]thiadiazolo[3,4-c]pyridine]	24
C_{60}	0.3
Graphene	2.5×10^5

51.2 Materials

Many conductive polymers have been synthesized to provide certain electronic features (e.g., band gap and electron affinity). The monomer repeat units are often based on five- or six-membered (benzene) carbon ring systems, including polypyrrole, polythiophene (and various other polythiophene derivatives), polyphenelenevinylene, and polyaniline [51.27]. The chemical structure of some of these materials is shown in Fig. 51.5. Such polymers generally show lower electrical conductivity than polyacetylene, however; they can have the advantage of high stability and processability.

Conductive polymers represent only one category of organic electrical conductors. Another important class are the charge-transfer compounds [51.28, 29]. These are formed from a variety of molecules, primarily aromatic compounds (i. e., based on benzene) which can behave as electron donors (d) and electron acceptors (a). Complete transfer of an electron from a donor to an acceptor molecule results in a system that is electrically insulating (e.g., the transfer of a valence electron in a Na atom to a Cl atom, forming the compound NaCl). However, if the ratio of the number of donor molecules to the number of acceptor molecules differs from 1 : 1, for example, the stoichiometry is 1 : 2 or 2 : 3, or if there is incomplete transfer of an electron from a donor to an acceptor (say, six electrons in every ten are transferred), then partially filled electron energy bands can be formed and electron conduction is possible.

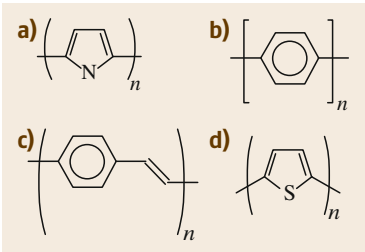

Fig. 51.5a–d Chemical structures of conductive polymers: **(a)** polypyrrole, **(b)** polyparaphenylene, **(c)** polyphenylenevinylene, **(d)** polythiophene

Charge-transfer interactions are strongest between donor molecules of low ionization potential and acceptor molecules of high electron affinity, provided that the donor and acceptor molecules have similar symmetry and are able to approach closely [51.29]. Well-known donor and acceptor molecules are tetrathiafulvalene (TTF) and tetracyanoquinodimethane (TCNQ) (Fig. 51.6a). The latter compound is a very strong acceptor forming first the radical anion and then the dianion (Fig. 51.6b). The stability of the semireduced radical ion, $TCNQ^{-\bullet}$, with respect to the neutral molecule mainly arises from the change from the relatively unstable quinoid structure to the aromatic one, allowing extensive delocalization of the π electrons over the carbon skeleton. As a consequence, TCNQ not only forms typical charge-transfer complexes but is also able to form true radical-ion salts, incurring complete one-electron transfer. Thus, on addition of lithium iodide to a solution of TCNQ, the simple lithium TCNQ salt is formed

$$\mathrm{TCNQ} + \mathrm{LiI} \Leftrightarrow \mathrm{Li^{+}TCNQ^{-\bullet}} + \frac{1}{2}\mathrm{I_2}\,.$$

Following removal of the free iodine precipitate, the TCNQ salt may be crystallized. The crystals show an electronic conductivity of about $10^{-5}\,\mathrm{S/cm}$.

A 1 : 1 TCNQ : TTF salt exhibits a high room-temperature conductivity ($5\times10^{2}\,\mathrm{S/cm}$) and metallic behavior is observed as the temperature is reduced to 54 K. The molecules in such compounds are arranged in segregated stacks, in which the donors and acceptors form separate donor stacks (ddddd...) and acceptor stacks (aaaaa...). The molecules are stacked in such a way that the π bonds on successive molecules can overlap to form bands. This overlap is different from the p-orbital overlap forming the π bands in conjugated polymers. The crystalline packing in these, and other, charge-transfer compounds generally leads to carrier mobility values that are higher than for semiconductive polymers.

Other electroactive compounds that may find application in molecular electronics are based on forms of pure carbon. Graphite consists of vast carbon sheets stacked one on top of another like a sheaf of papers. In pure graphite, these layers are about 0.335 nm apart, but they can be separated further by intercalating various molecules or by using adhesive tape, namely Scotch tape [51.30]. Finally, only one graphite sheet, graphene, can be obtained [51.30]. The bonding between the carbon atoms in the planes is mainly sp^2 hybridizations consisting of a network of single and double bonds. As noted earlier, graphene is a zero band gap material. In case of multilayer graphene, weak interactions between the delocalized electron orbitals hold adjacent sheets together. The delocalized electron system in the planes results in semiconductive electrical behavior.

Under certain conditions, carbon forms regular clusters of 60, 70, 84, etc. atoms [51.31, 32]. A C_{60} cluster, shown in Fig. 51.7, is composed of 20 hexagons and 12 pentagons and resembles a football. The diameter

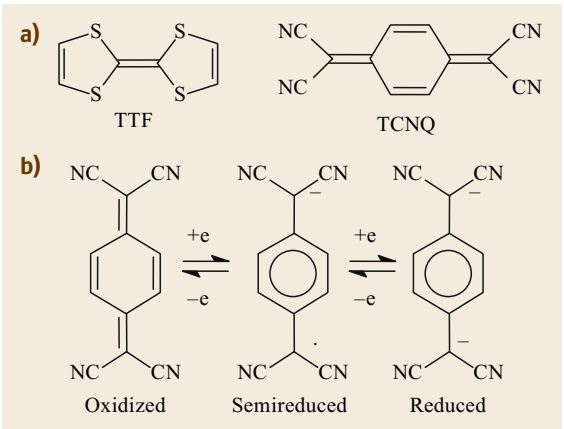

Fig. 51.6 **(a)** Chemical structures of the charge-transfer compounds tetrathiafulvalene (TTF) and tetracyanoquinodimethane (TCNQ). **(b)** Oxidation and reduction of TCNQ

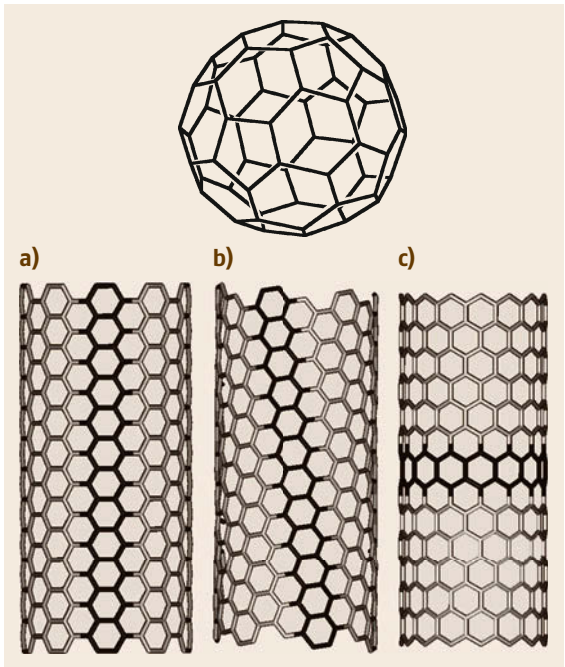

Fig. 51.7a–c Chemical structure of C_{60} (*top*) and three classes of single-wall carbon nanotube (SWNT) **(a)** (10,10) armchair SWNT, **(b)** (12,7) chiral SWNT, and **(c)** (15,0) zigzag SWNT

of the ball is about 1 nm. As with graphite, each carbon atom in C_{60} is bonded to three other carbon atoms. Thus, C_{60} can be considered as a rolled up layer of a single graphite sheet. The term buckministerfullerene was given originally to the C_{60} molecule because of the resemblance to the geodesic domes designed and built by Richard Buckminster Fuller. However, this term (or fullerene or buckyball) is used quite generally to describe C_{60} and related compounds. For example, a molecule with the formula C_{70} can be formed by inserting an extra ring of hexagons around the equator of the sphere, producing an elongated shell more like a rugby ball.

In addition to the spherical-shaped fullerenes, it is possible to synthesize tubular variations – carbon nanotubes [51.32, 33]. Such tubes are comprised of graphite-like sheets curled into a cylinder. Each tube may contain several cylinders nested inside each other. The tubes are capped at the end by cones or faceted hemispheres. Because of their very small diameters (down to around 0.7 nm), carbon nanotubes are prototype 1-D nanostructures. An important feature of a carbon nanotube is the orientation of the six-membered carbon ring in the honeycomb lattice relative to the axis of the nanotube. Three examples of single-wall carbon nanotubes (SWCNs) are shown in Fig. 51.7. The primary classification of a carbon nanotube is as either being chiral or achiral. An achiral nanotube is one whose mirror image has an identical structure to the original. There are only two cases of achiral nanotubes: armchair and zigzag (these names arise from the shape of the cross-sectional ring). Chiral nanotubes exhibit a spiral symmetry whose mirror image cannot be superimposed on the original structure. Carbon nanotubes are characterized by the chiral index (n, m), where the integers n and m specify each carbon nanotube uniquely [51.33]. An armchair nanotube corresponds to the special case $n = m$, while for a zigzag nanotube $m = 0$. All other (n, m) indexes correspond to chiral nanotubes. The electronic structure of a SWCN is either metallic or semiconducting, depending on its diameter and chirality.

At low temperature, a SWNT is a quantum wire in which the electrons in the wire move without being scattered. Resistance measurements for various nanotube samples show that there are metallic and semiconducting nanotubes [51.33]. Carbon nanotubes can also be doped either by electron donors or electron acceptors [51.34]. After reaction with the host materials, the dopants are intercalated in the intershell spaces of the multiwalled nanotubes, and, in the case of single-walled nanotubes, either in between the individual tubes or inside the tubes.

The above confirms carbon's uniqueness as an electronic material. It can be a good conductor in the form of graphite, an insulator in the form of diamond, or a flexible polymer (conductive or insulating) when reacted with hydrogen and other species. Carbon differs from other group IV elements, such as Si and Ge, which exhibit sp^3 hybridization. Carbon does not have any inner atomic orbitals except for the spherical 1s orbital, and the absence of nearby inner orbitals facilitates hybridizations involving only the valence (outer) s and p orbitals. The fact that sp and sp^2 hybridizations do not readily occur in Si and Ge might be related to the absence of *organic materials* made from these elements.

51.3 Plastic Electronics

51.3.1 Diodes and Transistors

Since the discovery of semiconducting behavior in organic materials, there has been a considerable research effort aimed at exploiting these properties in electronic and optoelectronic devices. The term *plastic electronics* refers to electronic devices incorporating polymeric organic compounds (although this term is often used more widely to include devices incorporating other semiconducting organic materials). Organic semiconductors can have significant advantages over their inorganic counterparts. For example, thin layers of conjugated small molecules and polymers can easily be made by low-cost methods such as spin coating. High-temperature deposition from vapour reactants is generally needed for inorganic semiconductors. Synthetic organic chemistry also offers the possibility of designing new materials with different band gaps. As noted in Sect. 51.1.3, the mobilities of the charge carriers in organic field-effect transistors (FETs) have exceeded $10\,cm^2/Vs$. Therefore, such performance and the simple fabrication techniques for conjugated small molecules and polymers have attracted much industrial attention for the fabrication of organic transistor applications such as data storage and thin-film device arrays to address LCDs [51.20–22, 24, 25, 35–37].

Semiconducting organic compounds have been used in a similar fashion to inorganic semiconductors (e.g., Si and GaAs) in metal/semiconductor/metal structures. A diode, or rectifying device, can be made by sandwiching a semiconductor between metals of different work functions. In the ideal case, an n-type

semiconductor should make an Ohmic contact to a low work-function metal and a rectifying Schottky barrier to a high work-function metal [51.38]. One example is that of a semiconductive organic film sandwiched between aluminum and indium-tin-oxide electrodes [51.39]. This device also exhibits PV behavior and is a basic structure of organic PVs.

Organic materials have been used as the semiconducting layer in FET devices [51.22, 40–42]. These are three-terminal structures: a voltage applied to a metallic gate affects the electric current flowing between the source and drain electrodes. For transistor operation, charge must be injected easily from the source electrode into the organic semiconductor and the carrier mobility should be high enough to allow useful quantities of source–drain current to flow. The organic semiconductor and other materials with which it is in contact must also withstand the operating conditions without thermal, electrochemical, or photochemical degradation. Two performance parameters to be optimized in organic FETs are the field-effect mobility and the on/off ratio [51.41].

The operating characteristics of organic transistors and integrated circuits have improved markedly over recent years. This has been brought about by both improvements in the material synthesis and in the thin-film processing techniques [51.20, 21, 24, 25, 43, 44]. State-of-the-art organic FETs possess characteristics exceeding those of devices prepared from hydrogenated amorphous silicon, with mobilities around $1\,\mathrm{cm}^2/\mathrm{Vs}$ and on/off ratios greater than 10^6. As organic FETs are moving closer to applications, their reliability under realistic atmospheric as well as electrical operating conditions has come under more intense scrutiny.

A number of groups have also demonstrated transistor devices incorporating carbon nanotubes [51.45–47]. However, some key issues need to be addressed before nanotubes can be exploited fully in such applications. These include the reproducible fabrication of low-resistance electrical contacts and the accurate control of nanotube growth parameters [51.48]. The nanotube transistor devices realized experimentally have typical dimensions in the micron range. The real promise of carbon nanotube devices, however, lies in the possibility of nanoscale devices. Transistors incorporating graphenes have also been extensively studied because of their high mobility (up to $200\,000\,\mathrm{cm}^2/\mathrm{Vs}$) [51.26, 30].

Thin-film transistors based on organic semiconductors are likely to form key components of plastic circuitry for use as display drivers in portable computers and pagers, and as memory elements in transaction cards and identification tags.

51.3.2 Organic Light-Emitting Structures

Reports of light emission from organic materials upon the application of an electric field (electroluminescence) have been around for many years. However, there has been an upsurge in interest following the initial report of organic light-emitting devices (OLEDs) incorporating the conjugated small molecules (tris(8-hydroxyquinolinato)aluminum, Alq_3 (Fig. 51.9) [51.49] or the conjugated polymer polyphenylenevinylene (PPV (Fig. 51.5)) [51.50]). The simplest OLED is an electroluminescent compound sandwiched between metals of high and low work function, as depicted in Fig. 51.8. The anode electrode is normally indium tin oxide (ITO) as this material is semitransparent, allowing the light out of the device. On application of a voltage, electrons are injected from the low work function electrode into the lowest unoccupied molecular orbital (LUMO) level (conduction or π^* band in the case of an organic compound possessing a delocalized electron system) of the organic compound and holes from the high work-function electrode into the highest occupied molecular orbital (HOMO) level (valence or π band in the case of an organic compound possessing a delocalized electron system). The recombination of these oppositely charged carriers then results in the emission of light. Work is focused on the use of low molecular-weight organic molecules and polymers and there is considerable industrial interest in the application of such materials to various display technologies [51.51–54]. It is estimated that the global

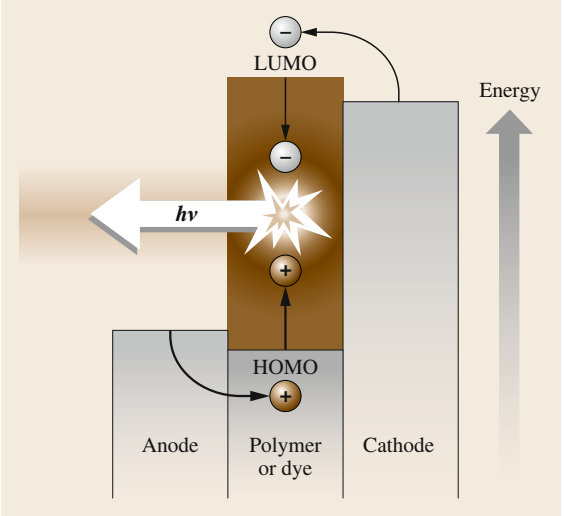

Fig. 51.8 Schematic energy band structure of an organic light-emitting device (OLED). The recombination of electrons and holes results in the emission of light of frequency ν and energy $h\nu$

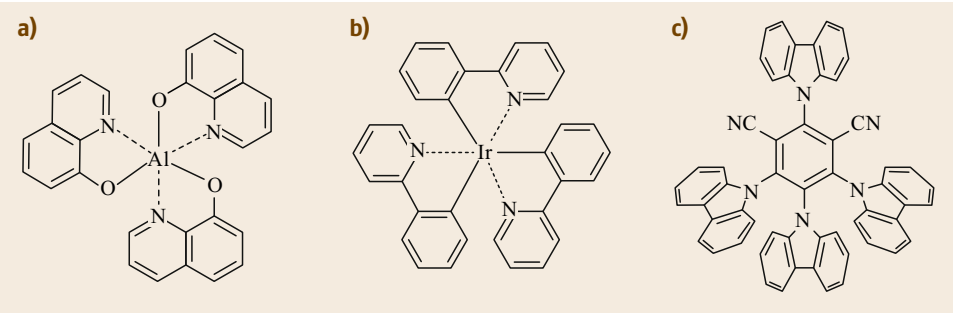

Fig. 51.9a–c Representative chemical structures of green **(a)** fluorescent, **(b)** phosphorescent, and **(c)** TADF emitters

market for OLED displays will increase to $16 billion by 2020 [51.55]. Organic light-emitting devices offer a number of advantages over LCDs and the other technologies that currently dominate the flat-panel display market: OLEDs do not require backlighting and they can be made thinner and lighter. Furthermore, OLED displays provide higher contrast and truer colors, higher brightness, wider viewing angles, better temperature stability and faster response times than LCDs [51.51].

Many techniques have been used in attempts to optimize the performance of OLEDs. For example, a thin inorganic insulating layer such as LiF, or an organic monolayer may be inserted between the cathode and the emissive material [51.56–58]. A thin insertion layer of poly(ethylene imine) (PEI) [51.54, 58] between a metal oxide such as ITO or ZnO as a bottom cathode and an emitting layer greatly improves the performance of OLEDs. Such inverted OLEDs, or iOLEDS, possess the configuration of substrate/cathode/PEI/emitting layer/anode (the configuration of conventional OLEDs shown in Fig. 51.8 is substrate/anode/emitting layer/cathode). In recent years, iOLEDs have attracted much attention because the absence of air-sensitive electron injection materials such as LiF, Ca, and Cs results in a long device lifetime [51.59, 60]. Stringent encapsulation of flexible/stretchable devices on flexible substrates, such as a plastic film, is rather difficult and hence the development of iOLEDs is essential for future flexible/stretchable displays.

Electron- and hole-transporting layers can also be introduced between the cathode and the emitting layer and between the anode and the emitting layer, respectively, to improve and balance the injection of charge carriers [51.61].

When an electron and a hole recombine to form an excited molecular state in an organic material, the spins of the electrons in the excited and ground levels can either point in the same direction (triplet state) or in the opposite directions (singlet state). For quantum-mechanical reasons, 75% of recombination events are associated with triplet states which, in most cases, do not emit photons when they decay to the ground state. Hence, the production of emission from the triplet state of organic materials is a further means to improve the device efficiency [51.62, 63]. Indeed, the internal quantum efficiency, which is defined as the ratio of the number of photons that can be extracted for electroluminescence to the injected current (i. e., the number of injected carriers), is 25% in fluorescent emitters. In contrast, the internal quantum efficiency of OLEDs using phosphorescent materials is 100% [51.64]. However, the design of the phosphorescent materials is greatly limited because the heavy atom effect (spin–orbital interaction) must be induced, for example, by using rare metals, to realize highly efficient radiative transition from the triplet excited state to the ground state. The internal quantum efficiency of 100% has also been achieved using the up-conversion of triplet excitons to singlet excitons by thermal energy, known as thermally activated delayed fluorescence (TADF) [51.65]. TADF emitters can include ubiquitous atoms such as C, H, and N without using rare metals. Recent studies have revealed that highly efficient delayed fluorescence can be achieved by optimizing the molecular design [51.62]. Representative fluorescent, phosphorescent, and TADF emitters are shown in Fig. 51.9.

Table 51.2 shows some important parameters of polymer-based OLEDs with different color outputs [51.54]. There is also a keen interest in developing white-light organic displays. For example, a large-area white-light-emitting OLED could provide a solid-state light source that might compete with conventional lighting technologies. Different methods of making an intrinsically white-emitting OLED by blending emissive species, either in single or multiple layers have been demonstrated [51.66–70].

51.3.3 Photovoltaic Devices

Concerns over global climate change, local air pollution, and resource depletion are making PVs an increasingly attractive method of energy supply. The current technology is based on single-crystal silicon solar cells. These have developed since the 1940s and now possess

Table 51.2 Performance of polymer-based organic light-emitting devices. (After [51.54], Data from Cambridge Display Technology)

Colour	Voltage (V)	Efficiency at 1000 cd/m^2 (cd/A)	Measured T50 lifetime[a] at fixed luminance (h) at 1000 cd/m^2
Red	4.2	31	350 000
Green	4.7	72	350 000
Blue	3.7	12	> 10 000

[a] T50 lifetime is defined as luminance depreciation to 50% of its initial value

conversion efficiencies of around 15% for commercial devices (although figures of around 25% are reported in the laboratory) [51.71]. However, the technology is more expensive than conventional power generation, and there is much research on alternative materials. Photovoltaics using organic compounds, such as polymers or dyes, offer the possibility of large-scale manufacture at low temperature coupled with low cost. Until the end of the twentieth century, little progress had been made and energy conversion efficiencies of up to only about 1% were achieved [51.72]. However, the availability of new conductive organic materials and different PV designs has significantly improved on this figure. To 2015, several laboratories have reported conversion efficiencies of around 10% [51.71, 73–76].

An organic solar cell device is very similar in structure to the OLED described in the previous section. If the incoming photons have energy greater than the band gap of the polymer (or greater than the HOMO–LUMO separation in the case of organic molecular materials) then the light will be absorbed, creating electrons and holes. In an inorganic PV cell, these electrons and holes would be generated within, or close to, a depletion region in the semiconductor and they would be free to migrate to opposite electrodes, where they can do useful work in an external electrical load. However, in the organic material the electrons and holes are bound together in excitons. An immediate problem in organic PV cells is to split these excitons. This can be conveniently done at an interface, the simplest being the junction between the electrodes and the organic material. Under open-circuit conditions, holes are collected at the high work-function electrode (e.g., ITO) and electrons at the low work-function electrode (e.g., Al). Generally, the open-circuit output voltage of the PV device depends on the work function difference between the electrodes. However, in a p-n junction, the maximum available voltage is determined by the difference of the quasi Fermi levels of the two charge carriers, that is, n-doped semiconductor energy level and p-doped semiconductor energy level, respectively. In organic PV, the open-circuit voltage is found to be linearly dependent on the HOMO level of the electron-donating material (p-type semiconductor quasi Fermi level) and the LUMO level of the electron-accepting material (n-type semiconductor quasi Fermi level) [51.77–79]. Improvements in the efficiency of the exciton-splitting process can be achieved using organic compounds incorporating electron-donating and electron-accepting species. By creating interfaces of differing electron affinities, it is possible to enhance the probability of electron transfer between the molecules. The creation of the interfaces is carried out by blending electron-donating and electron-accepting species, to produce a bulk heterojunction [51.80–82]. This exhibits a donor–acceptor phase separation on a 10–20 nm length scale. In such a nanoscale interpenetrating network, each interface is within a distance less than the exciton diffusion length from the absorbing site. The bulk heterojunction concept significantly increases the interfacial area between the donor and acceptor phases and results in improved efficiency solar cells.

An alternative approach to organic PVs exploits a dye-sensitized solar cell, or *Grätzel* cell [51.83]. Here, the incoming photons are absorbed by molecules of a dye on a semiconductor surface with subsequent energy and electron transfer to the semiconductor. An electron is returned to the oxidized dye via an electrolyte. The efficiency of such devices is 11.9% [51.71, 84].

51.4 Molecular-Scale Electronics

51.4.1 Moore's Laws

The second strand to molecular electronics (molecular-scale electronics) recognizes the spectacular size reduction in the individual processing elements in integrated circuits over recent years. The first microprocessor chip manufactured in 1972 by Intel (8008) had a clock speed of 200 kHz and contained 3500 transistors. There are 1.4 billion transistors on the Pentium Core i7 chip (June, 2014), fabricated using 22 nm process technology, and operating at a clock speed of 3–4 GHz.

Moore's law (or Moore's first law) states that the functions per chip double every 1.5 years. This will probably describe developments over at least the next

decade. The semiconductor industries have produced an international technology roadmap for the future of complementary metal oxide semiconductor (CMOS) technology [51.85]. Figure 51.10 shows the anticipated growth in the density of the transistors in both the microprocessor unit (MPU) and the dynamic random-access memory (DRAM) of a CMOS chip over the next decade. The prediction is for a 10 nm minimum feature size (gate length) for the MPU and 10^{11} transistors per cm^2 in the case of the memory by the year 2022. These figures are regularly updated. This device density is remarkable and provides the means to store significant amounts of data (Table 51.3 [51.3]). However, molecular-scale electronics has the potential for further increases in device density. For example, using $\approx 1-3$ nm organic molecules as the processing elements, $10^{13}-10^{14}$ *devices* could be fitted into 1 cm^2 [51.3].

There are, however, a number of technological issues that will need to be overcome for the predictions for the CMOS-based roadmap to be realized [51.86, 87]. Not least are the materials limitations of the silicon/silicon dioxide system. For example, charge leakage becomes a problem when the insulating silicon dioxide layers are thinned to a few nanometer. The scaling of physical dimensions can also be limited by minute variations in size and spatial fluctuations in the doping concentration. Lithographic techniques will face enormous challenges to achieve the high controllability needed to eliminate variations from device to device. Heat dissipation is another key factor. A Pentium Core i7 chip with about 1 billion transistors operating at the current nanosecond rate can emit 60–90 W of heat. Financial issues are also problematic as ever more complex integrated circuits are produced. Intel's Fab 32, a chip-fabrication facility (FAB) that opened in Chandler, AZ, USA, in August 2005, cost $3 billion to construct and equip. The cost of building a fab is expected to rise to over $10 billion by 2025 [51.88]. This significant increase in cost (Moore's second law) is due to the extremely sophisticated tools that will be needed to form the increasingly small features of the devices. Molecular-scale technology will, of course, also need to address such problems – plus many more.

51.4.2 Nanoscale Organic Films

Before organic molecules can be exploited in device architectures (i. e., those familiar from Si-based microelectronics) ways must be found to deposit them onto surfaces. Well-established methods of organic film deposition include electrodeposition, thermal evaporation, and spinning [51.89]. The Langmuir–Blodgett (LB) technique, self-assembly, and layer-by-layer electrostatic deposition are further means for producing layers of organic materials. These allow ultrathin-film assemblies of organic molecules to be engineered at the molecular level and are of particular relevance to molecular-scale electronics [51.90, 91].

Langmuir–Blodgett films are prepared by first depositing a small quantity of an amphiphilic compound (i. e., one containing both polar and nonpolar groups) dissolved in a volatile solvent onto the surface of purified water [51.91, 92]. The classical materials are long-chain fatty acids, such as *n*-octadecanoic acid (stearic acid). When the solvent has evaporated, the organic molecules may be organized into a floating two-dimensional *crystal* by compression on the water surface. As the area available to the organic molecules is reduced, the floating film will undergo several phase transformations. These are, to a first approximation, analogous to 3-D gas, liquid, and solid phases. The phase changes may readily be identified by monitoring the surface pressure as a function of the area occupied by the molecules in the film. This is the two-dimensional equivalent to the pressure-versus-volume isotherm for a gas. In the *gaseous* state the molecules are far enough apart on the water surface that they

exert little force on one another. As the surface area of the monolayer is reduced, the hydrocarbon chains will begin to interact. The *liquid* state that is formed is generally called the expanded monolayer phase. The hydrocarbon chains of the molecules in such a film are in a random, rather than regular orientation, with their polar groups in contact with the subphase. As the molecular area is progressively reduced, condensed phases may appear. There may be more than one of these and the emergence of each condensed phase can be accompanied by constant-pressure regions of the isotherm, as observed in the cases of a gas condensing to a liquid and a liquid solidifying. In the condensed monolayer states, the molecules are closely packed and are oriented with their hydrocarbon chain pointing away from the water surface. The area per molecule in such a state will be similar to the cross-sectional area of the hydrocarbon chain, that is, $\approx 0.19\,\mathrm{nm}^2/\mathrm{molecule}$.

If the surface pressure is held constant in one of the condensed phases, then the film may be transferred from the water surface onto a suitable solid substrate simply by raising and lowering the latter through the monolayer–air interface. Figure 51.11 shows a schematic diagram of the equipment required for LB film deposition. In this technique, introduced by Langmuir and Blodgett [51.91] the floating condensed monolayer is transferred, like a carpet, as the substrate is raised and/or lowered through the air/monolayer interface. A number of different LB deposition *modes* are possible. The most commonly encountered situation is Y-type deposition, which refers to monolayer transfer on both the upward and downward movements of the substrate. Instances in which the floating monolayer is only transferred to the substrate as it is being inserted into the subphase, or only as it is being removed, are also observed. These deposition modes are called X-type and Z-type depositions, respectively.

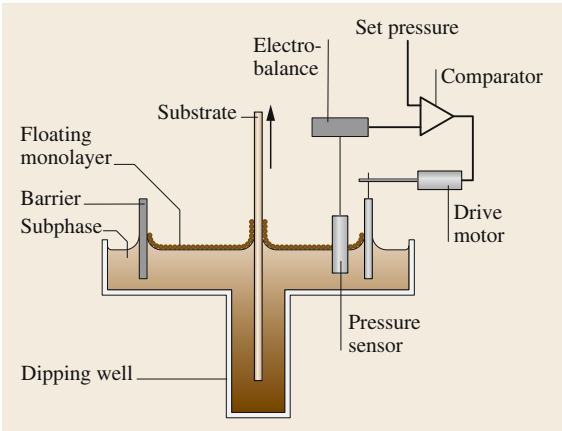

Fig. 51.11 System for the deposition of Langmuir–Blodgett films

Self-assembly is a much simpler process than that of LB deposition. Monomolecular layers are formed by the immersion of an appropriate substrate into a solution of the organic material [51.90]. The best known examples of self-assembled systems are organosilicon on hydroxylated surfaces (SiO_2, Al_2O_3, glass etc.) and alkanethiols on gold, silver, and copper [51.93]. However, other combinations include:

- Dialkyl sulfides on gold
- Dialkyl disulfides on gold
- Alcohols and amines on platinum
- Carboxylic acids on aluminum oxide and silver
- Phosphonic acids on aluminum oxide and ITO.

The self-assembly process is driven by the interactions between the head group of the self-assembling molecule and the substrate, resulting in a strong chemical bond between the head group and a specific surface site, for example, a covalent Si–O bond for alkyltrichlorosilanes on hydroxylated surfaces.

The combination of the self-assembly process with molecular recognition offers a powerful route to the development of nanoscale systems that may have technological applications as chemical sensing or switching devices. For instance, the complexation of a neutral or ionic guest at one site in a molecule may induce a change in the optical or redox properties of the system. Monolayers containing both an electroactive TTF unit and a metal-binding macrocycle assembled onto platinum have been shown to exhibit electrochemical recognition to Ag^+ ions [51.94].

The self-assembly process, as described above, is usually restricted to the deposition of a single molecular layer on a solid substrate. However, chemical means can be exploited to build up multilayer organic films. A method pioneered by *Sagiv* is based on the successive absorption and reaction of appropriate molecules [51.95, 96]. The head groups react with the substrate to give a permanent chemical attachment and each subsequent layer is chemically attached to the one before in a very similar way to that used in systems for supported synthesis of proteins.

Another technique for building up thin films of organic molecules is driven by the ionic attraction between opposite charges in two different polyelectrolytes, the so-called *layer-by-layer* assembly technique [51.97–100]. A solid substrate with a positively charged planar surface is immersed in a solution containing an anionic polyelectrolyte and a monolayer of polyanion is adsorbed (Fig. 51.12). Since the adsorption is carried out at relatively high concentrations of the polyelectrolyte, most of the ionic groups remain ex-

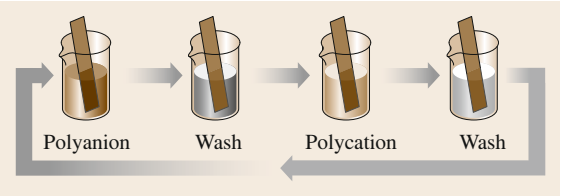

Fig. 51.12 Deposition of layer-by-layer polyelectrolyte films by the sequential immersion of a solid substrate in solutions of the polyanions and polycations

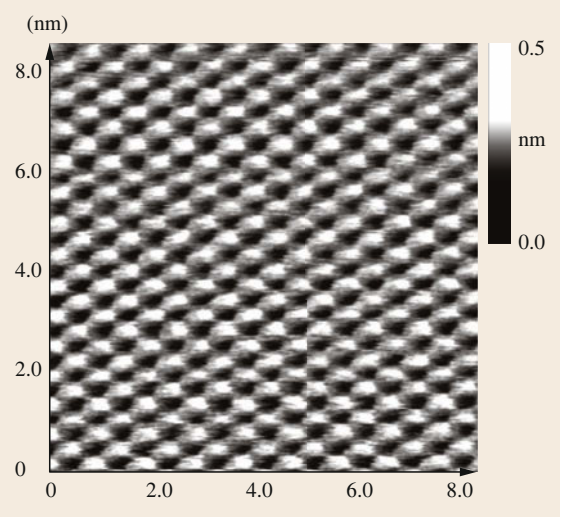

Fig. 51.13 Atomic force micrograph of a 12-layer, *n*-eicosanoic-acid Langmuir–Blodgett film deposited onto silicon. (From [51.105], with permission from ACS)

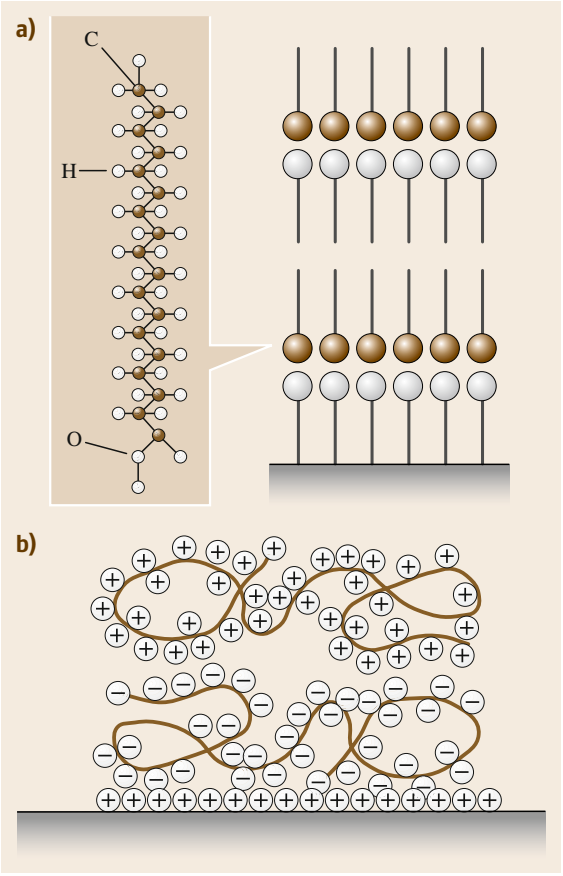

Fig. 51.14a,b Molecular organization in **(a)** a Langmuir–Blodgett multilayer assembly and **(b)** a polyelectrolyte multilayer deposited by the electrostatic method

posed to the interface with the solution and thus the surface charge is reversed. After rinsing in pure water, the substrate is immersed in a solution containing the cationic polyelectrolyte. Again, a monolayer is adsorbed but now the original surface charge is restored, resulting in the formation of a multilayer assembly of both polymers. It is possible to use a sensitive optical technique, such as surface plasmon resonance to monitor, in situ, the growth of such electrostatically assembled films [51.101]. The layer-by-layer method has been used to build up layers of conductive polymers, for example, partially doped polyaniline and a polystyrene polyanion [51.102]. Biocompatible surfaces consisting of alternate layers of charged polysaccharides and oppositely charged synthetic polymers can also be deposited in this way [51.103]. A related, but alternative, approach uses layer-by-layer adsorption driven by hydrogen-bonding interactions [51.104].

The organization of the organic molecules in multilayer assemblies may be investigated by a number of analytical techniques including x-ray and neutron reflection, electron diffraction, and infrared spectroscopy [51.91]. Figure 51.13 shows an example of an atomic force micrograph of a 12-layer *n*-eicosanoic acid LB film deposited onto single-crystal silicon [51.105]. Lines of individual molecules are evident at the magnification shown. Figure 51.14 contrasts the molecular organization expected in an LB multilayer with that in electrostatically deposited layer-by-layer films. For the latter case, the polyelectrolyte chains within each layer will become entangled, and may even penetrate into the layers above and below, leading to a less-ordered film than that produced by LB deposition.

51.4.3 Patterning Technologies

The problem of connecting together the individual processing elements in any future molecular computer is challenging. Each one of the 1.4 billion transistors in the Pentium Core i7 chip is addressable and connected to a power supply. Organic molecules can be difficult

to arrange on a surface or in a 3-D array such that each molecule is addressable. Planar inorganic materials are normally patterned using photolithography. Here, a surface is first covered with a light-sensitive photoresist, which is exposed to ultraviolet light through a contact mask. Either the exposed photoresist (positive resist) or the unexposed regions (negative resist) can then be developed to leave a positive or negative image of the mask on the surface. This approach is routinely used in the fabrication of devices based on inorganic semiconductors. However, difficulties can be encountered when used with organic films, as the photoresists themselves are based on organic compounds.

Brittain et al. [51.106] describe a series of *soft* lithographic methods that may be better suited to the patterning of organic layers. Pouring a liquid polymer, such as polydimethylsiloxane (PDMS) onto a *master* made from silicon forms a pattern-transfer element. The polymer is allowed to cure to form an elastomer, which can then be removed from the master. This replica can subsequently be used as a stamp to transfer chemical ink, such as a solution of an alkanethiol, to a surface.

Scanning microscopy methods offer a powerful means of manipulating molecules. Careful control of an atomic force microscope (AFM) tip can allow patterns to be drawn in an organic film [51.108, 109]. Such techniques can also be used to reposition molecules, such as the fullerene C_{60}, on surfaces and to break up an individual molecule [51.110]. A further approach that has recently been developed is called dip-pen nanolithography (DPN) [51.107] (Fig. 51.15). This is able to deliver organic molecules in a positive printing mode. An AFM tip is used to *write* alkanethiols on a gold thin film in a manner analogous to that of a fountain pen. Molecules flow from the AFM tip to a solid substrate (*paper*) via capillary transport, making DPN a potentially useful tool for assembling nanoscale devices. Recent developments of DPN have included an overwriting capability that allows one nanostructure to be generated and the areas surrounding that nanostructure to be filled with a second type of ink [51.111]. Perhaps the greatest

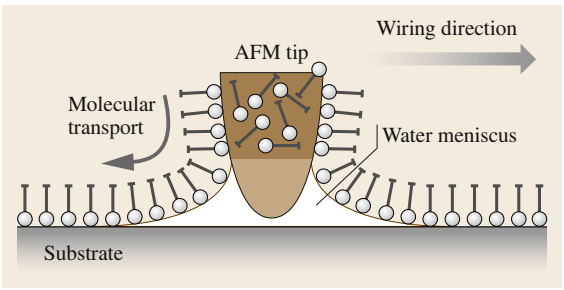

Fig. 51.15 Dip-pen patterning showing the transfer of an *ink* onto *paper* using the tip of an AFM. (After [51.107])

limitation in using scanning probe methodologies for ultrahigh-resolution nanolithography over large areas derives from the serial nature of most techniques. However, multiple-pen nanoplotters capable of performing parallel lithography have been reported [51.112, 113]. In addition, PDMS elastomeric tip arrays of up to 11 million pens that were made with a silicon master have been developed for low-cost, high-throughput patterning [51.114]. The DPN method has also been used to deposit magnetic nanostructures [51.115] and arrays of protein molecules [51.116].

The need to combine large-area coatings with device patterning has resulted in the development of direct-write fabrication methods, such as ink-jet printing [51.117–120]. Although ink-jet printhead droplet ejection can be achieved with thermal (bubble-jet) and piezoelectric modes of operation, the majority of published literature on ink-jet printing as a tool for manufacturing organic devices has been the result of using piezoelectric-actuated printers. Piezoelectric printhead technology is favored primarily because it applies no thermal load to the organic *inks* and is compatible with the printing of digital images. The combination of solution-processable emissive polymers with ink-jet printing offers some promise in the development of low-cost high-resolution displays [51.121]. The technique has also been applied to the manufacturing of all-polymer transistor circuits [51.122, 123]. Ultrafine printing with 1 μm resolution has recently been demonstrated using an ink-jet system with subfemtoliter ejection accuracy [51.124].

Liquid thin films exhibit a number of unique physical processes, such as dewetting, pinning, and capillary action, and these processes have been investigated as a potential tool of patterning organic micro- and nanostructures on large-area substrates by low-cost solution techniques. For example, the control of the dewetting behavior of liquid thin films using substrates having a prepatterned variation of surface energies or structures has been used to guide organic materials to desired surfaces [51.126, 127]. The capillary action of the liquid into narrow channels has also been utilized to manipulate and deposit organic materials [51.128, 129] and biomaterials [51.130, 131], in which PDMS stamps have been adopted to form hydrophobic channels. In several of these approaches, pattern length scale and feature sizes are limited to the lateral dimension of prepatterned templates. However, further investigation of the self-assembly of organic molecules and physical phenomena in liquid thin films enables us to downscale dimensions relative to the size of the templates. An example is shown in Fig. 51.16 [51.125, 132]. This method uses the convex surfaces of an elastomeric stamp as forming positive motifs. As the stamp is gen-

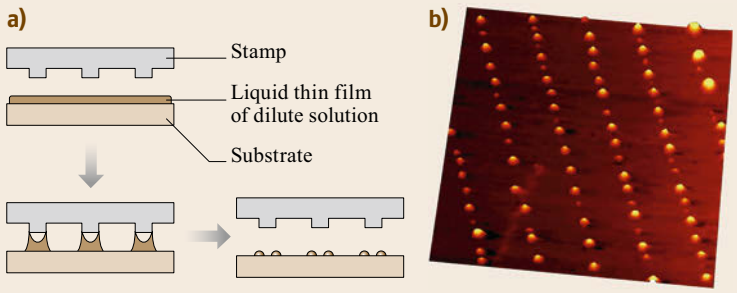

Fig. 51.16 **(a)** Schematics of stamp-assisted deposition process and **(b)** atomic force micrograph of dotted structures printed from a diluted solution of molecular magnets. (After [51.125], with permission from the ACS)

tly placed on a liquid thin film made of a dilute solution, capillary forces drive the solution to form menisci under the stamp instead of filling the grooves, as shown in Fig. 51.16a. Depending on the intermolecular and molecule–substrate interactions, organic molecules are self-assembled on the substrate into patterns of split nanowires or strings of nanodots (Fig. 51.16b). A capability of the method for nanopatterning has been demonstrated using a molecular magnet [51.125] and a molecular semiconductor [51.132].

51.4.4 Molecular Device Architectures

The *bottom-up* approach to molecular electronics offers many intriguing prospects for manipulating materials on the nanometer scale, thereby providing opportunities to build up novel architectures with predetermined and unique physical and/or chemical properties. Two relatively simple examples of organic superlattice structures are the incorporation of an electric polarization into a multilayer array to form thin films exhibiting pyroelectric behavior [51.133] and the use of noncentrosymmetric layers for second-order nonlinear optical response, for example, second-harmonic generation [51.134]. In both instances, the multilayer thin films can be built up using the LB approach.

To realize functional nanoelectronic circuits, a number of workers have investigated the electrical characteristics of structures in which organic molecules are sandwiched between two metallic electrodes. Of particular interest is the possibility of observing molecular rectification using monolayer or multilayer films. This follows the prediction [51.135] that an asymmetric organic molecule containing a donor and an acceptor group separated by a short σ-bonded bridge, allowing quantum-mechanical tunneling, should exhibit diode characteristics. There have been many attempts to demonstrate this effect in the laboratory, particularly in organic thin films [51.136–138]. Asymmetric current-versus-voltage behavior has certainly been recorded for many metal/insulator/metal structures, although these results are often open to several interpretations as a result of the asymmetry of the electrode configuration.

In other cases, *switching* behavior has been reported [51.3–8, 12, 13, 138, 139]. As with the work on molecular rectification, the origin of the switching is not always clear. For example, is this a property of the organic molecules, the metallic electrode or of the presence of any interfacial (e.g., oxide) layer (or a combination of these)? Bistable rotaxane molecules have been used as the basis of some of these studies; an example is shown in Fig. 51.17a. This molecule is amphiphilic and the ring component can move between the polar and nonpolar regions of the main part of the molecule. The molecules can be assembled on an electrode using the LB approach and a top electrode is then deposited to form the crossbar structure shown in Fig. 51.17b [51.5–7]. Alternatively, the molecules can be solution-cast between Pt source and drain electrodes (with gaps of 1–2 nm) in transistor structures [51.9]. In some of the experiments, the absence of switching using *control* compounds suggests that the rotaxane molecule itself is responsible for the bistability [51.7].

Bistable switching intrinsic to a molecular phenomenon has also been reported in single molecular layers formed by the self-assembly approach [51.139, 140]. A switching behavior trigged by an external voltage in a substituted conjugated molecular wire of bipyridy-dinitro oligophenylene-ethynylene dithiol [51.139] has been confirmed by studies both on monolayers and isolated molecules using various two-terminal configurations, such as crossed wire electrodes, a scanning tunneling microscope and a pair of electrodes with a nanometer-sized gap [51.140]. The experimental and theoretical studies indicate that such voltage-triggered switching originates in the presence of the nitro groups and their dipole moment facilitates molecular rotation during voltage sweeps [51.140, 141]. However, the fabrication of monolayer devices sandwiched metallic electrodes often suffers from electrical shorts, due to structural defects and/or the penetration of metallic atoms in the organic layer. In a pioneer-

ing work, monolayer formation in nanopores patterned by lithography has been exploited in device fabrication [51.15]. A simple approach that uses conducting thin films such as poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) [51.142] and multilayer graphene [51.143] as protecting interlayers for the metal penetration has recently been developed for high-yield, large-area fabrication of monolayer device arrays without electrical shorts. This technique has also been used to the demonstrate switching behavior in monolayer devices comprising photochromic molecules [51.144] and transition metal complex molecules [51.145]. Such results augur well for the development of molecular-scale logic circuitry.

Nanoscale organic devices can also exploit charge storage on nanoparticles or at interfaces. One important metal oxide semiconductor (MOS) device is the flash memory [51.146]. This is similar in structure to a MOS field-effect transistor (MOSFET), except that it has two gate electrodes, one on top of the other. The top electrode forms the control gate, below which a *floating gate* is capacitively coupled to the control gate and the underlying silicon. The memory cell operation involves putting charge on the floating gate or removing it, corresponding to two logic levels. Nanoflash devices utilize single or multiple nanoparticles as the charge-storage elements. These are usually embedded in the gate oxide of a FET and located in close proximity (2–3 nm) to the transistor channel [51.147]. Figure 51.18 shows the characteristics of a memory device incorporating metallic nanoparticles deposited by the LB technique [51.10]. The device structure is shown schematically in the fig-

ure. The gold nanoparticles (Q-Au) were of nominal diameter 10 nm and passivated with an organic capping layer. Cadmium arachidate ($CdAr_2$) LB layers were used to provide an insulating gate layer. Figure 51.18 also shows the normalized capacitance versus voltage (C–V) data, measured at 1 MHz and at a voltage scan rate of 40 mV/s for three different device structures:

- Al/SiO_2/p-Si
- Al/20 LB layers $CdAr_2$/SiO_2/p-Si
- Al/20 LB layers $CdAr_2$/one LB layer Q–Au/p-Si.

The C–V curve for the reference Al/SiO_2/Si sample reveals the usual accumulation/depletion/inversion characteristics associated with metal–insulator–semiconductor (MIS) structures, with a flat-band voltage of approximately −1 V. Negligible hysteresis was evident on reversing the voltage scan. The data for the Si/SiO_2/$CdAr_2$ structure also show clear accumulation, depletion, and inversion regions, again with no hysteresis on reversing the direction of the voltage scan. The most significant difference in the structures with and without the Q-Au nanoparticles is the relatively large hysteresis in the MIS structure containing the Q-Au layer. This was thought to be indicative of charge storage in the gold nanoparticles [51.10]. In a somewhat different approach, the same group has used a self-assembly technique to chemically attach gold nanoparticles to a SiO_2 surface [51.148]. When incorporated into a transistor structure, the resulting device was shown to behave as a nonvolatile electrically erasable programmable read-only memory [51.149]. Alternatively, gold nanoparticles deposited by layer-by-layer assembly using polyions have been applied to the fabrication of nonvolatile memory based on organic transistors [51.150, 151]. Recent progress involves the use of a mixed self-assembled monolayer of aliphatic and C_{60}-functionalized phosphonic acid molecules as a molecular charge storage dielectric layer, which allows low-voltage operation of the organic transistor memory [51.152].

Molecular-scale electronics may also offer increased device densities by fabricating 3-D architectures. In 1989, the principle of a 3-D memory based on LB films was described [51.153]. The device requires a molecule with a central conjugated region of high electron affinity (for an n-type material, the electron affinity is the energy difference between the bottom of the conduction band and the vacuum level) surrounded by aliphatic substituents of low electron affinity, A multilayer structure, as shown in Fig. 51.19, could be used to store one N-bit word, the presence or absence of charge on the n-th layer representing a 0 or 1 of the n-th bit. The LB film could be assembled on the gate of an

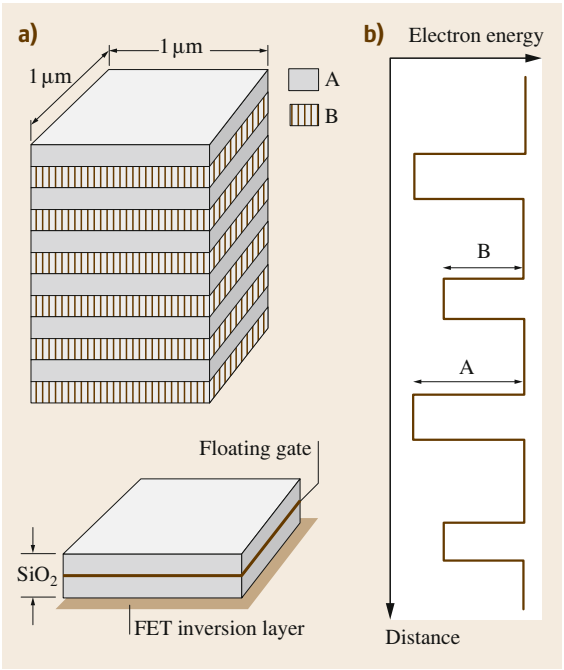

Fig. 51.19 **(a)** Molecular memory holding N bits (*top*) compared to a conventional silicon memory holding 1 bit (*bottom*). **(b)** Electron energy versus perpendicular distance for molecular memory with no applied electric field. (After [51.153], with permission from Elsevier)

FET and, on application of an electric field, transport of bits across the layers may be detected as induced charge on the gate.

Recent technological advancements have allowed the fabrication of structures in which one or few molecules bridge metallic electrodes through chemical bonds, such as SH terminal anchor groups. Such metal–molecule–metal junctions (molecular junctions) [51.154] have been extensively studied as potential building blocks for molecular integrated circuits. One of key technologies is the development of metallic electrodes with a few nanometers gap (nanogap electrode) capable of bridging small molecules. Currently, nanogap electrodes formed by mechanical break and electromigration of a prepatterned notched gold nanowire are most widely used for the fabrication of molecular junctions in planer configurations (these approaches have been referred to as break junction techniques) [51.155, 156]. The gap width of electrodes formed by the mechanical break junction technique can be tuned by bending a flexible substrate under in situ monitoring of tunneling current flowing in the gap, allowing forming a junction of a single molecule with electrodes reproducibly [51.155]. The electromigration break junction technique only provides a statistical for-

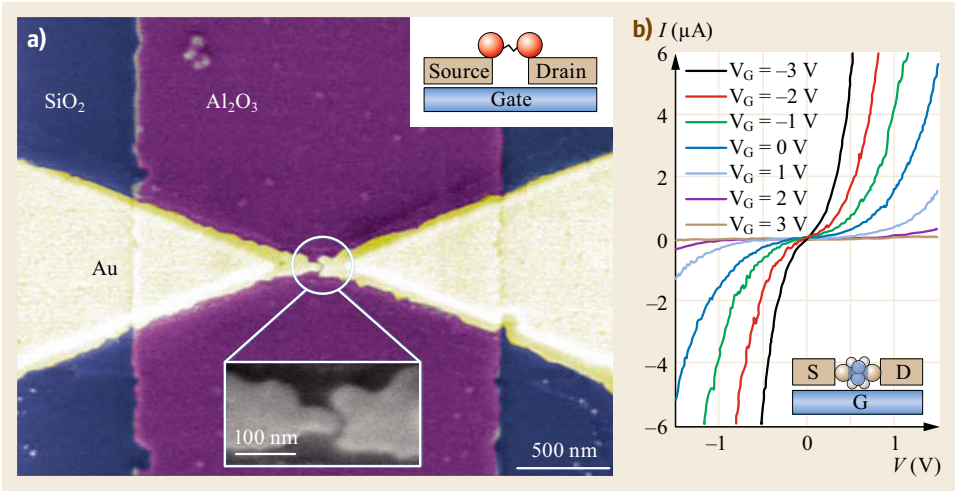

Fig. 51.20 **(a)** Scanning electron micrograph of gold nanogap electrodes formed by the electromigration break junction technique on a gate dielectric layer comprising a 3 nm thick aluminum oxide. (After [51.158], Courtesy of Nature Publishing Group)

mation of molecule–electrode junctions, but is able to form transistor structures using back-gate electrodes having a thin gate dielectric layer (e.g., Al_2O_3), as shown in Fig. 51.20a [51.157]. A molecular transistor that utilizes the electrostatic gating of molecular orbitals for the modulation of current flow has recently been demonstrated in benzene dithiols covalently bonded to gold electrodes (Fig. 51.20b) [51.158]. The effects of different anchor groups (e.g., NC, NH_3, and COOH), molecular length, molecular conformation and substituents on the electrical properties of molecular junctions have extensively been investigated by the break junction techniques including a scanning tunneling microscope-controlled break junction [51.159] toward the development of molecular devices with various electronic functions.

51.5 DNA Electronics

The study of the electronic behavior of organic compounds has led some scientists to work on the electrical properties of biological materials. DNA is arguably the most significant molecule in nature. It may also be an important material for molecular electronics applications. Reports into the electronic properties of DNA have already generated controversy in the literature [51.16, 160–164]. According to some, DNA is a molecular wire of very small resistance. Others, however, find that DNA behaves as an insulator. These seemingly contradictory findings can probably be explained by the different DNA sequences and experimental conditions used to monitor the conductivity [51.16].

The DNA strand in the double-helix arrangement consists of a long polymer backbone consisting of repeating sugar molecules and phosphate groups (Fig. 51.21). Each sugar group is attached to one of four bases, guanine (G), cytosine (C), adenine (A), and thymine (T). The chemical bonding is such that an A base only ever pairs with a T base, while a G always pairs with a C. Some of the electron orbitals belonging to the bases overlap quite well with each other along the long axis of the DNA. This provides a path for electron transfer along the molecule, in a similar fashion to the 1-D conduction seen in conjugated polymers (Sect. 51.1.2).

Theoretical and experimental work now suggests that a hole (i. e., a positive charge) is more stable on a G–C base pair than on an A–T base pair [51.16]. The energy difference between these two pairs is substantially larger than the thermal energy of the charge carrier. Under these conditions, a hole will localize on a particular G–C base pair. Because the A–T base pairs have a higher energy, they act as a barrier to hole transfer. However, if the distance between two G–C base pairs is small enough, the hole can tunnel quantum-mechanically from one pair to the next. In this way,

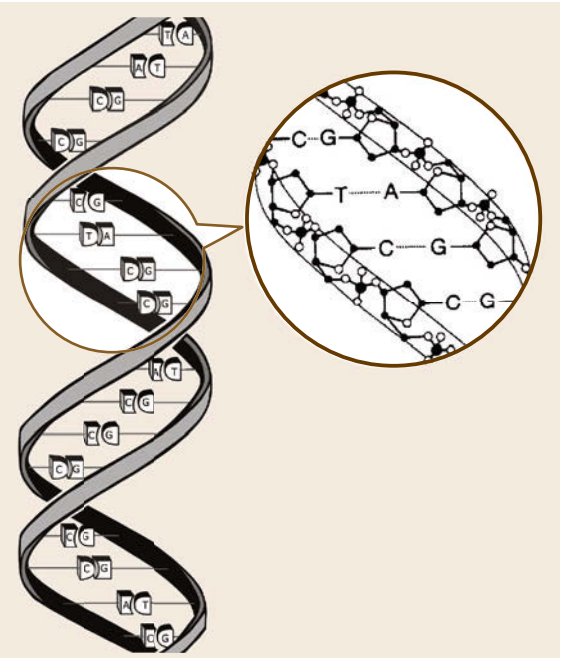

Fig. 51.21 DNA double helix showing the position of the four bases: guanine (G), cytosine (C), adenine (A), and thymine (T)

charge carriers are able to shuttle along a single DNA molecule over a distance of a few nanometers.

Recent experimental and theoretical results suggest that native DNA strands consisting of the specific sequence is a wide band-gap semiconductor [51.165–167]. However, the conductivity of DNA is still controversial, especially in experimental work, because it depends on conditions such as trapped water and counter ions in the DNA strands. Such factors may allow a different channel for conduction and also influence on the geometrical arrangements of base pairs DNA. In addition, modification of DNA with metals and ions can change the electronic behavior. For the realization of DNA electronics, it is imperative to predict the electronic properties theoretically as well as to control the experimental and useable conditions of the DNA.

DNA chips exploit the fact that short strands of DNA will bind to other segments of DNA that have complementary sequences, and can therefore be used to probe whether certain genetic codes are present in a given specimen of DNA. Microfabricated chips with many parallel DNA probes are becoming widespread in analytical and medical applications. Currently, the chips are read out optically, but further miniaturization might require new read-out schemes, possibly involving the electron-transfer properties of DNA.

Computations by chemical or biological reactions overcome the problem of parallelism and interconnections in a classical system. If a string of DNA can be put together in the right sequence, it can be used to solve combinational problems. The calculations are performed in test tubes filled with strands of DNA. Gene sequencing is used to obtain the result. For example, *Adleman* [51.168] calculated the *traveling-salesman problem* to demonstrate the capabilities of DNA computing. DNA computing on parallel problems potentially provides 10^{14} millions of instructions per second (MIPS) and uses less energy and space than conventional supercomputers. While CMOS supercomputers operate 10^9 operations per Joule, a DNA computer could perform about 10^{19} operations per Joule. Data could potentially be stored on DNA in a density of approximately 1 bit/nm^3 while existing storage media such as DRAMs require 10^{12} nm^3 to store 1 bit.

The fact that a DNA strand binds specifically with other strand having a complementary sequence is relevant to the formation of electronic nano-structures. This is so-called DNA origami in a literature. Using DNA strands having various designed sequences, many architectures such as 2-D sheets [51.169], various shapes and patterns [51.170], and 3-D structures [51.171], were formed by self-assembly. These structures are useful as scaffolds for other materials to implement an electronic function [51.172].

The differences in the electronic properties of the nucleotides have been expected to be usable for identifying the sequence of DNA. Since a DNA strand was shown to translocate through nanopores fabricated on solid state films, many efforts have been made to sequence DNA using electronic measurements [51.173–175]. The difference in tunneling current through the nucleotides was measured with small electrodes made by break-junction [51.176], which suggests the possibility of DNA sequencing electronically.

51.6 Conclusions

Organic compounds possess a wide range of fascinating physical and chemical properties that make them attractive candidates for exploitation in electronic and optoelectronic devices. It is not, however, anticipated that these materials will displace silicon in the foreseeable future as the dominant material for fast signal processing. It is much more likely that organic materials will find use in other niche areas of electronics, where silicon and other inorganic semiconductors cannot compete. Examples already exist, such as liquid-crystal displays, photoreceptors in electrophotography, and certain chemical sensors. Organic light-emitting structures are likely to make a major impact in the marketplace as display and lighting devices.

Over the first decades of the twenty-first century, classical CMOS technology will come up against a number of technological barriers. The bottom-up approach to molecular electronics provides an alternative and attractive way forward and, as such, it is currently an area of exciting interdisciplinary activity. However, the challenges in fabricating molecular switches and connecting them together are still formidable. Living systems use a different approach; these assemble themselves naturally from molecules and are extremely energetically efficient when compared with man-made computational devices. More radical approaches to materials fabrication and device design, exploiting self-organization, may be needed to realize fully the potential offered by molecular-scale electronics.

52. Organic Materials for Chemical Sensing

Asim K. Ray

Organic materials for chemical sensing are broadly classified into three categories: (i) macrocyclic compounds, (ii) conducting polymers, and (iii) cavitand molecules. A short review of current progress in inorganic sensing materials including graphene is given, pointing out their strengths and limitations. Principal wet techniques for depositing organic thin films are described and electrical, optical, and structural properties of all three types of organic materials are analyzed in relation to their importance in chemical sensing. Examples of recent advances in chemical sensing of different analytes and pollutants are presented.

The development of a new generation of sensors involves the study of fine-tuned sensor-active materials and transducers [52.1, 2]. Metal oxides, polymer/polymer composites, and dyes are regarded as key sensing materials. This chapter is organized into eight sections. The next section presents a summary of the needs for chemical sensing of different pollutants. The second section provides a brief description of different semiconducting oxide materials and their applications in sensor technology. Organized ultrathin organic films of molecular and polymeric semiconductors are currently the focus of considerable research with an emphasis on a molecular understanding of the sensing mechanisms. The low cost of fabrication, large-area processability, and widely diverse and tailorable physical, electronic, and optical properties have stimulated interest in their practical exploitation. Phthalocyanine and related macrocylic compounds have been extensively investigated for chemical sensing primarily because the desired functionality of phthalocyanine (Pc) molecules can be achieved by changing the central metal atom or by introducing substituents in their π-electron aromatic ring [52.3]. The third section is devoted to thin-film formulation of these interesting compounds and their structural, electrical, and optical properties relevant to sensing different types of pollutants. Important transduction methods and their applications in the development of practical sensors are presented in the fourth section, with an emphasis on the interaction at the analyte/film interface of macrocylic compounds. The ability of conducting polymers to change their physical properties during reaction with various redox agents makes them very useful for the development of gas sensors. The most common are polyaniline (PAni) and polypyrrole (PPY). It has been shown that the resistivity of polypyrrole increases in the presence of a reducing gas such as ammonia, but decreases in the presence of an oxidizing gas such as nitrogen dioxide. The

gases cause a change in the near-surface charge-carrier density by reacting with surface-adsorbed oxygen ions [52.4]. Sensing properties of polymers and their importance in the development of intelligent sensors are described in Sect. 52.5. A class of supramolecules, called cavitands, that exhibit discotic phases depending on the structure, are shown to have potential for sensing applications [52.5]. Section 52.6 deals with the applications of thin films of these molecules such as calixresorcinarene for recognition of organic vapors. The chapter concludes by highlighting future development trends for sensor materials and technology in Sect. 52.7.

52.1 Analyte Requirements

The detection of pollutant gases and volatile organic compounds (VOC) whether in gaseous phase or dissolved in water is of great environmental importance due to the extreme hazards posed by their presence in small amounts in the ambient. Nitrogen dioxide (NO_2), ozone (O_3), sulfur dioxide (SO_2), particulate matter (PM), carbon monoxide (CO), and lead (Pb) are six principal pollutants of major concern for maintaining the quality of air in urban areas (Table 52.1). Some of these pollutants, like CO, Pb, NO_2, PM, and SO_2, are emitted directly from a variety of sources including industrial production growth and increased traffic congestion. Ozone is generally formed when emissions of NO_2, SO_2, ammonia (NH_3), VOCs, and other gases react in the atmosphere. The presence of ozone in high concentration is also possible in offices where laser printers and photocopiers are heavily used. Conversely, water is commonly treated with O_3 to destroy microbial contaminants such as *Escherichia coli* and *Salmonella* [52.6, 7] and there is a need for accurate calibration of ozone content. Because of its ability to absorb ultraviolet (UV) radiation from sunlight, stratospheric ozone filters out damaging ultraviolet radiation from the sun. Monitoring of ozone in the stratosphere has thus become a global issue as it forms a protective shield for all forms of life on Earth.

Stringent domestic and international standards for emission control require the monitoring of threshold limit values of these pollutants in order to protect primarily against adverse public health hazards. For example, VOCs and nitric oxide (NO_x) resulting from combustion processes cause respiratory problems. Benzene itself is regarded as a human carcinogen and vehicle exhaust is primarily composed of these toxic gases. Spillage in fuel stations also contribute to the emission of excessive amounts of aromatic hydrocarbons in the atmosphere. VOCs also bind with ground-level ozone and form a photochemical smog, causing breathing difficulty for asthma sufferers. The secondary requirement of pollution monitoring is to reduce disastrous effects on the preservation of ecosystems, plants, and animals. Safeguards should also be in place to protect from decreased visibility due to the presence of PM and damage to crops, vegetation, and buildings due to atmospheric pollution. SO_2 content is known to attack buildings both internally and externally, and in particular the surface of historical glasses. A wide variety of preventive conservation tools and routines have been sought to protect historical and cultural objects against deterioration and degradation [52.8, 9].

The activities of chemical sensing are not solely limited to environmental control. Hydrogen (H_2) fuel cells are clean, quiet, more efficient generators of electricity than any other known technology. Hydrogen is also an important raw material for the aerospace, chemical, and semiconductor industries. As hydrogen is explosive above the lower explosive limit (LEL), H_2 sensors have now become important safety devices in all these applications. The oxygen sensor which detects the air-fuel mixture of a gasoline engine by measur-

ing the amount of oxygen in the exhaust gas is an essential component of the car engine management system. The development of reliable oxygen sensors for medical application has received considerable research attention in recent years [52.10–12]. Drinking, industrial, and swimming pool water must be disinfected with suitable oxidizing agents such as chlorine or chlorine compounds. The dosing of the appropriate oxidizing agents must be carefully controlled to suit the application as a higher concentration can result in corrosion effects, impairment of taste, or skin irritation. The ability to detect chlorine at sub-ppm level is therefore essential [52.13]. Ammonia is increasingly being used as a refrigerant alternative to ozone-depleting chlorofluorocarbon (CFC). Large quantities of ammonia can also be found in fertilizer factories, resin-production plants using urea, explosive munitions plants, semiconductor industries, and water utility facilities. The presence of ammonia can cause inhalation problems at a very low concentration (0.6–53 ppm). Airborne ammonia gas dissolves in the moisture on the skin, forming corrosive ammonium hydroxide. Exposure to ammonia at 10 000 ppm is mildly irritating to moist skin but the effects become more pronounced with increasing concentration, producing chemical burns with blistering at 30 000 ppm. Its solubility in water can cause it to cauterize respiratory tracts, resulting in deaths at concentrations of 5000 ppm. Research into the development of reliable ammonia sensors with a fast response to a wide range of concentrations is intensive [52.14–16].

It is obvious from the brief survey above that growing demand exists for the fabrication of low-cost, low-power, robust, and portable chemical sensors for a variety of pollutants, contaminants, and analytes, showing improved sensitivity and selectivity for industrial, health care, and environmental control. Analytical chemical tools provide advanced and reliable methods for detection of different analytes but those methods are in many cases prohibitively expensive, unsuited for large-scale field measurements, or mobile monitoring. For instance, there is currently a good market for detection systems for ozone at low concentration (ppb level) to replace more expensive techniques such as UV absorption measurements [52.17]. Existing devices for the detection of ozone are now mostly based on electrochemical measurements [52.18], or on solid-state semiconductor devices [52.19]. Similarly, the detection of organic vapors involves extracting air samples and subsequently analyzing them using standard laboratory techniques such as gas chromatography [52.20], mass spectroscopy, and Fourier-transform infrared (FTIR) spectroscopy [52.21, 22]. The major disadvantages associated with these techniques are their complexity, the capital cost of the instruments used, and the requirement for trained human resources for both operation and the interpretation of data. Apart from environmental applications, the development of detection instrumentation for these species is also important for both human health monitoring [52.23, 24] and for odor detection [52.25].

52.2 Brief Review of Inorganic Materials

Different types of oxide semiconductors have been used for fabrication of gas sensors with a high degree of sensitivity and specificity. The physically interesting electronic and opto-electronic properties of 2D materials have also been exploited over last two decades for environmental and security control.

52.2.1 Oxide Semiconductor Sensors

Solid-state semiconductor gas sensors are usually made of tin oxide (SnO_2) in the form of thick films, porous pellets, or thin-film coatings to monitor the presence of various gases [52.26]. These sensors are being used in the intelligent automatic control of a large number of processes, ranging from microwave cooking to the efficient combustion of motor engines. SnO_2 sensors operate at high temperatures of 300–400 °C. Gases are adsorbed onto the surface in the presence of air and the semiconductivity of the metal oxide changes due to the formation of a surface depletion layer. The thickness of this layer can be expressed in terms of the Debye length $L_D = \sqrt{\varepsilon_0 \varepsilon k_B T/(q^2 n_0)}$, where ε_0 is the permittivity of free space, ε is the dielectric constant of the semiconducting material, n_0 is the total carrier concentration, q is the electronic charge, k_B is the Boltzmann constant, and T is the absolute temperature [52.27]. The sensitivity of the sensor is generally defined as the ratio of the change in conductance after treatment to the conductance of the sensor in air and can simply be written as $\Delta n L_D/n_0$, where Δn is the change in carrier concentration due to analyte exposure. It is therefore possible to optimize the sensitivity by reducing grain size, lowering the carrier concentration, and increasing the Debye length. The maximum sensitivity is assumed to have been achieved when the Debye length is about half the particle size.

Figure 52.1 shows a photograph of a comb-like interdigitated electrode (IDE) system used for most

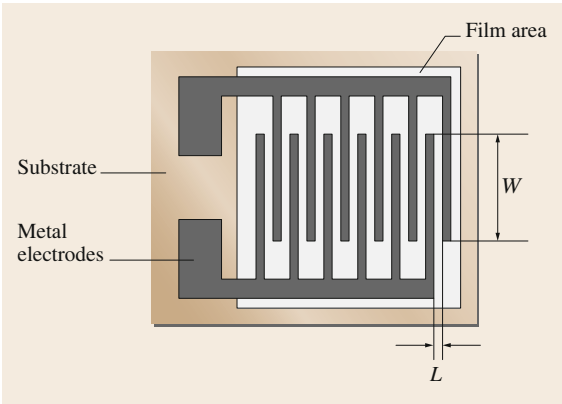

Fig. 52.1 Interdigitated electrode (IDE) system for an SnO_2 sensor

conductivity measurements. The original idea was developed by *Taguchi* [52.28] and the sample resistance in this configuration is smaller than that obtained from the four-contact geometry. The output signal is normally logarithmic to gas concentration. The conductivity change of SnO_2 thick-film sensors was monitored on exposure to compounds forming in smouldering and combustion processes of natural materials, e.g., paper and wood. A strong response was observed for compounds with hydroxyl groups and the highest response was obtained for phenolic structures such as methoxyphenols and benzenediols [52.29]. The response of a SnO_2 sensor element operating at 270 °C produced no sensor response to toluene, furfural, and acetone [52.30]. The impedance output from the SnO_2 sensor array was measured at 300 °C in terms of conductance changes and peak frequency changes. These changes were more sensitive to oxygenated VOCs than other VOCs. The sensor's sensitivity could also be enhanced by using Pd- and Pt-doped sensors [52.31].

Considerable development work is being carried out to integrate the semiconductor sensing membrane with the interrogation and control circuitry on a silicon chip using conventional silicon technology. Using an industrial 0.8 μm complementary metal-oxide-semiconductor (CMOS) process with subsequent micromachining steps, a CO gas-sensor chip was fully integrated with advanced analogue and digital circuitry on a chip for temperature control in the range 170–300 °C with an error of ±2 °C. The whole device was encapsulated using standard microelectronic packaging methods. It was reported that the integrated sensor was capable of measuring CO at the concentration of 5 ppm with a resolution of ±0.1 ppm [52.32].

Solid-state sensor technology relies on the preparation of semiconductor films. SnO_2 sensors suffer from a lack of selectivity and drift. The high temperature required for the surface reactions encourages the growth of grains by coalescence, giving rise to unstable materials. Recent progress in the synthesis of nanomaterials has been employed to overcome some of these problems. Oxide powders were thermally evaporated under controlled conditions without the presence of a catalyst to deposit single-crystalline SnO_2 nanobelts on a platinum IDE structure on an alumina substrate. The surface-to-volume ratio was very high but the size was large enough to contain the depletion layer within the belt. SnO_2 nanobelts were sensitive to CO, NO_2, and ethanol and therefore suitable for applications in breath analysis and food control [52.33].

Advanced methods of information technology are increasingly being used to address the issues regarding selectivity and specificity. A sensor array of two commercial metal-oxide gas sensors was developed to discriminate six organic solvents over a wide concentration range of 2–200 ppm in air. The baseline drift was considerably reduced over a test period of several months by temperature cycling. Further reduction in drift was achieved by suppressing the influence of humidity via additional signal preprocessing. Relatively low computing power was required for the hierarchical pattern classification to evaluate shape features generated from the sensor response curve during temperature cycling. The technique was found to be adaptable to different operating environments, for example, to suppress false alarms from interfering gases [52.34].

Apart from SnO_2, titania (TiO_2), ferric oxide (Fe_2O_3), titania-doped chromium oxide ($Cr_{1.8}Ti_{0.2}O_3$), molybdenum trioxide (MoO_3), tungsten oxide (WO_3), indium oxide (In_2O_3), and perovskite-type thick films ($LaFeO_3$) were studied for sensing a host of analytes such as H_2, CO, NO_2, H_2S, NH_3, and CH_4 in the ppb range. The characteristics of titanium dioxide nanotube hydrogen sensors were found to be completely reversible, highly selective, and free from hysteresis. The sensors showed response times of approximately 150 s at a nominal operating temperature of 180 °C. The sensitivity of the nanotubes was believed to be due to chemisorption of hydrogen onto the titania surface as electron donors. Increased operating temperature improved the sensitivity significantly but reduced the response time. Samples with smaller pore diameter (46 nm) were more sensitive to hydrogen than those with larger pore diameter (76 nm). The sensor showed a response to high concentrations of oxygen but the response time was long and the recovery was not complete [52.35]. Ion-beam-deposited thin films of MoO_3 on alumina substrates with gold IDEs showed selective response to NH_3 at 450 °C. Similarly prepared WO_3 thin-film samples were highly sensitive to NO_2. Both films exhibited orthorhombic structure but the polymor-

phic dissimilarities between two types of materials were responsible for the difference in their sensing behavior [52.36].

52.2.2 Graphene Based Sensors

Successful mechanical exfoliation of a highly oriented pyrolytic graphite sample to produce thin layers of graphene was reported in 2004. A one-atom-thick single layer of graphene consists of sp^2-hybridized carbon atoms arranged in a hexagonal lattice. The overlap between the conduction and valence bands is found to occur in ambilar monocrystalline thin films showing a large carrier concentration of $10^{17}\,cm^{-2}$ and high mobility up to $10\,000\,cm^2V^{-1}s^{-1}$ [52.37]. Mechanical exfoliation, sonication-assisted liquid exfoliation, and chemical vapor deposition (CVD) are commonly used to synthesize high-quality graphene films with a reduced number of defects by annealing. However, these methods are not suitable for deposition over large areas. Printing can be used as an alternative technique to make conductive graphene films. Some of the advantages of graphene printing are the low processing temperature under ambient conditions without using a vacuum or inert atmosphere. The other benefit of graphene printing is that films can be obtained over large areas on flexible substrates, at a reduced cost. Figure 52.2 shows the scanning electron microscopic (SEM) image of a drop-cast film of graphene. The graphene ink was formulated with few-layer graphene particles of lateral dimensions $< 40\,\mu m$, which were obtained by liquid-phase exfoliation. The graphene particles were dispersed in an acrylic polymer system to obtain the ink suitable for thin-film deposition on flexible substrates. The sample consisted of a disordered layered structure with a single isolated graphene flake as shown in the inset.

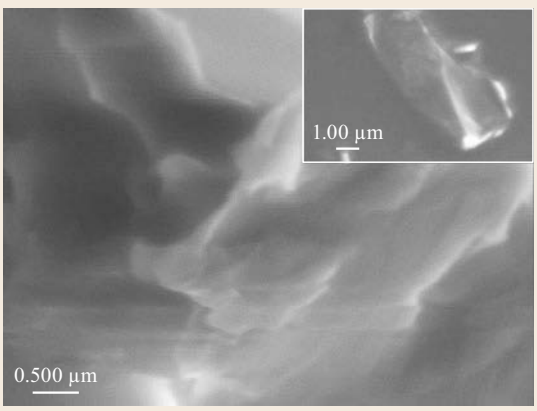

Fig. 52.2 Scanning electron microscopic image of a graphene ink sample drop cast onto aluminum foil

Considerable research efforts have been spent over the last two years to exploit the unique optoelectronic properties of these highly π-conjugated two-dimensional (2-D) materials for the development of a variety of sensors with potential applications in security, environmental and safety control, and disease detection and diagnosis [52.38]. Intrinsic graphene is found to be highly sensitive in detecting industrial toxic gases such as CO, NO_x, and NH_3, but selectivity is poor for practical applications. Considerable improvement in selectivity can be achieved using hybrid structures of graphene blended with metal oxide nanoparticles [52.39]. The electrochemical potential window of 2.5 V for the graphene electrode in 0.1 M phosphate-buffered saline with a pH value of 7.0 is very comparable to those obtained for glassy carbon (GC) and boron-doped diamond. Also, AC impedance measured graphene charge-transfer resistance is smaller than their competitive electrodes. These superior electrochemical properties of graphene have been exploited in recent years to develop the oxidase sensors for detecting the presence of hydrogen peroxide H_2O_2 in food, pharmaceutical, clinical, industrial and environmental analyses with a high degree of reliability and sensitivity [52.40]. The presence of heavy metals such as lead (Pb^{2+}), cadmium (Cd^{2+}), chromium (Cr^{3+}, Cr^{6+}), mercury (Hg^{2+}), copper (Cu^{2+}), and arsenic (As^{3+}) ions in atmosphere and water is recognized by the World Health Organization as a severe threat to human health. Field-effect transistors (FET) using protein-functionalized reduced graphene oxide (RGO) films as an active channel have been employed to record the change in transconductance due to the contamination of target metal atoms. A value of $2.5\times10^{-8}\,mol\,l^{-1}$ for the detection limit and a faster response time of less than 10 s were observed in Hg^{2+} monitoring with thermally reduced GO film decorated with thioglycolic-acid-functionalized gold nanoparticles (AuNps) in an active FET channel. These FET sensors are portable and cost-effective compared to turn-on fluorescence sensors based upon fluorescence resonance energy transfer. It is, however, reported that fluorescence based upon hybrid graphene-gold nanoparticles (AuNp) is able to detect Pb^{2+} ions selectively up to the limit of $10^{-8}\,mol\,L^{-1}$ over the common metal pollutants in an aqueous solution. This effect is attributed to accelerated leaching of AuNp by Pb^{2+} ions. The highly hydrophobic surface with a large specific surface area in the order of $2600\,m^2g^{-1}$ makes graphene very suitable for adsorbing aromatic organic pollutants in water [52.41]. Cofactors such as nicotinamide adenine dinucleotide hydrogen (NADH) are catalytic agents for many important biological activities in the human body. During mitochondrial respiration, the electron transfer takes place

through the NADH producing sufficient adenosine triphosphate (ATP) enzymes for cellular energy supply. The concentration of NADH varies in different parts of the body depending on the energy requirements. An unexpected elevation or lowering of NADH may cause severe diseases like brain ischaemia and Leigh syndrome. The oxidation of the NADH serves as the anodic signal and regenerates the NAD^+ cofactor. The shift of peak potentials of NADH oxidation from 0.70 V on the GC to 0.40 V on the RGO electrode makes graphene a suitable material for highly sensitive electrochemical biosensors of low working potentials, offering low detection limits and long-term stabilities [52.42]. Graphene oxide (GO) and its reduced form (RGO) are studied extensively in the field of biotechnology because of their multivalent functionalization and efficient surface loading with various biomolecules. The negative surface charge originating from a free π-electron cloud can be utilized to condense genes and anticancer drugs. For example, when 6-armed polyethylene glycol (PEG) was covalently linked to the surface of GO sheets to form biocompatible GO-PEG, which is nontoxic to human lung and breast cancer cells. Graphene may act as a potential antimicrobial coating for surgical equipment by preventing the formation of pathogenic and corrosive microorganisms and even killing bacteria. Real-time high-resolution optical imaging as well as electrophysiological recording of neuronal locations are essential for examining the operation of individual neural circuits in neurological disorders. As conventional metallic microelectrodes are opaque, they shadow the investigator's view, making it necessary to record the imaging and electrophysiological data separately. However, transparent, flexible graphene electrodes may now be used for the simultaneous temporal and spatial resolution required for neuroscientific treatments. The nonmagnetic and anti-corrosive properties of graphene offer added advantages [52.43].

52.3 Macrocylic Compounds for Sensing

Phthalocyanine molecules belong to a class of macrocylic compounds. Because of their 18 π-electron aromatic macrocyclic structure these molecules exhibit important optoelectronic, photophysical, conduction, and photoconduction properties [52.44]. As shown in Fig. 52.3, the Pc structure is closely related to the naturally occurring porphyrins, which form a core skeleton in hemoglobin and chlorophyll. Organic molecular nanostructures have huge potential but suffer from unstable device characteristics, low resistance to adverse environments (e.g., temperature, humidity, oxygen, etc.) and lack of reproducibility of material composition, purity, and fabrication conditions. Phthalocyanines (Pcs) are, however, tinctorially strong, and chemically and thermally stable. The materials are abundantly available in a highly purified form.

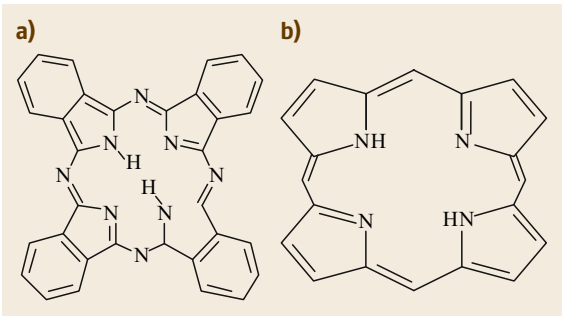

Fig. 52.3a,b Chemical structure of: **(a)** a metal-free phthalocyanine and **(b)** porphyrin molecule

52.3.1 Preparation of Sensing Membranes

Sensing is essentially an interaction mechanism of a solid surface and analytes and the molecules are organized in ultrathin films, offering a large surface-to-volume ratio to improve the probability of these reactions taking place. A variety of methods such as direct-current DC and radio-frequency RF sputtering [52.45], thermal evaporation [52.46], Langmuir–Blodgett (LB) [52.47], spin coating [52.48], and self-assembly (SA) [52.49] are employed to produce organized thin organic films.

The substrates play a key role in determining the film quality and the structure. It is found that the island density and coverage ratio of copper tetra-*tert*-butyl phthalocyanine (CuTTBPc) on hydrophilic glass surfaces were small during the early growth stage of vacuum deposition due to a small nucleation rate arising from the weak interaction of molecules. The film surface was also rough. The high nucleation rate of CuTTBPc on a silanized surface, on the contrary, produced a much smoother morphology consisting of densely distributed fine-grained clusters. The aggregation of the molecules took place in domains during the formation of the LB monolayer, separately distributed on the glass surface. These domains acted as active sites for the nucleation and growth of the later deposition process and high-density clusters were thus found in the early growth stage. X-ray diffraction (XRD) patterns demonstrated

that the LB films grown on the glass substrate were more crystalline than those on other substrates [52.50].

The wet techniques, namely LB, spin coating and SA, are preferred to high-energy deposition because the deposition takes place at room temperature, reducing the possibility of chemical decomposition of the molecules due to thermal damage. These deposition methods are considered below.

Langmuir–Blodgett (LB) Technique

The LB method involves the transfer of individual Langmuir monolayers of amphiphilic molecules which self-assemble in an ultra-clean water subphase onto a suitably prepared solid substrate. An LB film, which may consist of a single or many layers, up to a depth of several visible-light wavelengths, is generally produced with fine control over the thickness and geometry to a precision at the molecular level. With the Y-type construction, these LB films are essentially layered materials with alternating hydrophobic/hydrophillic regions. Noncentrosymmetric LB films can be obtained by X-type construction on immersion of the substrate from air into water only, or Z-type deposition on withdrawal of the substrate from water to air [52.51].

Macrocylic molecules are not generally amphiphilic and are therefore not considered suitable for LB deposition. The synthesis of a series of specially designed Pc molecules for LB deposition has been reported in the literature over the last two decades [52.52–54]. Figure 52.4 shows the chemical structure of asymmetrically substituted 1,4-bis(6-hydroxyhexyl)-8,11,15,18,22,25-hexa-octylphthalocyanine molecules belonging to this family of custom-designed molecules [52.55].

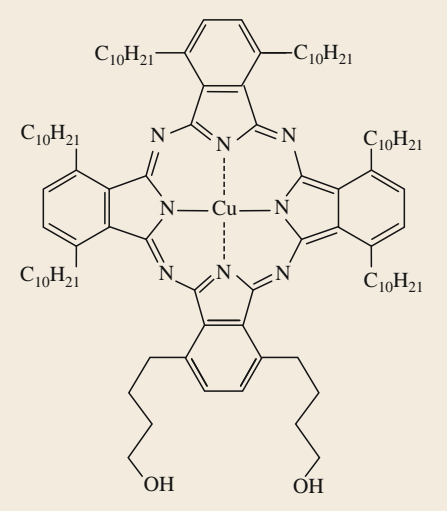

Fig. 52.4 Chemical structure of 1,4-bis(4-hydroxybutyl)-8,11,15,18,22,25-hexakisdecyl phthalocyaninato copper molecules

To start with LB deposition, a Langmuir monolayer is formed from a spreading solution of substituted Pc derivatives in an appropriate volatile solvent (such as chloroform) on the highly purified water subphase (Milli-Q water of resistivity 0.18 MΩm) contained in an LB trough made of a hydrophobic material (Teflon). The solvent is allowed to evaporate fully and the molecules are then slowly compressed to the desired organization by closing a servo-controlled Teflon barrier straddling the air–water interface at a constant speed (say about 100 mm/min). As shown in Fig. 52.5, the phase changes of the molecules during the compression are monitored by recording the surface pressure–area isotherm. The pressure begins to rise rapidly as the solid phase is reached while the area per molecule remains approximately constant. The molecules are transferred from the water–air interface to the substrate by dipping the substrate in at a constant speed of about 10 mm/min when the surface pressure is

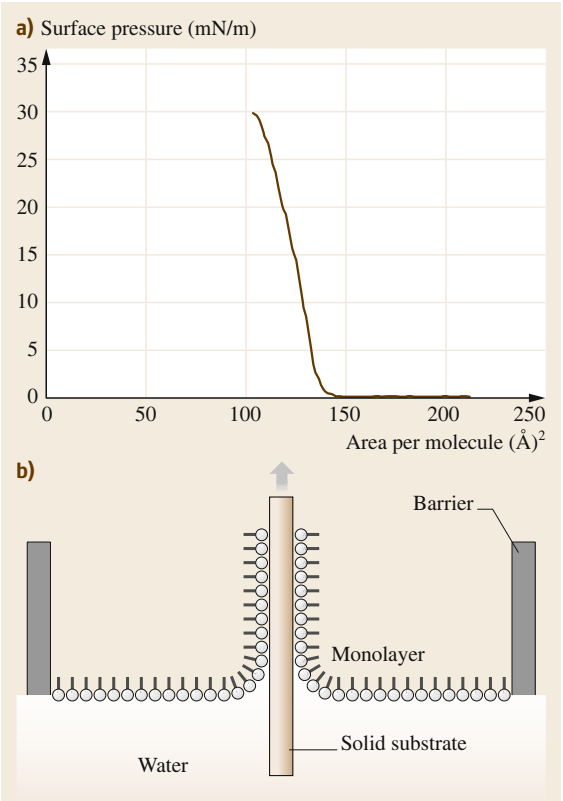

Fig. 52.5a,b Deposition of Langmuir–Blodgett film: **(a)** surface pressure–area isotherms and **(b)** transfer of floating monolayer onto a suitable substrate floating monolayer

in the range 20–40 mNm^{-1}. However, a dipping rate as high as 1000 mm/min was used to produce LB films of 5,10,15,20-tetrakis(3,4-bis[2-ethylhexyloxyphenyl])-21*H*,23*H*-porphine (EHO) molecules. Atomic force microscopy (AFM) showed a morphology of these films which is highly conducive to the host–guest interaction. The presence of isolated micron-sized domains, which were themselves composed of grains of several nm in diameter, was observed [52.56].

The molecular orientation in LB films of these novel substituted Pc derivatives was investigated by spectroscopic methods, including electron spin resonance, reflection adsorption infrared spectroscopy (RAIRS), polarized infrared (IR) spectroscopy, and AFM. Amphiphilic mesogenic Pcs afforded the best films. These all contained a good degree of molecular order. Furthermore, the type of molecular stacking in the films was found to depend upon the length of the side chains and the central metal [52.57].

Spin-Coating Method

The spin-coating method, designed for defining patterns on silicon wafers in integrated circuit (IC) technology, has now been adapted for deposition of thin organic films on suitable substrates [52.58]. Substrates are vacuum held onto the rotating chuck of a photoresist spinner. The spread solution was prepared in the same way as done for the LB deposition and a small volume of the solution is dispensed onto the rotating substrate surface from a microsyringe held at a distance of 5 mm above the spinner platform. A spinning time of 30 s for a solution concentration of 0.5–5.0 mg/ml is found to be sufficient in order to produce a uniform, homogeneous film. The rotation speed is normally varied between 1000–6000 rpm and the speed of spin and the concentration of solution largely determine the thickness of the resulting films. The dependence of the film thickness d on spin speed ω and time t may be written in terms of an empirical expression [52.59]

$$d = \frac{C}{\sqrt{t}}\omega^{-x}\,, \tag{52.1}$$

where C depends upon the evaporation rate of the solvent, and the viscosity and density of the solution. The index x is predominantly determined by the evaporation rate of the solvent. If the evaporation of the solvent is independent of the spin speed, x takes on a value of $2/3$. For most solvents used, the evaporation varies with $\sqrt{\omega}$ and x becomes $1/2$. A value of $x = 1$ is a valid approximation for slow evaporation [52.60, 61].

Spin coating is a simpler and more cost-effective method than LB deposition and also there is no requirement for the molecules to be amphiphilic. The LB technique, however, provides more precise control over the film thickness [52.62]. Both spun and LB thin films of octa-alkyl-substituted phthalocyanine molecules displayed similar characteristic features in their optical absorption spectra. The appearance of Davydov splitting and the XRD pattern indicated the same crystallinity of the films [52.63]. Different physical structure and molecular packing may result from the use of different wet techniques. For instance, asymmetrically substituted phthalocyanine molecules (Fig. 52.4) were deposited by LB and spin-coating techniques. XRD patterns and UV-Vis spectra of these films indicated some degree of anisotropic ordering within the LB films compared to spun films [52.64]. The spin-coated films were, however, exceptionally smooth, even and free from crystallites. A noncompact spin-coated film of phthalocyanine molecules bearing one crown on the ether ring exhibited a faster response and reversal time than the well-ordered and tightly packed LB films [52.65].

Self-Assembled Monolayers (SAMs)

Self-assembled monolayers (SAMs) have attracted considerable interest because of their simplicity of preparation, stability, and versatility. The introduction of due functional groups into SAMs allows changes of state and property on surface or interface. These attributes make SAM films attractive for sensor technology [52.66, 67]. SAM films are formed via reaction of a functional group within a molecule with the surface of a solid substrate. The methoxy or trichlorosilylalkyl derivatives of molecules form weak bonds with hydroxyl groups and are suitable for the formation of a SAM on an oxide surface such as indium tin-oxide (ITO) and glass (SiO_2) [52.68]. A monolayer layer can also be self-assembled on gold or silver substrates if the molecules are attached with thio or disulfide groups at one end [52.69]. In supramolecular aggregation during the self-assembly process, the interactions between the adsorbate molecules are as important as those between adsorbates and the surface. The size and aggregation pattern for the formation of supramolecular structures (J-aggregates) are controlled by changing the number of polar sulfonic groups of meso-tetra (4-sulfonatophenyl) porphine [52.70].

Much fundamental work on SAM films was initially undertaken with simple functionalized alkane derivatives [52.71]. In the case of alkylthiols on gold, it is well established that the monolayer films were densely packed with a high degree of order, with chains typically oriented at about 65° to the substrate surface. In recent years, work has been undertaken to include a single tether chain with thiol or disulfide derivatives for SAM formation on gold-coated glass substrates.

The molecular orientation with respect to the gold surface was found to depend upon the different alkyl-connecting chain lengths and different macrocyclic peripheral side chains [52.72]. The core of substituted Pc molecules bearing mercaptoalkyl groups is not parallel to the surface if the tether chain is increasingly long. For sufficiently long tethers, the core becomes oriented almost normal to the surface [52.73]. SAM films of thiol-derivatized cobalt phthalocyanine complexes on gold electrodes were susceptible to destruction via oxidative and reductive desorption and their potential applications as a sensor were therefore limited [52.74].

Self-assembled ultrathin films have recently received considerable interest because they allow fabrication of supramolecular assemblies with tailored architecture and properties [52.75]. Multilayered films can also be built up by sequential deposition of polycations and polyanions based upon electrostatic attraction [52.76–78]. Alternate deposition of planar functional molecules meso-tetra (4-sulfonyl) porphyrin ($TPPS_4$) or copper phthalocyaninetetrasulfonic acid, tetrasodium salt (CuTsPc) and cationic bis (pyridinium) salt was made to produce a self-assembled multilayered film [52.79]. Multilayer assemblies of porphyrin and phthalocyanine were also prepared by alternating deposition of oppositely charged rigid planar molecules of sodium (phthalocyanine tetra-sulfonate)cobalt $Na_4[(CoTsPc)]$ and tetrakis(N,N,N-trimethyl-4-anilinium) porphyrin cobalt $[(CoTAP)]Br_4$ [52.80]. A further investigation of the C-11 Pc derivative SAM has shown that the monolayer film was stable, exhibiting no oxidation and only minor orientation changes on the gold surface over a period of 24 months as determined by infrared and fluorescence spectroscopy. The long active life of the Pc SAM was thought to be due to the macrocyclic ring possibly preventing oxidation of the thiolate root [52.81].

52.3.2 Thin-Film Properties

Surface/interface composition at the nanometer scale is believed to affect the organization and chemical/physical properties of organic thin films. This long-range organization determines both the optical and electrical properties of thin-film materials, leading to unique, new chemical sensor platforms. The overlap of π-electron wave functions from Pc molecule to Pc molecule is likely to occur between adjacent stacks in a thin-film form, giving rise to the broadening of energy levels [52.82].

Phthalocyanine Films

Phthalocyanines can exist in different polymorphic forms: α and β are among the most common. Both forms possess the herringbone structure for the stacking arrangement. The angle between the stacking axis and the normal to the molecular plane depends upon the method of preparation, types of phthalocyanine (metallo or metal-free), and substituents. For example, this angle is generally 25° and 45° for the α and β phases, respectively [52.83]. A typical absorption spectrum in the UV-visible range is shown in Fig. 52.6 for a substituted metal-free phthalocyanine (Pc) deposited on a glass substrate (similar to one shown in Fig. 52.3). The Q absorption band of the LB film was broader than one for the chloroform solution and appeared at wavelengths between 650–800 nm. The Davydov splitting became apparent when compared with the spectra for the molecules in chloroform. The film-forming properties and the stack order were both found to be influenced by the chain length of the ring substituents [52.84, 85]. An analysis into the in-plane molecular arrangements in the LB films of Pc compounds with short and long alkyl chains was performed by decomposing the absorption spectra into Gaussian–Lorentzian components. Long-chain molecules were found to be organized in a *herringbone* structure leading to the Davydov splitting of the Q-band. For short-chain molecules, the largely broadened blue component of the Davydov doublets was suppressed possibly due to the domination of an anisotropic stack-like molecular arrangement in LB films [52.86]. Characteristic Q-bands observed at about 630 nm in the UV-Vis spectra of the self-assembling monolayers (SAMs) of 2,9,16-tri(*tert*-butyl)-23-(10-mercaptodecyloxy)phthalocyanine and its disulfide on gold substrates were broadened and blue-shifted relative to those observed in solution [52.87]. The formation of high-quality Langmuir–Blodgett films of copper (CuPc) and nickel phthalocyanine (NiPc) derivatives

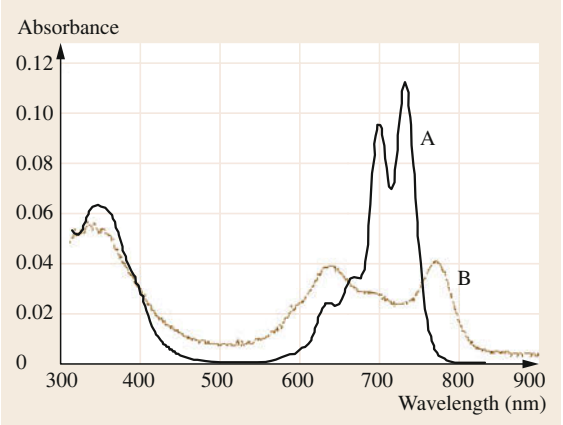

Fig. 52.6 Typical UV-visible spectra for thin films of metal-free phthalocyanine molecules in: (A) chloroform and (B) an LB film

substituted with short branched chains is reported. Ellipsometric and polarized optical absorption measurements suggest that the phthalocyanine molecules have a preferred orientation, with their large faces perpendicular to the dipping direction and to the substrate plane [52.88].

Electrical properties of Pc molecules are very dependent upon the doping and the nature of the substituents in the macrocyclic compounds. Copper(II) tetrasubstituted phthalocyanine complexes, CuPcX (where X = $-NO_2$, $-NH_2$, $-SO_3H$, and $-OH$) exhibited an improvement of conductivity by five orders of magnitude over its unsubstituted counterpart. Further enhancement in conductivity was achieved by iodine doping. This increase in conductivity was attributed to the possible decrease in the metal–metal bond distance [52.89]. The effect of oxygen on charge transport was investigated by measuring the time-dependence behavior of the film conductivity of zinc Pc (ZnPc) layers at a stable pressure of about 0.1 mbar of air and it was found that the conductivity gradually decreased by an order of magnitude with time. The conductivity reached saturation within several minutes for the film thickness smaller than 500 nm whereas similar electrical degradation in a 7 μm-thick film required more than half an hour. This thickness-dependent decrease in conductivity was caused by the velocity of the oxygen out-diffusion processes in the films [52.90]. The effect of doping on conductivity of a thermally deposited composite film of α-nickel phthalocyanine (NiPc) and the strong electron acceptor tetracyanoquinodimethane (TCNQ) was investigated by exposure to air. The doping took place at a much faster rate in the composite than in the NiPc films. Values of 1.3 and 1.9 eV for the activation energy were obtained for devices incorporating TCNQ and the non-TCNQ devices, respectively, and the conductivity of the composite film was therefore found to be 20 times larger than the NiPc film [52.91]. Because of the excellent ability to photogenerate free charge carriers, the conductivity of the metal phthalocyanine (MPc) film is increased considerably as can be seen in Fig. 52.7 showing the dark and illuminated current–voltage characteristics of a 10 nm-thick spun nickel phthalocyanine (NiPc) sandwiched between two metal electrodes.

Phthalocyanines of rare-earth metals primarily occur in the form of bisphthalocyanines with a sandwich-type structure and the cation is eightfold coordinated to the two macrocycles. One of these phthalocyanine rings is virtually planar while the other is significantly distorted [52.92]. The Q-band in the absorption spectra of spun films of substituted lutetium bisphthalocyanine molecules becomes broader and red-shifted compared to the molecules in chloroform solution. Heat treatment of the film at temperatures above 120 °C introduced molecular ordering, possibly due to the edge-to-edge interaction between neighboring Pc moieties [52.93]. All these factors have led to successful formulation of phthalocyanines as chemically sensitive membranes for environmental monitoring [52.94–98].

Porphyrin Films

Inherent stability, unique optical properties, and synthetic versatility of porphyrins and metalloporphyrins are exploited in sensor applications. Synthetic porphyrins and metalloporphyrins incorporated into polymers, glasses, and Langmuir–Blodgett films matrices are used for detection of NO, CO_2, and O_2 because of the ability to bind these gases. Metalloporphyrin sensing arrays have been used for the detection of organic odorants, such as amines, thiols, and phosphines [52.99]. Porphyrins also combine readily with metals, coordinating with them in the central cavity. Many gas sensors take advantage of analyte binding to the center metal atom in the porphyrin ring and a detectable optical change occurs as a result. In particular sensing properties of iron, zinc, copper, nickel, and cobalt containing porphyrins have now been studied [52.100–103]. The porphyrin rings of thiol-derivatized cobalt(II)-5,10,15,20-tetrakis(4-*tert*-butylphenyl)-porphyrin (CoTBPP) molecules were immobilized on the surface of a 4-aminothiophenol (4-ATP) self-assembled monolayer (SAM) on gold (111) by in situ axial legation. The reconstruction of the herringbone structure took place probably due to adsorption/desorption processes of molecules [52.104].

Substituents have considerable effects on the structure of porphyrin monolayers; for example, the interaction between the porphyrins deposited on the ITO

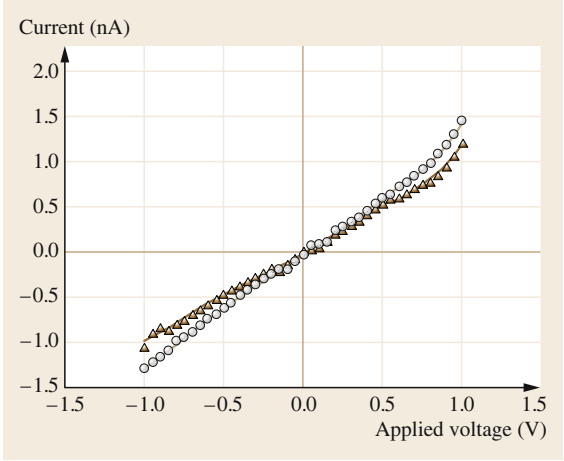

Fig. 52.7 Dark- (*triangles*) and photoconduction (*circles*) through spun NiPc films

substrate without bulky *tert*-butyl groups was much stronger than that of the porphyrins with bulky *tert*-butyl groups [52.105]. Hybrid molecule-silicon capacitors were formed by attaching [5-(4-dihydroxyphosphorylphenyl)-10,15,20-trimesitylporphinatozinc(II)] porphyrin complexes to silicon oxide via a phosphonate linkage and the presence of multiple distinct peaks in electrical characteristics were associated with oxidation and reduction of the molecular monolayer [52.106]. Multilayered thin films of porphyrins bearing bulky alkoxyphenyl substituents at two of the four meso-positions and phenyl phosphonates at the other two were deposited on the ITO substrates using the zirconium phosphonate linkage. Molecular aggregation was prevented by the addition of sterically demanding 2,6-di(*n*-hexoxy)phenyl substituents to the meso-positions of the porphyrin skeleton. The compounds were able to form thin films without the presence of large molecular chromophore interaction relative to sterically unhindered porphyrins [52.107]. Highly conducting tetraruthenated cobaltporphyrin (Co (TRP)) and tetrasulfonated zincporphyrin (Zn (TPPS)) multi-bilayer films were prepared by electrostatic assembly for sensor applications [52.108].

52.4 Sensing with Phthalocyanine and Porphyrin

The interaction of reactive gases such as O_2, NO_2 and NH_3 with the phthalocyanine group of compounds has been shown to result in conductivity changes of these compounds. This effect was associated with charge transfer between the electron-donating phthalocyanine molecule and the electron-accepting gas [52.109].

52.4.1 Amperometric Sensor

The action of the oxidizing gases O_2 and NO_2 and the reducing gases NH_3 and H_2 diluted in N_2 on the electrical conductivity of thin layers of zinc hexadecafluorophthalocyanine ($ZnF_{16}Pc$) and zinc phthalocyanine (ZnPc) was investigated. The conductivity $ZnF_{16}Pc$ increased in the presence of NH_3 whereas ZnPc exhibits no sensitivity to this gas. The sensitivity to H_2 was higher for $ZnF_{16}Pc$ than for ZnPc. This behavior was related to the redox potentials of the two phthalocyanines [52.110, 111].

Response and recovery times for LB CuTTBPc films on platinum IDE are shown in Fig. 52.8 for different gas concentrations of 1–5 ppm. These times were determined from a model based upon the kinematics of adsorption and desorption of NO_2 gas molecules. It was found that recovery times were longer than response times, irrespective of gas concentration. The response time constant varied in the range 105–159 s. Repeated exposures to NO_2-air mixtures resulted in gradual degradation of reproducibility. The response was also believed to be influenced by the past history of the exposure of the sensor to the NO_2 gas, if the recovery time constant was longer than the switch-off time. These factors show that CuTBPc is a material that is suitable for fabricating a disposable *single-shot* NO_2 sensor for practical uses [52.112]. LB films of asymmetrically substituted phthalocyanine, 1,4-bis (4-hydroxybutyl) 8,11,15,18,22,25-hexaoctylphthalocyanine molecules showed selective responses to 1–5 ppm concentrations of NO_2 at the room temperature. Moisture had no effect on the response because of the hydrophobic nature of the alkyl groups. Exposure to Cl_2, NH_3, SO_2, and CO at ppm levels produced no measurable response [52.113]. Further work on the LB films showed that the NO_2 response was larger for the LB film produced by dipping the substrate perpendicular to the electrode finger than those dipped parallel to the fingers. This preferential behavior was attributed to the ease of conduction along the long chains [52.114]. LB films of meso,meso′-buta-1,3-diyne-bridged Cu(II) octaethylporphyrin dimer molecules were used to fabricate amperometric sensors operating at a temperature of 90 °C. LB multilayers were reported to be selectively sensitive to small concentrations of NO in air without being affected by contemporary presence in NO_2, CH_4, C_2H_5OH, and CO [52.115].

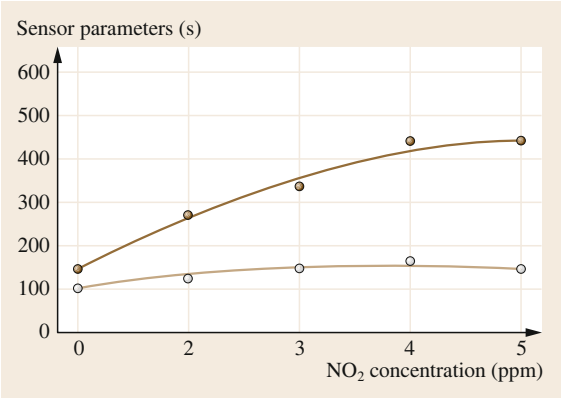

Fig. 52.8 Response (*broken line*) and recovery (*solid line*) of a 15-layer LB film of CuTTBPc when exposed to NO_2 periodically at 2 min intervals at 1, 2, 3, 4, and 5 ppm levels in succession

Thickness, operating temperature, doping and postdeposition treatment of sensing membranes all affect sensor performance. Vacuum-deposited CuPc of thickness 50–400 nm onto gold IDEs on glass substrate were exposed to NO_2 gas of concentration 10–100 ppm. The film thickness had little effect on room-temperature sensitivity, but the recovery ratio decreased with increasing film thickness. Thicker films showed improved recovery at 100 °C [52.116]. Because of the tetra-*tert*-butyl substitution on the periphery of phthalocyanine, CuTTBPc films have a larger lattice spacing and higher film resistance. Sublimed CuTTBPc film showed a higher recovery ratio in the NO_2 sensing experiments [52.117].

NO_2 and O_2 treatment of evaporated CuPc films that were 160–200 nm thick on IDE improved the sensitivity and recovery time when exposed to 0.5–5 ppm of NO_2 gas. A Langmuir behavior was predicted for the adsorption/desorption processes on the weakly binding surface sites of NO_2-treated CuPc films having a single activation energy [52.118]. When the CuPc films were subjected to postdeposition treatment by cooling down to 77 K, the mechanism of NO_2 adsorption, however, followed the Elovich model [52.119]. CuPc and iron Pc (FePc) films (100 nm thick) were heat treated at 240 °C under vacuum and then the responses of the films to the exposure of NO_2 in the 8–12.8 ppm range were monitored. The CuPc films were transformed to a stable β-phase and the adsorption occurred on the ligand rings. Conversely, NO_2 was adsorbed on both the ligand ring and the central ion of the FePc films [52.120]. An amperometric sensor was fabricated using the spun film of tetra-*iso*-propoxyphthalocyaninato copper(II) (*i*-Pro-CuPc), and the response, recovery, and cyclic properties of the sensor were very temperature sensitive. The results showed ideal gas sensitivity at 65 °C and a good linear relationship existed between the resistance of the gas sensor and the concentration of NO_2 [52.121]. NiPc films (25 nm thick) were deposited between the source and the drain of a field-effect transistor (FET) and the change in the drain current exhibited a linear dependence on the ozone concentration in air, in the range 0–150 ppb [52.122, 123].

Water-soluble copper phthalocyanine tetrasulfonate (CuTsPc) molecules were alternatively self-assembled with a bipolar pyridine salt on a 3-mercaptopropionic-acid-modified Au electrode to produce copper ion-selective electrodes (ISE). These ISE were found to have low resistance, short conditioning time, and a fast response. The electrode potentiometric response showed a selective potentiometric response to Cu^{2+} ions in the range from 10^{-5}–10^{-1} M, independent of the pH of the solution between pH 1–5. The response was dependent on the nature of the medium and the detection limit was found to be 7×10^{-6} M in acetate buffer (0.2 M, pH 4.5) [52.124]. Carbohydrates were detected by flow-injection analysis at the water-soluble cobalt phthalocyanine tetrasulfonate (CoTsPc)-modified electrode with high sensitivity. Detection limits obtained in this manner range from 150 pmol injected for glucose and fructose to 600 pmol injected for maltose and sucrose [52.125].

52.4.2 Optical Sensors

The amperometric approach generally suffers from long response times and their use is restricted due to possible fire and explosion hazards caused by electrical power. Organic systems are also prone to slow degradation arising from the chemical reactivity of charge carriers. Conversely, optical transduction techniques offer high speed, high precision, immunity to interference, and remote sensing capabilities for detection of trace gas species.

Optical Absorption and Fluorescence Spectra

Optical transmittance of thermally evaporated lead phthalocyanine (PbPc) and nickel phthalocyanine (NiPc) thin films changed on exposure to NO_2 in the IR region of the optical absorption spectrum [52.126]. The disappearance of Davydov splitting from the UV-Vis absorption spectra of 20-layer-thick LB films of 1,4-bis(4-hydroxybutyl)-8,11,15,18,22,25-hexakisdecyl phthalocyaninato copper molecules was observed when the films were exposed to 100 ppm of NO_2 [52.127]. The local interaction between the central metal atoms and NO_2 distorted the herringbone structure. Gas adsorption and desorption processes were described by exponential functions, both characterized by a single time constant. The dispersion relation in Fig. 52.9 for the refractive index was obtained by using the simple Kronig–Krammer transform of absorption spectra of the LB thin film of another octasubstituted metal-free phthalocyanine molecule. The full recovery of the refractive index to its original value was achieved after flushing with the N_2 gas for wavelengths larger than 782 nm. Ellipsometry measurements on thin films of tetrasulfonated copper phthalocyanine showed increases in the real and the imaginary parts of the dielectric constant on exposure to NO_2 gas possibly due to the rise in the density of dipoles and higher absorption, respectively [52.128].

LB films of 5,15-bis(4-aminophenyl)-10,20-bis[3,4-bis(2-ethylhexyloxy)phenyl]-21H,23H-porphine prepared at a dipping rate as high as 500 mm/min showed an inhomogeneous structure with high porosity. These porphyrin films showed much faster response to 4.6 ppm of NO_2 gas and a sensitivity of 60% relative to absorbance change at 439 nm was achieved.

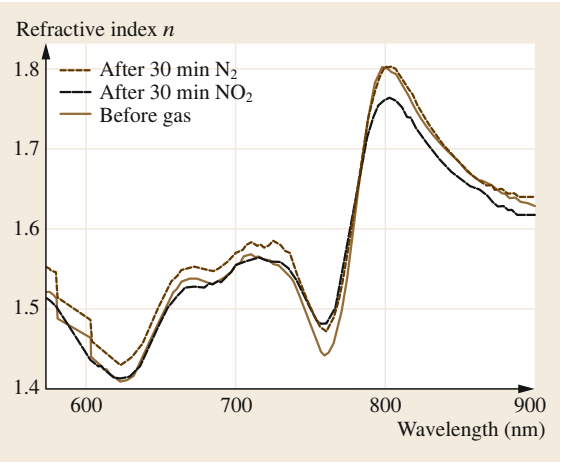

Fig. 52.9 The dependence of the refractive index of octa-substituted phthalocyanine on the wavelength before and after exposure to 90 ppm NO_2 gas for 30 min. The recovery was examined after flushing of the LB films with N_2 for 30 min

Full and accelerated recovery of the original spectrum was also achieved by gentle heating at 353 K. The sensor was reported to have a shelf-life as long as one year [52.129]. Kinetic UV-Vis spectroscopic measurements were made on a porphyrin-entrapped sol–gel film for NO_2 sensing. The method was capable of detecting levels as low as 176 ppb of NO_2 at room temperature and showed a fast and full recovery [52.130]

The blue color of rhodium phthalocyanine LB films becomes transparent upon chlorination. A pronounced quenching of the characteristic triplet centered on the Q-absorption band took place at 662 nm, but the absorption band in the near UV part of the spectrum remained almost unaffected. Optical spectra partially recovered when the exposed film was left in air for several hours. Overall effects of chlorination (quenching and recovery) depended on the period of exposure [52.131]. LB gadolinium phthalocyanine films were exposed to 10 ppm of chlorine and changes in optical absorption spectra were observed as a result of the oxidation of the film by chlorine to form $[Gd(Pc)_2]^+$ species. The kinetics of such changes were described by a polyfunctional process with different decay time constants and the effects were found to be highly reversible [52.132].

SAM films are of interest because the chemically bound monolayer is intrinsically more robust than LB films and the response times are also expected to be faster. Monolayers of diphthalocyanine disulfide Pc molecules were self-assembled on gold-coated glass substrates with the Pc macrocycle oriented parallel to the metal surface. Changes of the reflectivity signal were observed on exposure to NO_2 gas in proportion to the concentration [52.133]. The fluorescence emission spectrum of each of the Pc SAMs was obtained by exciting each monolayer along the longitudinal axis of the optical waveguide via laser-induced evanescent-wave stimulation. The use of the longer mercaptoalkyl connecting chain appeared to inhibit quenching of the electronically excited state through energy transfer to the metal layer. Fluorescence response to 10 ppm NO_2 was found to be selective with no interference from CO and CO_2 [52.134].

Surface Plasmon Resonance Technique

The surface plasmon resonance (SPR) technique is based on the excitation of surface electromagnetic waves of transverse magnetic (TM) modes traveling along the interface between a metal and a dielectric medium. Using a semicylindrical prism of high refractive index n_p in *Kretschmann*'s configuration, as shown in Fig. 52.10, these waves are excited by a p-polarized light of wavelength λ via the evanescent field [52.135]. The evanescent field will be completely attenuated at a particular angle of incidence corresponding to resonance and there will be no reflection. Figure 52.11 shows the SPR results when a spun film of nickel(II) tetrakis(4-cumylphenoxy)phthalocyanine (NiPc) molecules was subjected to a sequence of exposure to ozone (O_3) at 2 ppm. A period of 20 mins was allowed for the film to recover to its original state. The shift of the resonance angle $\Delta\theta_a$ was believed to be caused by a change in the refractive index of the film due to the interaction of O_3. $\Delta\theta_a$ is usually written in the form [52.136]

$$\Delta\theta_a = \frac{(2\pi/\lambda)(|\varepsilon_m|\varepsilon_i)^{3/2}d}{n_p \cos\theta(|\varepsilon_m| - \varepsilon_i)^2\varepsilon}(\varepsilon - \varepsilon_i)\,, \qquad (52.2)$$

where $|\varepsilon_m|$ is the modulus of the real part of the dielectric constant of the gold film; ε_i is the dielectric constant of the medium (air in this case) in contact with the organic thin layer of thickness d and the di-

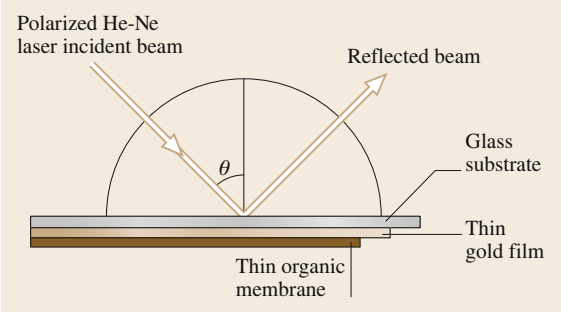

Fig. 52.10 A Kretschmann-type configuration for optical sensing interrogation

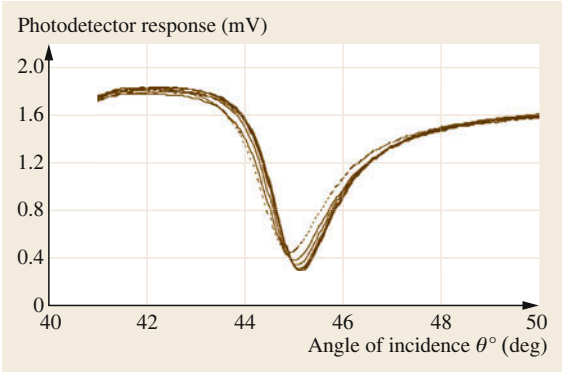

Fig. 52.11 The effect of a sequence of exposure at 20 min intervals of 2 ppm O_3 on a NiPc spun film. The *broken line* represents the system prior to exposure

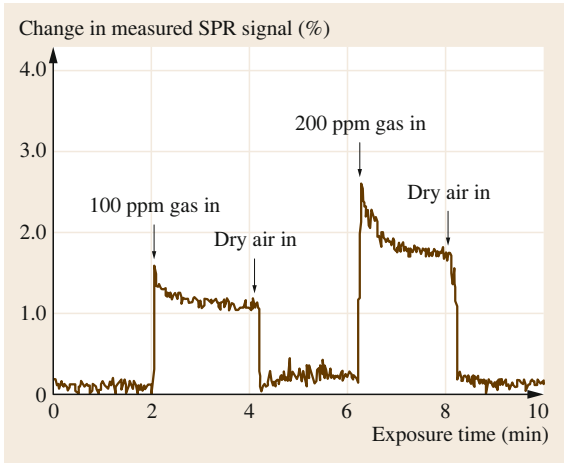

Fig. 52.12 Kinetics of the SPR response of copper hexadecafluorophthalocyanine ($CuPcF_{16}$) film to NH_3 gas at 100 ppm and 200 ppm. Measurements were at a fixed angle of $\theta^* = 46°$

electric constant ε. The resonance minimum moved to an increasingly larger angle after each exposure to ozone. The half-width became narrower at the same time and this was believed to be the consequence of oxidation of the phthalocyanine ring by ozone, which resulted in bleaching of the dye. SPR responses are in general slower and less readily reversible than semiconductivity changes but the technique is capable of providing additional information on the interaction between the gas and films as the shifts in both the angle and depth of the resonance can be monitored. Experimental data from the SPR response of CuPc films to nitrogen dioxide were input to a design process using an evolutionary algorithm. Gold layers with a thickness of 25 nm were found to exhibit 42.9% greater contrast than layers with a thickness of 50 nm. Using evolutionary design predictions, further modifications could be tested for available materials, and redundant layers may be eliminated. By inclusion of the external optics, a design could be selected to accommodate poor precision ($+/-0.5°$) in the incident angle and a possible multilayer solution was shown using Teflon AF 1600, with a refractive index similar to 1.3. The predicted NO_2 response showed an improvement compared with the classical SPR configuration, and the incident angle chosen by the genetic algorithm for the interrogation of these layers was close to a stationary point in the absolute response curve [52.137].

Figure 52.12 shows the transient response when thick films of copper hexadecafluorophthalocyanine ($CuPcF_{16}$) were exposed to 100 ppm of NH_3 for 2 min followed by the injection of dry air for a further 2 min period. The film was exposed to 200 ppm of NH_3 for the next cycle. The SPR response was very rapid and the recovery was complete. Unsubstituted CuPc was practically insensitive to this gas. Strong electron-withdrawing fluorine substituents made this substituted compound sensitive to reducing gases such as NH_3 [52.138].

SPR experiments were performed on films of different phthalocyanine derivatives in order to investigate the interaction mechanism with NO_2. SPR signal concentration as low as 1 ppm was measured using spun films of crown-ether-substituted phthalocyanines and octa-3,7,11-trimethyldodecyloxy phthalocyanine [52.139]. Adsorption of NO_2 took place both on the surface of the film and into the bulk. The surface adsorption increased the film thickness while the change in the real part of the film refractive index occurred due to the diffusion of NO_2 into the LB film. These processes were reversible and had no effect on the optical absorbance of the LB film. The SPR response of the bare Ag film to the exposure of NO_x (the equilibrium mixture of nitrogen dioxide and dinitrogen tetroxide) was slightly slower than the LB films of the tetra-4-*tert*-butyl-phthalocyanitosilicon dichloride (ttb-$PcSiCl_2$/Ag) system. This effect was associated with the high affinity of the phthalocyanine to NO_x gas. The NO_2 gas was also able to reach the Ag/Pc interface film and the reaction with the metal film resulted in the growth of a surface layer. This irreversible effect was found to be predominant during the recovery cycle and considerably reduced by the presence of a buffer LB layer of ω-tricosenoic (ω-TA) acid [52.140]. SPR studies showed that exposure of thin films of 18-crown-6 metal-free phthalocyanine molecules to NO_2 decreased the film absorbance. The optical permittivity of the NO_2-treated Pc over-layer was regarded as being an average of the optical permittivities of both components since the optical fields associated with surface plasmon po-

laritons sampled both the Pc and the NO_2 molecules. The disruption in the charge conjugation of the phthalocyanine molecules was observed because of the generation of organic radical cations as end products of the charge transfer during the physisorption process [52.141].

Using the excitation at wavelengths of 488 and 632.8 nm, SPR measurements were made on LB films of porphyrin molecules of EHO type deposited on an Ag-coated glass substrate. The resonance shift observed was larger at 488 nm than at 632.8 nm when the EHO films were exposed to NO_2 gas. The thickness and the complex dielectric constants at 632.8 nm were attributed to the island structure of the EHO LB films but the derived properties at 488 nm were believed to be caused by dispersion due to optical absorption [52.142]. Similar results were further obtained from UV-Vis absorption in these films [52.56].

52.4.3 Detection of Volatile Organic Vapor Compounds

Phthalocyanine molecules have also been extensively investigated for the recognition of volatile organic compounds (VOC). Langmuir–Blodgett (LB) and evaporated films of lutetium bisphthalocyanine ($LuPc_2$) molecules were deposited on indium tin-oxide (ITO) interdigitated electrodes in order to study the changes in their conductivity at room temperature due to the presence of a variety of organic vapors with different chemical functionalities. The results demonstrated the viability of the phthalocyanine thin films as the active species for systems specifically designed for the monitoring of aromatic components in food. The majority of the work on vapor sensing has, however, been based upon quartz crystal microbalance (QCM) transduction techniques. The frequency shift Δf from the nominal resonance frequency f_0 of the crystal due to the change in the mass Δm due to the adsorption of the vapors is [52.143]

$$\Delta m(\mathrm{mg/cm^2}) = \frac{\Delta f(\mathrm{Hz})}{2.26\times10^{-6} f_0^2} \,. \qquad (52.3)$$

It was demonstrated that monomeric soluble transition-metal phthalocyanines R_4PcM ($R =$ *tert*-butyl or 2,2-dimethyl-3-phenyl-propoxy) used as sensitive coatings for quartz microbalance transducers show reversible interaction and high sensitivity for organic solvents with high boiling point [52.144]. Quartz microbalance devices coated with LB films of copper(II) tetra-(*tert*-butyl)-5,10,15,20-tetraazaporphyrin exhibit good sensing response to the vapor of benzene and toluene at room temperature [52.145]. Soluble tetrakis-hexyl- and dodecylthiophthalocyaninato nickel(II) and the corresponding Pd(II) and Ag(I) complexes were investigated as sensitive materials for the detection of organic solvent vapors using quartz microbalance and interdigitated capacitance transducers. Sensor responses were found to be reversible at room temperature with response times on the order of several seconds depending on the partition coefficients of the organic solvents in the phthalocyanine film [52.146]. LB films of lanthanide diphthalocyanines such as praseodymium, ytterbium as well as octa-*tert*-butyl praseodymium diphthalocyanines were known to display spectroscopic changes when exposed to tobacco smoke [52.147]. The sensitivity and partition coefficient for ethanol, dichloromethane, acetone, and *n*-hexane were found to be larger for the QCM sensor using thermally annealed ordered membranes of octa(13,17-dioxanonacosane-15-sulfanyl)-substituted mesomorphic nickel(II) phthalocyanine molecules than as-coated untreated films. It was found from Raman spectroscopy that molecules with saturated C–C bonds such as ethanol interact with phthalocyanine films predominantly by the formation of hydrogen bonds and the sensor response to π-bond-containing compounds such as acetone is the result of their π–π interaction with the conjugated phthalocyanine ring [52.148].

Changes in refractive index of lutetium bisphthalocyanine ($LuPc_2$) in the presence of ethanol, hexanal, *n*-butyl acetate, and acetic acid were successfully exploited to produce an optical-fiber sensor operating at the wavelength of 1310 nm, capable of monitoring changes up to 10 dB in the reflected optical power for the detection of an 88 mmol/l concentration of acetic acid [52.149]. UV-Vis spectra of spin-coated layers of 29H,31H-(2,4-di-*t*-amylphenoxy)phthalocyanine, Zn(II) tetra-4-(2,4-di-*t*-amylphenoxy)phthalocyanine, and Zn(II) tris-(2,4-di-*t*-amylphenoxy)-[4-(4-mercapto-phenylimino-methyl)-phenoxy] phthalocyanine were found to be sensitive to *tert*-butylamine, diethylamine, dibutylamine, 2-butanone, and acetic acid. The selectivity was determined by both the metal and the peripheral substituents [52.150]. The synthesis of specially designed bispthalocyanine derivatives for VOC detection has been reported and their UV spectra are selectively sensitive to vapors depending on both the metal and the peripheral substituents. This observation has led to the fabrication of an *electronic optical nose* using an array of as-manufactured sensors for the analysis of some volatile organic compounds (VOC) that are of interest in food analysis [52.151].

The electrical conductivity of sol–gel-derived spun hybrid cobalt porphyrin-SnO_2 thin films showed a fast and reversible response to methanol vapors; the highest responses were observed at 250 °C. The porphyrin

was thermally stable up to 300 °C within the SnO_2 matrix and enhanced the methanol detection sensitivity at lower working temperatures. The incorporation of porphyrin into SnO_2 film had no effect on the detection of CO [52.152]. Hybrid thin films were produced using porphyrin and phthalocyanine and the response of absorption bands of the blend systems to the presence of VOCs was different from that obtained with a single compound [52.153].

Toluene vapor sensing has been successfully demonstrated using LB films prepared from copper tetrakis-(3,3-dimethyl-l-butoxycarbonyl) phthalocyanine (CuPcBC), copper tetrakis-(3,3-dimethyl-1-neopentoxycarbonyl) phthalocyanine (CuPcNC), and nickel tetrakis-(3,3-dimethyl-1-butoxycarbonyl) phthalocyanine molecules. Exposure to toluene resulted in a partially reversible shift in the resonance depth and position of the SPR curves and toluene could be detected down to at least 50 ppm [52.154].

52.4.4 Phthalocyanine for Biosensing

Immobilization of proteins on different surfaces offers a range of applications in biomedical engineering and the development of biosensors. The quantity and mode of adsorption of proteins are important characteristics of biomedical materials used for artificial blood vessels, heart, kidneys, and other organs after their implantation in the human body. Different surface properties of materials like roughness, charge, coverage, hydrophilicity, hydrophobicity, steric hindrance as well as structure, sign and charge of proteins influence protein adsorptions on implanted materials. Serum albumin, the most abundant protein in serum, has several functions for example, regulation of colloidal osmotic pressure of blood, transportation of fatty acids etc. It is often used as a stabilizer of dilute enzyme solutions, protein standard, cell culture media additive, blocking agent of nonspecific protein binding in enzyme-linked immunosorbent assay (ELISA) and Western blot [52.155].

The binding between bovine serum albumin (BSA) and phthalocyanine derivatives has already been studied by the measurements of fluorescence emission [52.156]. The interaction BSA and octahexylthio-substituted Cu(II) phthalocyanine derivative ($(C_6S)_8PcCu$) molecules has recently been reported by us and it was found that the mechanism involved a range of noncovalent interactions including hydrogen bonding especially with the nitrogen in the phthalocyanine ring, ionic interactions between negatively charged residues and the core metal ion, as well as Van der Waal's interactions. Heat treatment produced changes in the orientation of phthalocyanine stacks, making a favorable contribution to the protein adsorption and surface coverage profile [52.157]. The kinetics were measured for adsorption of lysozyme, bovine serum albumin, immunogamma globulin (IgG) on $(C_6S)_8PcCu$ films using a quartz crystal microbalance with dissipation technique. Lysozyme was found to reach to saturation value faster than BSA and IgG. The adsorption of IgGs on the phthalocyanine surface was much slower than that of BSA [52.158].

Using a CCD camera, the surface plasmon resonance imaging (SPRI) method has been employed to investigate BSA protein adsorption on spin coated films of liquid crystalline copper octakishexylthio phthalocyanines ($(C_6S)_8PcM$). Figure 52.13b,c shows the variation of reflected light intensity of these films with wavelength. Phosphate-buffered saline (PBS) washing is found to increase the resonance intensity. As shown in 52.13a, the blue shift in the resonance wavelength from 635 to 628 nm occurred due to PBS washing. As

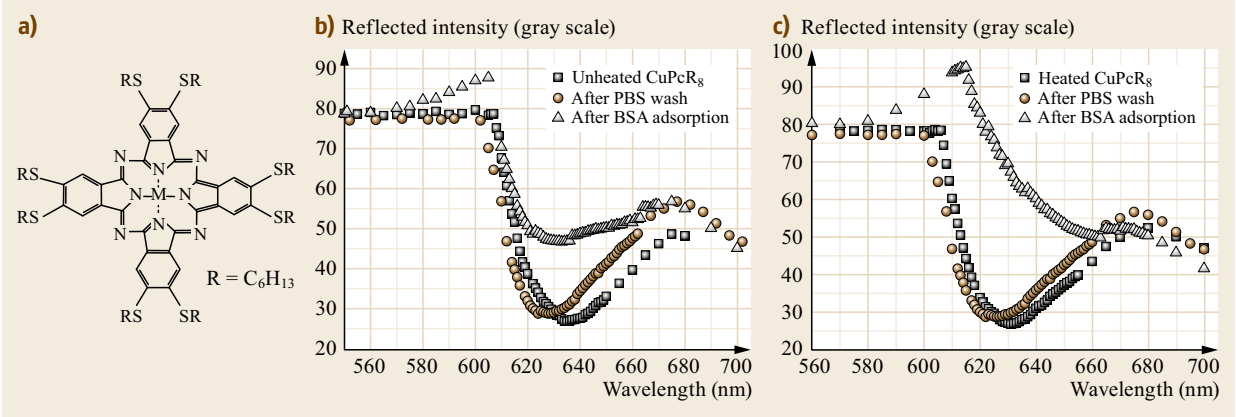

Fig. 52.13 (a) Molecular structure of octakisalkylthiophthalocyanine ($(C_6S)_8PcCu$). Reflected light intensity versus wavelength from SPRI measurements for BSA conjugation with $(C_6S)_8PcCu$ films as-deposited (b) and heated (c)

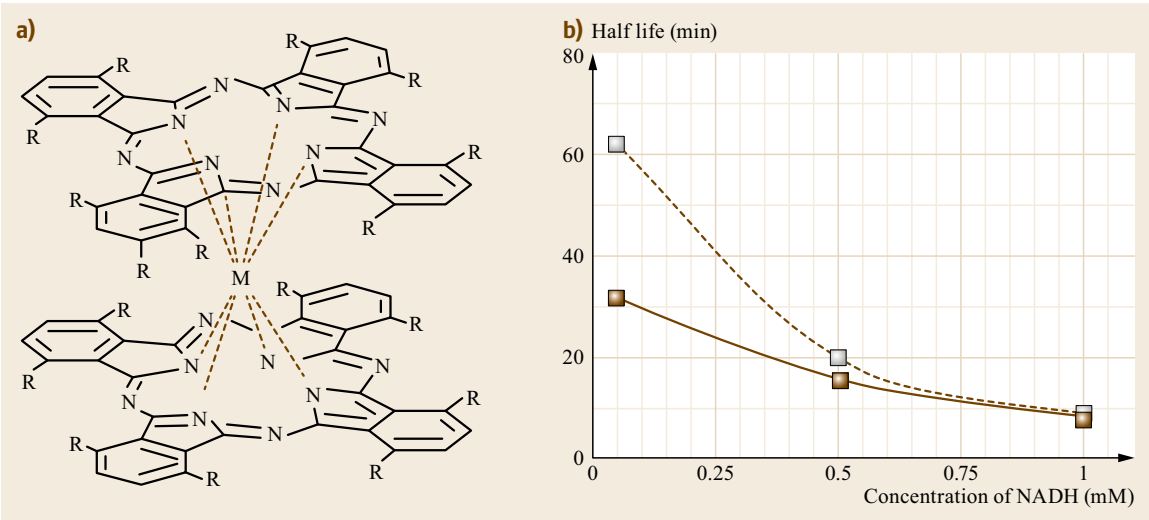

Fig. 52.14 **(a)** Chemical structure of C_8LuPc_2, M = Lu(III) and R = C_8H_{17}. **(b)** Dependence of oxidation half-life on NADH concentration for freshly prepared (*solid line*) and 3-month-old films (*dashed line*)

a result, salts of the PBS buffer are adsorbed on the film.

The reflected light color from the uneven film surface was visually yellowish green. The resonance was observed at 633 nm for the film after BSA adsorption. The mean intensity value for BSA adsorbed film increases up to 73% more than the phthalocyanine film. The spectrum was broader than that of the $(C_6S)_8PcCu$ overlayer because of the presence of damping. The shift in resonance wavelength from 622 to 663 nm was observed after BSA adsorption on the PBS-washed heated phthalocyanine film (Fig. 52.13c). The reflected color from the heat-treated film was visually more yellowish green than that from the as-deposited film. The surface coverage of the protein film and the amount of bounded BSA were higher than that obtained for the as-deposited $(C_6S)_8PcCu$ film. The calculated reflected intensity from the SPR image of the BSA film was increased by 170% at 631 nm compared to the phthalocyanine film. It is clear that the resonance curve is heavily damped for this film thickness. The BSA adsorbed onto the phthalocyanine film both before and after heat treatment was nonuniform as observed by SPRI as the substrate area was sufficiently large [52.159].

Spin-coated films, approximately 100 nm thick, of a newly synthesized bis[octakis(octyl)phthalocyaninato] lutetium(III) complex (chemical structure shown in Fig. 52.14) on ultrasonically cleaned glass substrates exhibit pronounced chemichromic behavior with potential application in health care. Oxidizing of a phthalocyanine film using Br_2 vapor or by applying a certain potential was shown to be effective by redshifts in optical absorption spectra. Using UV-Vis spectroscopy, a simple method was developed to detect NADH and vitamin C in a solution wetting the surface of an ITO-coated glass substrate modified with spin-coated electrochromic films [52.160]. The study showed satisfactory response times, and linear concentration ranges up to two orders of magnitude: 0.05−3 mM for NADH and 0.03−3.48 mM for vitamin C. The method of sensing NADH and vitamin C works well up to a concentration of 10^{-5} M and the complete recovery of the neutral bisphthalocyanine from the oxidized film via NADH reduction leads to the realization of developing reusable membranes. The reduction rate was greatly increased when redox biomolecules were added to the aqueous medium of water and $LiClO_4$. The reduction of the oxidized film in the presence of NADH and vitamin C was described in terms of first-order kinetics. The detection of NADH and vitamin C was found to be reproducible. As shown in Fig. 52.14b, the C_8LuPc_2 film remains sensitive for at least three months even when left in an open space.

52.5 Polymeric Materials

A polymer comprises of repeating molecules with the same chemical structure. The electrical conductivities of the intrinsically conducting polymer systems now range from 10^{-10}−10^{-5} S/cm. The common electronic feature of pristine conducting polymers is the π-conjugated system, formed by the overlap of carbon

p_z orbitals and alternating carbon–carbon bond lengths. Doping of the polymers can increase the conductivity to as high as 10^{+4} S/cm, a value comparable to that of a metal.

52.5.1 Conducting Polymers

Figure 52.15 shows the chemical structure of a few commonly used conducting polymers such as polyaniline, polypyrrole, and polythiophene for chemical sensors. In addition to the deposition techniques described earlier, conducting sensing filaments were produced using the scribbling and platinum-wire techniques [52.161]. Sensing membranes were also prepared by laser-induced chemical vapor polymerization [52.162].

LB films of stearic acid, a polyaniline oligomer (16-mer), and polypyrrole were deposited on the IDEs. Composite films of polyaniline and polypyrrole mixed with stearic acid in equal ratio by weight were also deposited on similar electrodes. Different brands of mineral water, tea, and coffee were sensed by impedance measurements on the films over the frequency range of

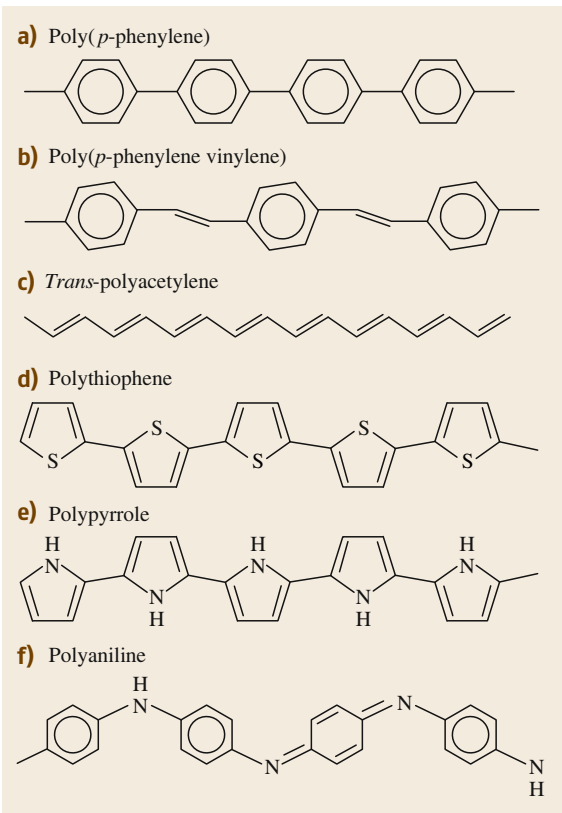

Fig. 52.15a–f Chemical structures of typical conducting polymers for sensors

20–10^5 Hz. The sensor arrays composed of these films were able to differentiate tastants below the human detection threshold [52.163]. The Brunauer, Emmett and Teller (BET) surface area for an amperometric polyaniline/Au/Nafion sensor prepared by the cyclic voltammetry (CV) method was found to be higher than structures prepared by the constant current (CC) method; the maximum sensitivity of CV-fabricated NO_2 gas sensors was 3.04 μA/ppm [52.164].

The type of doping is known to influence conducting-polymer-based sensors. Composite polyaniline emeraldine salts doped with an inorganic metal complex dopant, chromium(III) trioxalate (CTO) were produced by the chemical oxidative polymerization method. Polyanilines were also electrochemically doped with naphthalene-1,5-disulfonic acid (NSA). The conductivities of these materials were monitored by using the four-probe method when pellets of these materials were exposed to several saturated vapors of organic solvents for 30 min; the results are summarized in Fig. 52.16. The conductivity of the CTO-doped pellets was reduced by 18% on exposure to CH_2Cl_2 whereas the exposure had no effect on NSA-doped material. The response of undoped composite polyaniline salt to CH_2Cl_2 was also very small. Conversely, NSA-doped pellets showed a significant change in conductivity on exposure to CCl_4, while only very small changes were observed for the two other polymers. The responses to dimethylsulfoxide (DMSO) and *N*-methylpyrrolidone (NMP) were consistently higher for all three materials than the responses to the solvents

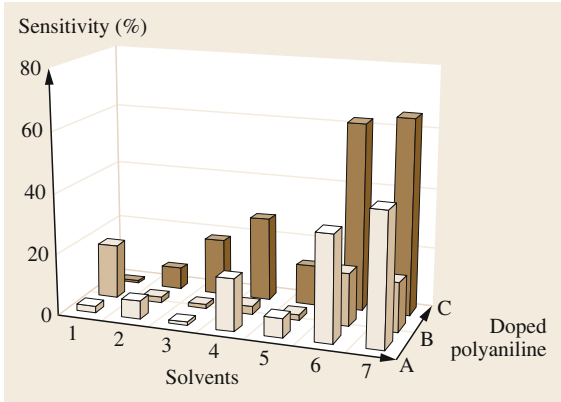

Fig. 52.16 Effects of vapor of: (1) dichloromethane (CH_2Cl_2), (2) chloroform ($CHCl_3$), (3) carbon tetrachloride (CCl_4), (4) acetonitrile (CH_3CN), (5) methanol (MeOH), (6) dimethylsulfoxide (DMSO), and (7) *N*-methylpyrrolidone (NMP) on the conductivity of: (A) pristine polyaniline emeraldine salt, and the salt doped with (B) chromium(III) trioxalate (CTO), and (C) naphthalene-1,5-disulfonic acid (NSA)

CH_3CN and methanol (MeOH). It became apparent that the interaction of solvents with the polyaniline salt became stronger with increasing polarity of the solvents. The response was reversible for all three materials. The nature of the dopant in the material and the consequent change in polarity, especially at the dopant site, and the resultant effect on π-electron delocalization and conductivity are primarily responsible for the characteristic sensing ability of the materials [52.165]. Extruded polymer blends containing polyaniline doped with dodecyl benzene sulfonic acid were dispersed in polystyrene (PSt) matrix filaments and the electrical conductivity of these filaments increased by a few orders of magnitude when exposed to a homologous series of alcohols, including methanol, ethanol, and 1-propanol. The effect was reproducible and recovery was satisfactory. The sorption of analyte molecules was believed to facilitate conduction through the insulating PSt moieties by enhancing charge-carrier mobility through hopping processes between adjacent polyaniline particles [52.166].

Multilayered thin films of polypyrrole were prepared by modifying a preformed Langmuir–Blodgett (LB) film of stearic acid by exposure to gaseous reactants such as hydrochloric acid and pyrrole vapors. A change in the electrical resistance of the film was observed when the film was exposed to polar molecules such as methanol, ethanol, and acetone, while the effect of nonpolar molecules on the resistivity of the film was found to be smaller. The response of LB films to exposure to ethanol was faster than that of electrochemically deposited polypyrrole, possibly due to the high ratio of surface area-to-bulk volume in the LB film [52.167]. Changes in mass and conductivity of polypyrrole thin films were measured to sense the primary alcohols [52.168].

Attempts have been made to integrate polyaniline optical sensor elements with optical communication technology for remote sensing by using 1300 nm as the operating wavelength. A 1% increase in transmission was observed at 1300 nm for electrochemically prepared polyaniline films when exposed to gaseous ammonia levels as low as 6 ppm at 50% relative humidity (RH). Different concentrations of ammonia were read by calibrating the sensors at intervals of 15 s. The response time was found to be insensitive to relative humidity variations in the range 30–70% [52.169]. Certain specially prepared polyaniline films showed partially reversible absorbance changes in the wavelength range 620–728 nm when exposed to 50–100 ppm of ozone at room temperature. The maximum sensitivity was attained at 620 nm. The cost-effective commercial exploitation of this effect was possible since the wavelength range was compatible with implementation on low-cost plastic optical fibers and small light sources [52.170].

Efforts have been invested in the use of information technology techniques to produce smart sensors. The sensor system, consisting of an acoustic two-port resonator operating at 433.92 and 380.8 MHz was configured as a frequency oscillator, including an integrated electronic module. The polymeric membranes were tested at room temperature for response to NO_2, NO, NH_3, CO, CH_4, SO_2, and H_2S in N_2. Responses to relative humidity (RH), and organic vapors (ethanol, acetone, and ethyl acetate) were also monitored. The sensitivity was found to be high. Principal component analysis (PCA) was performed to distinguish between different vapors of low concentrations [52.171]. Fluorescence emission from polymer-immobilized dye molecules on the multifiber tips was studied on exposure to organic vapors. Temporal responses were found to depend upon chemical nature (for example, polarity, shape, and size) of both the vapor and the polymer; these were used as input signals to train a neural network for vapor recognition. The system was able to identify individual vapors at different concentrations accurately [52.172]. Similar work was reported using the solvatochromic dye, Nile red. The dye was immobilized within various polymers. The substrate played a role in determining the sensitivity of the sensor. The sensitivity attained with microstructure glass (MSG) substrates was seven times greater than that with SU-8 photoresist-coated glass substrate and a 50% faster recovery was also achieved with the MSG substrates. The MSG sensor array was able to fingerprint the response for separate analytes with a high degree of repeatability. Using pattern-recognition techniques, sensor arrays were adaptable for gas identification and discrimination [52.173].

52.5.2 Ion Sensing

Water purification requires calibration of metal-ion contents. Polymeric ion-selective electrodes (ISEs) for Pb^{2+} incorporating *N*,*N*′-bis(salicylidene)-2,6-pyridinediamine with 2-nitrophenyl octyl ether and 50 mol% lipophilic additive were reported to have rapid response and excellent selectivity towards lead ions over other interfering metal ions [52.174]. *N*,*N*′-bis(5-methyl salicylidene)-*p*-diphenylene methane diamine formed a complex with Pb^{2+} and its selectivity was high, possibly due to the fact that the distance between the two nitrogen atoms and the position of the two hydroxyl groups is matched with the size of Pb^{2+} ions. ISEs based upon a dispersion of this Schiff base compound into the polyvinylchloride (PVC) membrane were characterized by a fast response time, a wide

linear dynamic range, and a fair selectivity coefficient with a slope of 29.4 mV per decade. The sensor had a low detection limit and an active life of three months without displaying considerable divergence in potentials [52.175]. A cleaned gold microelectrode was soaked in the freshly prepared solution of *o*-amino thiophenol (*o*-AT) and the metal nitrate of Cu, Hg, and Pb in *N*,*N*-dimethylformamide (DMF) for 4 h at room temperature. Simultaneous interaction took place between the thiophenol group of *o*-AT and the gold surface and its thiophenol and amino groups and M^{2+}. The ratio of 4 : 1 was found to be appropriate for *o*-AT:M^{2+} for the self-assembly of the *o*-AT on the gold surface and the formation of recognition cavities. The prepared ISEs showed specific selectivity to the template metal ions in mixed solutions containing the three heavy-metal ions. The limits of detection for ISEs were found to be 1.46×10^{-8} M, 3.73×10^{-8} M, and 4.34×10^{-8} M for Hg^{2+}, Cu^{2+} and Pb^{2+} ions, respectively [52.176]. Membranes containing five-layer LB films of tetracarboxylic perylene derivative and polypyrrole molecules were able to detect trace levels of Cu^{2+} ions in water [52.177]. The thiol-Cu-SAM particles were doped by the adsorption of thioxylenol or decanethiol into the porous polypyrrole film surface, resulting in an improvement in the sensitivity of the film to NH_3 [52.178]. Water-soluble regioregular polythiophenes containing acid C side chains were found to be suitable for the development of new Zn^{2+}, Mn^{2+}, and Cd^{2+} sensors [52.179].

52.5.3 Examples of Other Polymeric Sensors

A coordination polymer poly(CuMBSH) was formed via reaction of the bifunctional amphiphilic ligand, 5,5′-methylenebis (*N*-hexadecylsalicylideneamine) and copper ions at the water subphase. The response of LB films of poly(CuMBSH) to exposure of benzene, toluene, ethanol, and water was monitored by SPR measurements. The film became swollen, possibly due to the diffusion of solvent vapor into the polymer film. Poly(CuMBSH) is regarded as a relatively nonpolar material and its interactions were expected to be greater with vapors having a smaller dipole moment; the sensitivity increased with smaller dipole moment and higher refractive index of the vapor. The refractive index of the film increased because of an increase in the film density with the vapor filling the free volume inside the film. Similar results were obtained from admittance spectroscopic measurements on the same organic systems [52.180, 181].

The electrical properties of poly(methyl methacrylate) polymer (PMMA) films have been exploited for sensing applications (Fig. 52.17a shows the chemical formula). An increase in resistance of up to three orders of magnitude was observed for composite thin films of PMMA with carbon nanotubes when exposed to dichloromethane, chloroform, and acetone. The sensing mechanism is explained on the basis of volume expansion and polar interaction of various vapors on the nanotube surface [52.182, 183]. SPR measurements were made to investigate the room-temperature response of spun PMMA films to benzene, toluene, ethyl benzene, and *m*-xylene (BTEX) vapors under dynamic conditions. The response of PMMA to benzene was fast and reversible. The dissolution of benzene in the bulk of the polymer film formed a heterogeneous layer, primarily giving rise to swelling of the film and the value of the partition coefficient was estimated to be 112. Figure 52.18 shows that the increase in angular shift per ppm was linear with decreasing dipole moment of the solvent vapors. Benzene is a nonpolar solvent and toluene, ethyl benzene, and *m*-xylene are expected to show stronger solvation than benzene. Dissociated solvent ions may have formed a shell of bound ions and, as a result, the effective radius for dissolution in the polymer matrix would have increased. This dissociation might not easily occur for benzene, producing

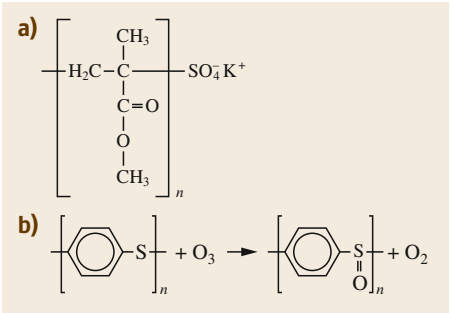

Fig. 52.17a,b Chemical structures of **(a)** poly(methyl methacrylate) derivatives and **(b)** reaction of polyphenylsulfide molecules with ozone

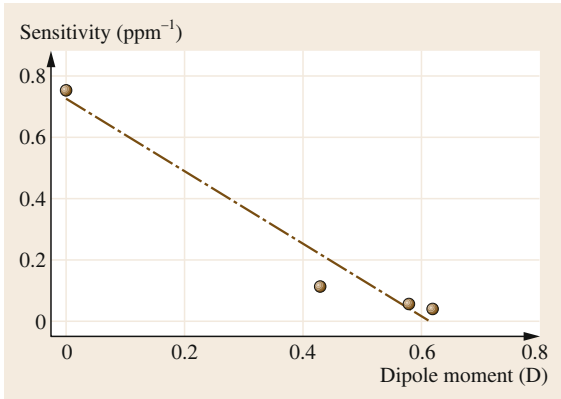

Fig. 52.18 Response of spun PMMA films on exposure to benzene (0 D), toluene (0.43 D), ethyl benzene (0.58 D), and *m*-xylene (0.62 D)

the highest SPR response [52.184]. A sensor has been made from a permselective poly(dimethylsiloxane) (PDMS) hollow-fiber membrane, showing a fast response time, very high oxygen permeability, and optimized oxygen/nitrogen selectivity. This sensor was suitable for monitoring the oxygen content in the outlet stream generated by medical oxygen concentration units [52.185].

Single-polyaniline films generally suffer from poor mechanical stability and polyaniline-blend films were prepared for practical applications using PMMA and PSt. The presence of water vapor, functioning as the interference gas, led to the lowering of the NH_3 response of the sensor in a humid atmosphere. The humidity effect was larger for PMMA than the PSt blend film. The difference was, however, not as large as expected from the water-sorption ability of PMMA [52.186]. The detection limits of ISE membranes with solid contacts are generally lower than a traditional liquid inner contact because of the diminished ion fluxes. Poly(methyl methacrylate)/poly(decyl methacrylate) (PMMA/PDMA) copolymer was employed as a solvent-cast membrane matrix on a layer of poly(*n*-octyl)thiophene (POT) deposited on Au as the internal contact. Ca^{2+}- and Pb^{2+}-selective electrodes were not sensitive to O_2 and the presence of a water film between the membrane and the internal contact was not found. The limits of detection were better by an order of magnitude and the response at low concentrations was much faster than for the liquid-contact electrode. For example, the drift was found to be smaller than 0.4 mV/min after 2 min when the concentration was increased from 10^{-9} to $10^{-7.7}$ M [52.187].

An amperometric hydrogen sensor was proposed using a proton-conducting solid polymer electrolyte membrane (PEM), a blend of palladium and platinum as the anode, and platinum as the cathode. The sensor operated as a fuel cell (H_2/Pd-Pt//PEM//Pt/O_2) and the short-circuit current was found to be linearly related to the hydrogen concentration [52.188].

It has recently been reported that thin films of polyphenylsulfide (PPS) (commercially termed noXon) act as efficient scrubbers of ozone from atmospheric ambient through the oxidation of the PPS molecules [52.189]. Thin films of this compound are found to be a useful material for the fabrication of sensing membranes suitable for the detection of ground-level ozone at concentrations of a few ppm or even lower [52.190, 191]. A 1 h exposure to 2 ppm of O_3 was shown to cause at least a 1.1% change in the refractive index of the film [52.192]. As shown in Fig. 52.17b, oxidation of the PPS polymer by ozone exposure results in an irreversible increase in the index of refraction of the polymer [52.193].

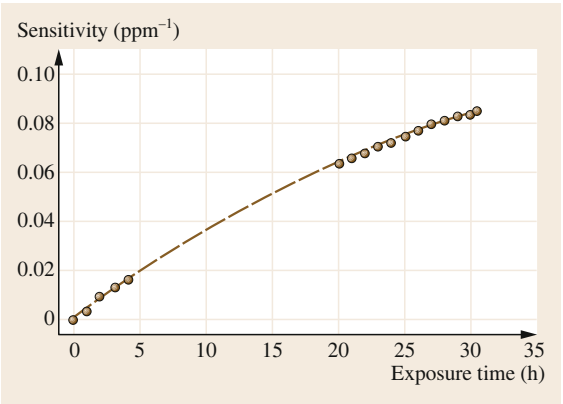

Fig. 52.19 Time-dependence behavior of ozone sensitivity of PPS films. Two sets of hourly readings, separated by 16 h of continuous exposure without SPR measurements (*dashed line*)

Figure 52.19 shows the results of SPR measurements on PPS films when exposed to 1.5 ppm ozone. The increase in the refractive index Δn was found to be linear over the first few hours of exposure with an estimated slope of 10^{-4} refractive index units (RIU)/min. The sensitivity was defined as the ratio of Δn to the concentration of ozone. The interaction of O_3 with PPS films is believed to be an accumulative effect and such mechanisms can therefore serve as both a scavenger as well as an indicator of ozone in a certain ambient. The density of the binding of oxygen to a PPS film after 5 h of exposure to 2 ppm ozone was estimated from QCM measurements to be about 5×10^{18} cm^{-3}.

Electrospun nanofibers with diameters of 100–400 nm were deposited on the surface of a QCM by electrospinning homogenous blend solutions of crosslinkable poly(acrylic acid) (PAA) and poly(vinyl alcohol) (PVA). The NH_3 sensing properties were mainly affected by the content of the PAA component in the nanofibrous membranes, the concentration of NH_3, and relative humidity. The sensitivity of nanofibrous-membrane-coated QCM sensors was also much higher than that of continuous-film-coated QCM sensors [52.194].

Molecularly imprinted polymers (MIPs) are now well recognized as robust, cost-effective, and highly durable synthetic receptors for specific targets having variable sizes and shapes. MIPs which provide interaction points and a coordination sphere around the template molecule have applications ranging from liquid chromatography to assay and sensor technologies and drug delivery [52.195].

The synthesis method of MIPs includes the selection of the required target molecule used as the molecular template, and embedded in the presence of

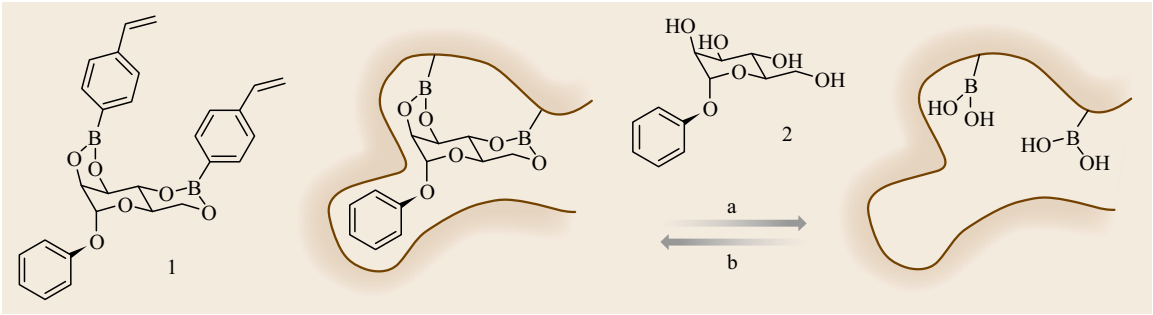

Fig. 52.20 Schematic representation of a cavity obtained by polymerization (1) starting molecule (2) formation of cavity (a) and (b) route to successive chemical formation

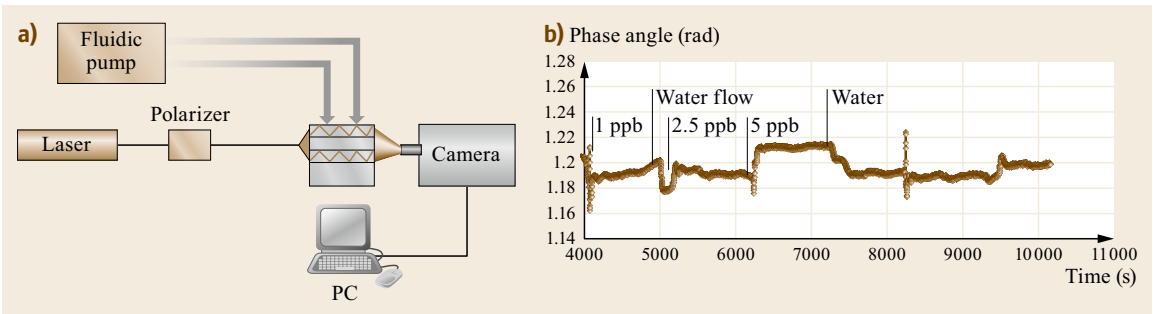

Fig. 52.21 **(a)** Schematic diagram of dual polarization interferometer (DPI) **(b)** DPI time trace transverse electric phase angle in radians upon adding 1, 2.5 and 5 ppb atrazine to atrazine MIP immobilized on a DPI chip

functional monomers, whereby the monomers interact with and engross into sites of the template forming a complex followed by further polymerization. After the completion of the polymerization the functional sites of the molecule template are held in position and surrounded by the highly crosslinked polymeric structure, followed by the removal process of the template molecule which subsequently results in the formation of cavities, specific in size, shape, and chemical functionality of the target molecule (Fig. 52.20). These imprinted functional cavities are then capable of identifying, rebinding, and quantifying the target molecules with excellent degrees of selectivity and sensitivity and are therefore an ideal immobilization method of sensor layers [52.196].

For the specific detection and quantification of the herbicide atrazine, a triazine molecule is used as the template molecule and reacted with the monomer methacrylic acid (MAA) in addition to the crosslink agent ethylene glycol dimethacrylate (EGDMA) initiated by azobisisobytyronitrile (AIBN) during the synthesis process. The polymerization is driven and influenced by heat, whereby the triazine molecule is removed by Sox extraction using acetic acid and chloroform. The optimization process of the final MIP influences the guest capacity factor, as some of the functional sites present remain inaccessible due to the presence of residual template molecules, excessive crosslinking restricting the diffusion or deformation of the network during the extraction process by swelling or relaxation caused by the solvent. Under these influences the guest capacity for MIPs is limited with typical values of 0.1 mg per 1 mg of MIP, however advanced polymeric systems with trifunctional crosslinker agents or higher offer significant increases in capacity which in turn enhances the recognition and decreases possible retention times. The selection of the optimal solvent also plays an essential role in the type of interaction involved and consequently determines its polarity and dissociating energy, capable of influencing the morphology of the material during synthesis, including the size, shape, and quantitative distribution of the cavities. It is therefore crucial during analysis stages to incorporate a solvent similar to the synthesis solvent involved in the production of the original network in order to exclude the possibility of restructuring the effective morphology and to obtain the selectivity to the initial degree [52.197].

Atrazine is a man-made chemical which is very widely used as a herbicide. It can be harmful to wildlife, is long-lasting in the environment, and a potential groundwater contaminant. Commercially available

molecularly imprinted polymer (MIP) is dispersed into the chloroform solution of poly(methyl methacrylate) (PMMA) to produce the sensing membrane for the herbicide atrazine. The interaction of MIP/PMMA matrices with atrazine was investigated using the dual polarization interferometric (DPI) technique (as shown schematically in Fig. 52.21a). The interferometer is able to interrogate the sensor/sample interface by coupling transverse electric (TE) and transverse magnetic (TM) waves representing light parallel and perpendicular to the plane of the chip [52.198]. A thin film of MIP dispersed in PMMA solution was spin-coated onto the silicon oxynitride surface of the DPI chip. Distilled water was used as the running buffer and this was switched to 400 µl injections of 1 ppb of atrazine in solution. The running buffer was switched back to distilled water following completion of each injection loop. As shown in Fig. 52.21b), it was possible to measure the change in phase due to increasing exposure levels of atrazine. The atrazine effect was effectively removed by switching the running buffer back to distilled water. This suggested that the detection of atrazine by the MIP/PMMA thin film integrated to the DPI chip was reversible. However, given that the bound atrazine could be removed by a simple water wash suggests that the herbicide was not strongly bound to the MIP trapped in the PMMA film. Normally a more stringent elution stage is required to remove the atrazine from the MIP.

52.6 Cavitand Molecules

Thin films of some novel cavitand compounds such as crown ethers [52.199] and calixarenes [52.200, 201] can form inclusion complexes with some organic guest molecules. This effect is being extensively exploited for the development of sensors for organic vapors [52.202, 203]. Thin films can be prepared using LB film deposition, spin coating, and self-assembly techniques [52.204–207]. The nanoporous flexible structure of thin LB films of amphiphilic calixresorcinarene derivatives were found to provide a suitable matrix for the incorporation of aromatic molecules [52.208]. This adsorption process was very fast, and full recovery of the film was observed after flushing with clean air. It has to be pointed out, however, that the detected vapors were of a high concentration (a few percent by volume) and the adsorption was not selective since all vapors studied yielded a similar response. However, this may lead to the development of a sensor for explosives, where specificity is not considered relevant. These effects are attributed to weak and nonspecific interactions between the guest molecules and the calixarene LB film. It was also shown that the adsorption of organic vapors occurs in the whole bulk of the LB films, and that the number of adsorbed molecules is much higher than the number of calixarene molecules [52.209]. The adsorption mechanism involved the swelling of the film and even condensation of the adsorbate within the film. The swelling of the film was confirmed by independent measurements using ellipsometric and surface plasmon resonance (SPR) techniques [52.210]; the adsorption mechanism still remained unclear. For all the studied analytes, the number of adsorbed molecules was found to be much larger than that expected from the geometrical dimensions of the intrinsic calixarene cavity and the empty space between the molecules. This discrepancy was explained by either film swelling or the condensation of vapor molecules inside the film, or both [52.208]. Spun films of calixresorcinarenes, however, were found to be homogeneous, and the porosity of the film was similar to that of LB-deposited films. Both LB and spun films of comparable thickness exhibited similar SPR response on exposure to toluene vapor [52.62]. Prolonged irradiation of the CA films with a focused laser beam caused an initial increase in film sensitivity to various organic vapors [52.211].

Figure 52.22 shows the chemical structure of an amphiphilic calixresorcinarene derivative with several different types of substituents. Exposures of layers of CAs to vapors of benzene, ethylbenzene, toluene, and *m*-xylene in low concentrations produced changes in the optical properties, i. e., the film thickness and refractive index of the layers. Fast response and recovery processes have been observed, with response times as short as a few seconds. The normalized SPR responses are shown in the three-dimensional (3-D) diagram in Fig. 52.23. It is apparent that the interaction of the analyte was, in general terms, specific to the thin film of a particular CA derivative. The adsorption mechanism was interpreted in terms of the accumulation of the vapor molecules in the liquid phase inside the film matrix, probably caused by capillary condensation in the porous structure of the CA films [52.212]. These LB films had a characteristic pore size of about 1 nm. Condensation of vapor occurred inside capillaries similar to the porous structure of calixarene films at pressures lower than their saturated pressure at a certain temperature. The saturated vapor pressures of ethylbenzene and *m*-xylene are similar and therefore their exposure to the CA derivatives produced similar effects. Conversely, benzene, with the highest saturated

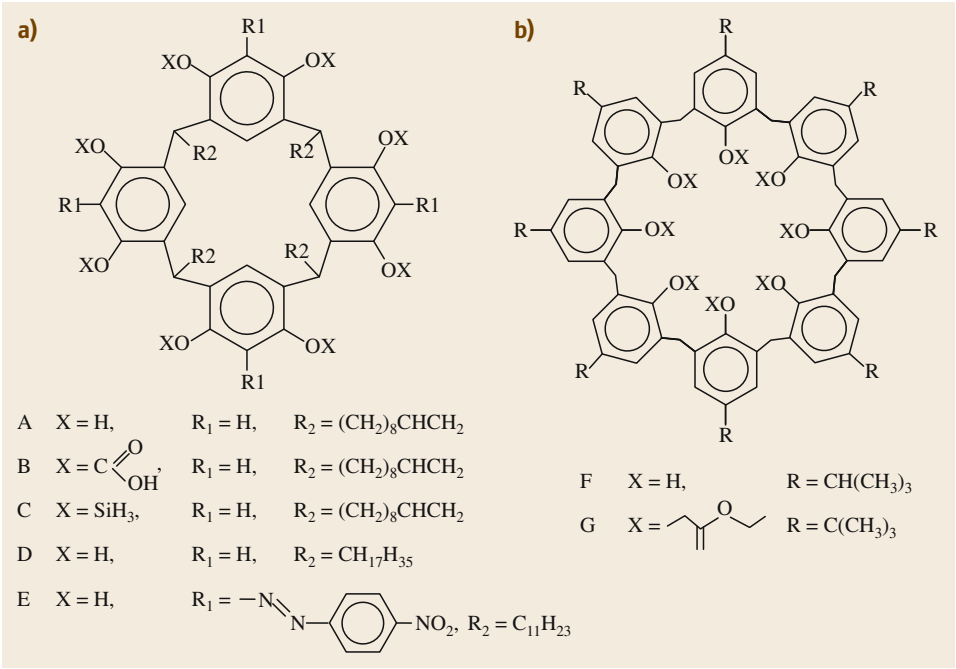

Fig. 52.22a,b Chemical formulae of calixresorcinarene derivatives

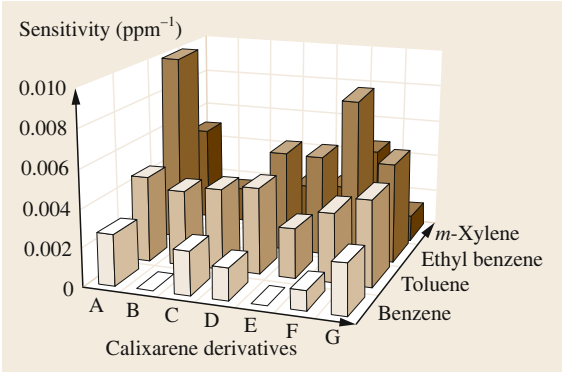

Fig. 52.23 A 3-D representation showing the response of different calixarene derivatives to different organic vapors (benzene (B), *m*-xylene (X), toluene (T), and ethylbenzene (E)) at a concentration of 375 ppm

vapor pressure, yielded the smallest detectable SPR signal.

Composite LB films of amphiphilic CA and PPS were exposed to 2 ppm of O_3 [52.190]. The competition between the permanent oxidation process of the PPS polymer by the adsorbed O_3 molecules and the release of O_3 from the CA matrix was found to depend on the molar ratios of the CA and PPS compounds. Recovery became slower with lower CA proportions in the film matrix.

The conductivity of the CA derivative is intrinsically low. CA films were deposited on the gate between the source and the drain of a charge-flow transistor and the turn-on response for the transistor upon exposure to organic solvent was recorded. The increase in the membrane conductivity is partially attributed to condensation of the vapors in the highly microporous membrane even below the saturation vapor pressure and partially to the effect of the polar analyte molecules complexing inside and between the OH groups of the cavities. The technique offers several advantages over existing methods:

1. Immunity to water vapor, because of the hydrophobic nature of the membrane
2. No catalytic poisoning of the membrane, as is commonly observed for doped SnO_2
3. No accumulative effects, which are responsible for baseline drift in quartz-crystal-type sensors, are observed
4. No porous metal layer, the adhesion of which may be prone to degradation, is needed on top of the membrane [52.213].

52.7 Concluding Remarks

The scope of organic materials for chemical sensing is huge and it is impossible to provide a complete description of these materials. Electronic artificial noses are being developed as systems for the automated detection and classification of odors, vapors, and gases. These instruments consist of three main components:

1. An array of chemical membranes
2. Electronic circuitry for data acquisition, signal processing, and display
3. A pattern-recognition algorithm.

Up-to-date information on applications of materials for electronic noses and tongues is available in a recent review [52.214]. Problems associated with human senses are many: individual variability, impossibility of online monitoring, subjectivity, adaptation, infections, harmful exposure to hazardous compounds, and mental state. These limitations can be overcome by developing intelligent sensor systems. Gas sensors tend to have very broad selectivity, responding to many different analytes of varied concentrations. The electronic nose/tongue, therefore, offers a definite advantage in many applications in the food and utility industries, the health care and medical care sectors, and security services. The demand for advanced electronic noses will continue to stimulate the search for novel sensing materials.

Mathematical and computational tools are expected increasingly to play a part in the design of advanced electronic-nose systems. An electronic nose has been developed to monitor breathing air in human habitats. A molecular modeling study was undertaken to investigate the interactions between resistive sensors of a polymer–carbon black (CB) composite and analytes. Poly(4-vinylphenol), polyethylene oxide, and ethyl cellulose were considered for modeling, based on their stereoisomerism and sequence isomerism. The CB was modeled as uncharged naphthalene rings with no hydrogen. Molecular mechanical and molecular dynamics techniques were employed and the equilibrium composite structure was constructed by inserting naphthalene rings into the polymer matrix. The radial distribution profiles produced information on the composite microstructure. The sensor response was predicted in terms of the interaction energies of the analytes with the composites. Studies included both inorganic and organic analytes [52.215].

Research efforts are also growing in the mineralization of VOC pollutants to innocuous compounds [52.216]. Visible-light-assisted removal of organic pollutants by photocatalytic action of dye-sensitized TiO_2 surfaces offers several attractive advantages. Firstly, the nanoscale device architecture is versatile with several methods of solar energy conversion whilst producing a chemical fuel in the form of pure H_2. Secondly, pollutant species and concentrations of mixtures in industrial waste streams can be identified [52.217]. Results so far reported are encouraging. For example, 40–75% degradation of aromatic pollutants such as phenol, chlorophenol, trichloroethylene, and surfactants was achieved with TiO_2 surfaces modified by methylene blue and rhodamine B dyes after less than 5 h of irradiation with a 150 W xenon lamp [52.218]. Individual VOCs including methylene chloride, ethanol, benzene, acetone, xylene, and isopropanol produced unique signatures as they were oxidized on the sensor surface [52.219]. Interest in hybrid hetero-supramolecular structures will therefore remain alive for the foreseeable future.

Acknowledgments. The author is grateful to the Engineering & Physical Research Council (UK) and the European Union for financial support of their work over the last 20 years. Gratitude is also due to Dr. S. C. Thrope of the Health Safety Executive (UK), Dr. M. Hofton of TQ Environmental Plc., Prof. K. C. Thompson of ALControl, and Dr. F. A. Grunfeld of NIMA Technology for their collaboration and support. Prof. M. J. Cook of the University of East Anglia has remained a generous provider of novel phthalocyanine compounds for sensing experiments over the years. The contributions from Drs. R. Capan, O. Omar, and A. V. Nabok are acknowledged with gratitude. Above all, the author is enormously indebted to his parents Chittarajan and Sarashi of Belgram (India) for stimulating his interest in academic career in science.

53. Packaging Materials

Darrel Frear

This chapter is a high-level overview of the materials used in an electronic package including: metals used as conductors in the package; ceramics and glasses used as dielectrics or insulators; and polymers used as insulators and, in a composite form, as conductors. There is a need for new materials to meet the ever-changing requirements for high-speed digital and radio frequency (RF) applications. There are different requirements for digital and RF packages that translate into the need for unique materials for each application. The interconnecting and dielectric (insulating) requirements are presented for each application and the relevant material properties and characteristics are discussed. The fundamental material characteristics of materials are: dielectric constant, dielectric loss, thermal and electric conductivity, resistivity, moisture absorption, glass transition temperature, strength, time-dependent deformation (creep), and fracture toughness. The material characteristics and properties are dependent upon how they are processed to form the electronic package, so the fundamentals of electronic packaging processes are discussed including wirebonding, solder interconnects, flip chip interconnects, underfill for flip chip and overmolding. The relevant material properties are given along with requirements (including environmentally friendly Pb-free packages) that require new materials to be developed to meet future electronics needs for both digital and RF applications.

An electronic package is a configuration of materials that interconnects electronic signals from one area to another. This scheme must isolate these signals so that there is no interference and must also protect the electronics from a degrading environment. A package typically consists of the semiconductor mounted and interconnected (with solder or Au or Cu wires) to a dielectric substrate (with a leadframe or with metal traces) that is encapsulated to seal the device from the environment. The electronic package must serve four functions:

1. Provide electrical (or photonic) contact to and from the chip
2. Act as an electrical space transformer to take electronic functionality from the dense surface of the chip to the coarser pitched *outside world*

© Springer International Publishing AG 2017
S. Kasap, P. Capper (Eds.), *Springer Handbook of Electronic and Photonic Materials*, DOI 10.1007/978-3-319-48933-9_53

3. Provide environmental isolation to the semiconductor, and
4. Provide an avenue for conduction of heat away from the device.

In the past, advances in silicon semiconductors had little or no effect on the electronic package design or process. New advances in silicon devices have driven increases in chip speed, the device density (e.g., the number of transistors/mm^2), and power dissipation. These changes, and those planned in the future, require larger numbers of interconnects to and from the devices, improved electrical performance, more effective thermal management, software systems to design and model the assembly, and different sets of materials to make these changes happen. Furthermore, the package is shrinking to a minimalist version of the products that traditionally have been called packaging. The chip and board have become a conjugate packaging system that must provide the traditional levels of electrical, mechanical, thermal interfaces, and environmental protection, with the additional challenge of increased performance. Furthermore, the boundary between where the device ends and where the package begins has become blurred with passive devices (e.g., resistors, capacitors, etc.) in the package and redistribution layers that act as space transformers on the chip. Electronic packaging is becoming one of the greatest challenges in manufacturability, performance, and reliability in advanced electronics applications. With the tremendous growth of wireless telecommunication, RF applications are beginning to drive many areas of microelectronics traditionally led by the development of the microprocessor. An increasingly dominant factor in RF microelectronics is electronic packaging and the materials needed to create the package because the package materials strongly affect the performance of the RF electronics. Many challenges remain for packaging of microprocessors as well. These challenges include increased speed, numbers of input/outputs (I/O), decreased pitch, and decreased cost.

53.1 Package Applications

Electronic packages are divided into four levels, with three that exist beyond the integrated circuit:

- Level 0: Semiconductor chip level (integrated circuits). The materials are: the semiconductor (Si, SiGe, GaAs, etc.), metalization on the circuit (Al, Cu, Au) and interconnects on the die.
- Level 1: Chip in a carrier. The die is bonded (with a conductive or nonconductive adhesive or solder) into a package carrier (substrate or leadframe) and interconnected by either wirebonds or bulk conductive interconnects (flip chip) or solder of conductive adhesives. An example of a wirebonded package is shown in Fig. 53.1. Figure 53.2 is a representation of a flip chip package interconnect. The die is protected either by a lid or encapsulated with a polymer overmold.
- Level 2: The chip carrier mounted to a board. The package is solder, or conductive adhesive, attached to a circuit board. An example of a package mounted to a board using area array interconnects is shown in Fig. 53.2.

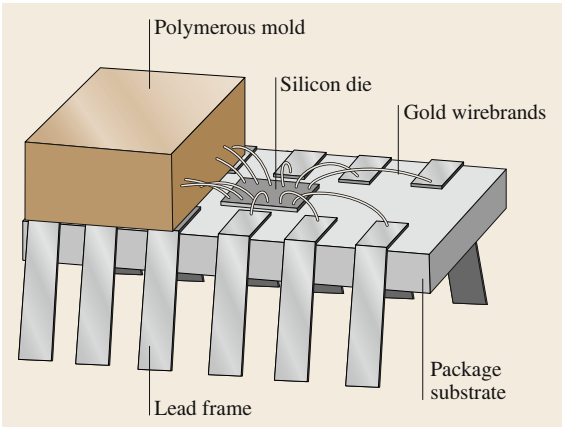

Fig. 53.1 Isometric section schematic that illustrates a peripheral package showing a dual-in-line-package (DiP) that is wirebonded

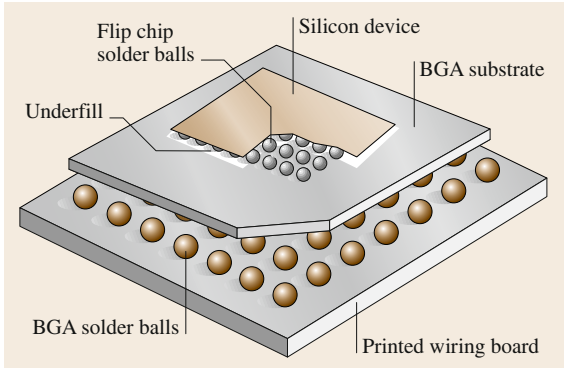

Fig. 53.2 Schematic illustration of an area array package with a flip chip device interconnect and a ball grid array package

- Level 3: Board to board interconnects. The boards are interconnected to the final electronic system using friction interconnects, solder interconnects, or fiber-optic connectors.

53.2 The Materials Challenge of Electronic Packaging

Electronic packaging is arguably the most materials-intensive application today. The families of materials included in a package include: semiconductors, ceramics, glasses, composites, polymers, and metals. A list of the types of materials used in an electronic package is shown in Table 53.1. The processes required to assemble a package are equally varied: welding, soldering, curing, cold and hot working, sintering, adhesive bonding, laser drilling, and etching.

Each of these materials and how they are used in an electronic package could be the topic of an entire book. This chapter is a high-level overview of the materials used in an electronic package. The focus is on the following classes of materials:

Table 53.1 Examples of materials used in electronic packaging

Semiconductors	Si, SiGe, GaAs
Metals	Solders for interconnects (Sn-Pb, Sn-Ag, Sn-Ag-Cu, Sn-Au, Sn-Sb) Au or Cu wirebonds Cu leadframes (Kovar, CuBe, Alloy 42) Cu traces in substrates W, Mo traces in cofired ceramics Ag, Au, Pd for thin/thick films on ceramics Ni diffusion barrier metalizations Al heat sinks
Ceramics	Al_2O_3 substrates modified with BaO, SiO_2, CuO, etc. LTCC substrates Al_2O_3 modified with low-temperature glass (e.g., PbO) SiN dielectrics Diamond heat sinks
Polymers	Epoxies (overmold) Filled epoxies (overmold) Silica-filled anhydride resin (underfills) Conductive adhesives (die bonding, interconnects) Laminated epoxy/glass substrates Polyimide dielectric Benzoyclobutene Silicones Photosensitive polymers for photomasks (acrylates, monomers, etc.)
Glasses	SiO_2 fibers for optoelectronics Silicate glasses for sealing Borosilicate glass substrates Glass fibers for epoxy/glass substrates (FR-4)

Metals are used as conductors in the package, primarily electrical but also thermal for power devices. This includes the thin metal interconnects on the integrated circuit made of Al, Cu or Au and the interconnects between the integrated circuit and the package that are either wirebond interconnects or solder joints. Metals are also used to act as heat sinks for power devices and as shields for RF applications

Ceramics and glasses are used as dielectrics or insulators. Ceramics are used in devices as dielectrics to form capacitors and inductors. In the package itself, the ceramics are used as insulating materials and as substrates that provide a structural base that electrically isolates lines and pads.

Polymers are used as insulators and, in a composite form, as conductors. As an insulator, polymers are encapsulants, underfills and substrates (note: in these applications, polymers are used as composites with silica or glass fillers). Polymers are also used as insulating adhesives to glue components to a substrate or board to provide mechanical strength. The addition of metal particles to the polymer can make it a conductive material used as a conductive adhesive interconnect.

Composite materials are a mix of materials that can be tailored for either mechanical behavior improvements, thermal enhancement or as an electrical conductor. Many of the composite materials used in packages are based on a polymer matrix as noted in the polymer section above.

There is a wealth of general information on materials in electronic packaging. Some additional resources are found in [53.1–8].

53.2.1 Materials Issues in High-Speed Digital Packaging

The ability to decrease line width and feature size in semiconductor technology is decreasing below 90 nm. As the feature size shrinks, the function per unit area on the die increases. This increased functionality means either smaller die or more I/Os per die. The reduced die size also reduces the available perimeter of the package for wirebond pads while increased functionality requires more I/Os. The decreased perimeter area also drives wirebond capability down to 44 µm pitch with 10 µm gold wire. An attractive solution to this decreasing size is to use the entire surface of the chip (flip chip) rather than just the periphery (wirebond). Figure 53.3

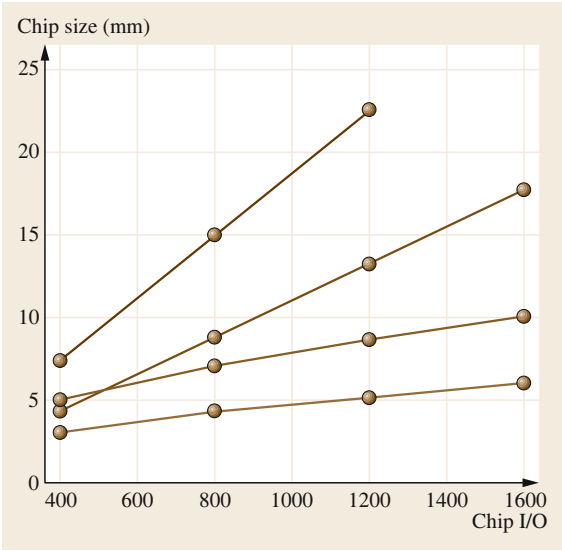

Fig. 53.3 Plot of bond pitch requirements as a function of I/Os and die size for current wirebond (75 μm) and flip chip (250 μm) and state-of-the art wirebond (44 μm) and flip chip (150 μm)

shows a comparison of available I/Os for a given chip size for standard, and state-of-the-art, wirebond and flip chip pitch.

From an overall digital package perspective, the trend is to move from perimeter-bonded die and packages to an array package and then array die bond in an array package that offers increased numbers of I/Os and performance potential. This trend is shown in Fig. 53.4. Materials used in the package and substrate (e.g., ceramic (Al_2O_3), low-temperature cofired ceramic [LTCC] and organic laminants) and package style affect performance as well as area array versus peripheral interconnects. Ceramic packages are the material of choice for hermetic high-performance applications. Ceramic is typically 96% Al_2O_3 with tungsten metalization. The ceramic is fired and sinters at high temperatures that preclude the use of Cu or Al metalization, which would melt in the ceramic sintering process. Multilayer ceramic packages with thin-film metalizations also offer a thermal expansion coefficient similar to the Si die (6×10^{-6} /°C for alumina ceramic versus 3×10^{-6} /°C for Si) so strain that can arise during thermal cycling can be minimized. However, Al_2O_3 ceramic is expensive and has limited use in commercial applications. LTCC is of interest because it offers the hermeticity and thermal expansion advantages of ceramics at a lower cost. The LTCC is an alumina ceramic/glass composite that is fired at sufficiently low temperatures that Cu or Ag can be used as the metallization.

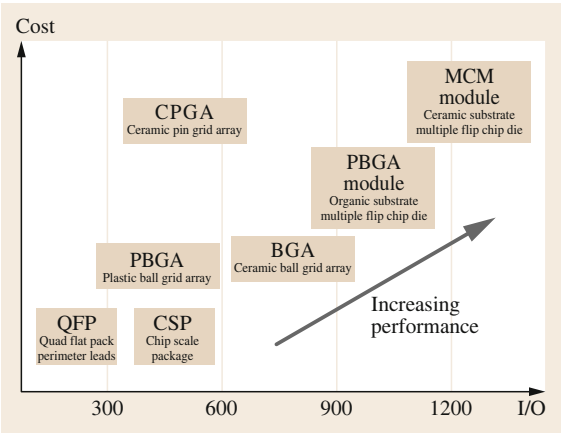

Fig. 53.4 Plot of package style as a function of cost and I/O

Table 53.2 Dielectric constants of packaging substrate materials

Material	Dielectric constant (ε_r)
Epoxy	5.0
FR-4	3.5–4.0
Other laminates	2.5–4.5
Kapton	3.1–3.5
Multilayer ceramic	5.0–9.5
Low-temperature cofired ceramic (LTCC)	3.9–7.8

For the interconnects in the package, flip chip appears to provide substantial improvements in I/O and pitch but wirebond will remain as a packaging solution because there is a great deal of capital invested in wirebond equipment that cannot be ignored.

In addition to smaller size driving finer pitch, increased signal speed will drive package requirements. Digital signal delays must be minimized. The total delay is a function of the total distance and the delay per unit length that is a function of the transmitting medium's dielectric constant and is the square root of the dielectric constant (ε_r) times the free space delay in vacuum (33 ps/cm). Therefore, a material with a high dielectric constant increases the delay. Table 53.2 shows a variety of dielectric constants used in packaging.

For minimal signal delays, an optimal dielectric substrate material is required. The signal length can also be shortened by changing from a wirebond solution to flip chip.

53.2.2 RF Packaging Materials Issues

High-speed and microwave circuits are defined for digital devices with clock speeds faster than 100 MHz

and 0.1 to 100 GHz for analog circuits. For analog, this is also termed radio frequency (RF) circuits. The microwave, or RF, circuit module is defined as microstrip elements composed of transmission lines and matching networks on a substrate with discrete components (resistors, inductors, capacitors and transistors) attached, or embedded, in the substrate. A monolithic microwave device has all the above elements integrated onto a semiconductor die. The semiconductor used for RF applications is typically GaAs because of its high resistivity and suitability for circuits that operate at high frequencies. The following is a discussion of critical packaging materials issues related to RF devices and modules.

One of the most significant differences between RF and digital packaging is that the package is part of the RF circuit due to the interaction of the RF electric field with all adjacent conductors and insulators. This is one of the most significant challenges in the design of RF circuits. This will be further exacerbated as the trend is to move from a single die RF package into multiple die packages (or RF modules) with passive components. For example, the wireless communication industry is striving toward a solution of a *phone-in-a-package* where the entire electronic functionality of a cellular phone can fit into a package with a size on the order of 1 cm^2. Materials used in the package of these RF applications are significant to the performance and cost of the solution.

It is clear that the electronic package is a complex materials system that is driven by a variety of thermal, mechanical and electrical performance requirements. These requirements are also application-dependent for both digital and RF packages. The remainder of this chapter is an overview of the key materials required for microelectronic packaging.

53.3 Materials Coefficient of Thermal Expansion

The coefficient of thermal expansion (CTE) is the length of increase of a macroscopic sample for a given temperature increase. The units of the CTE are length/length °C. The CTE is a critical physical property of materials used in an area array package. A wide variety of materials with a variety of CTEs, such as metals, ceramics, and polymers are joined together in an electronic package assembly. As processing (or in-use) temperatures change, the materials expand or contract to various degrees that could result in the formation of extensive, and nonuniform, strains in the package assembly. A set of materials typically used in electronic packages and their CTEs are shown in Table 53.3.

53.4 Wirebond Materials

Wirebonding is the process where a thin wire (can be less than 25 μm in diameter) made of Au or Al is bonded to the surface of an integrated circuit then to a pad or leadframe in the package (Fig. 53.1). Gold ball thermosonic bonding is the typical method used to form these interconnects. The thermocompression bond is a weld between two metals where thermal energy (preheating of the capillary tool and wire), force and ultrasonic energy are imparted to the wire causing it to melt on the surface and rapidly interdiffuse with the bond pad to form a joint. The integrated circuit pad surface finish is typically Al or Au and the package bond pad finish is typically Au or Cu.

One of the biggest transitions in materials for electronic packaging occurred when the price of Au dramatically increased in the early 2000s, which forced a change to dramatically increased use of Cu as the wirebond material. By the end of 2010, the installed base of copper wire capable bonders approached 25% of the total installed fine-pitch wirebonder base from 5% in 2009 [53.9], and by 2015 more than 33% of all wirebond machines bond Cu [53.10].

53.4.1 Wirebond for Digital Applications

The challenges for decreased wirebond pitch are primarily related to the process of accurate machine control to move bonding heads across shorter distances (44 μm pitch) with increased accuracy. However, there are materials challenges. The metallurgical challenges of wirebonding Au to Al have been well addressed. The classic, early failures were dominated by *purple plague* and the definitive work in this area is by *Philofsky* [53.11]. Purple plague resulted when the Au of the wirebond extensively reacted with Al to form brittle $AuAl_2$ that resulted in bond failures. (Purple plague derives its name from the purple tinge of the $AuAl_2$ intermetallic.) This was addressed by reducing the

wirebond process temperature to below 300 °C, which reduced the extent of the $AuAl_2$ formation. Current wirebond failures are the result of surface impurities or corrosion. These are addressed by plasma or ultraviolet (UV)-ozone cleaning of the surface prior to wirebond.

Wirebonding problems have also been caused by plating impurities in Au bond pads. The impurities in the Au diffuse to the molten front that occurs during wirebonding and concentrate in a plane in the bond. If there are a sufficient number of impurities, they precipitate and act as sinks for vacancies that can become voids and lower the bond strength. The impurities have been identified as Ni, Fe, Co and B [53.12]. The contaminants are present in the Au film as a result of the plating process. This can be addressed by optimizing the plating process to form pure metallic Au.

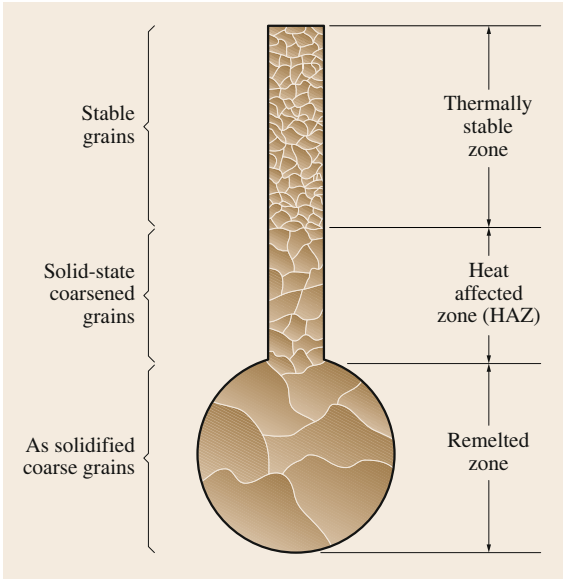

Fig. 53.5 Schematic illustration of the grain size in a Au wirebond. (After [53.13])

With finer pitch wirebond the Au wire must also decrease in size, approaching 10 μm in diameter. This thin wire poses a materials challenge. The wire must have sufficient ductility to deform to the required wirebond shape but retain sufficient strength to not deform or move during the molding process (wire sweep). The Au alloy must be optimized for these opposing requirements. Au wire is typically stabilized with Cu and Ag dopants at levels less than 100 ppm by weight. These dopants keep the grain size small to retain strength without deleteriously affecting ductility. As the Au wire decreases in width, the levels of dopants may need to be increased reducing the Au to less than the current 99.9% level. Proposed dopants include Be and Cu. The critical region in the wirebond is above the ball and below the wire called the heat affected zone (HAZ). A schematic of the zone is shown in Fig. 53.5. This zone forms above the ball that was molten and cools to form a very large as-solidified grain size. The HAZ forms a large grain size while coarsening in the solid-state while the molten ball is created. (The ball is formed under a flame or high current, solidifies, and is then placed on a Au or Al pad and with the addition of energy (pressure/heat/vibration) forms a solid-state ball bond.) The strength in the HAZ is reduced by the Hall–Petch relationship that states strength is inversely proportional to grain size. The HAZ would be susceptible to poten-

tially high levels of strain during molding and would be the most likely failure location. In thinner wires, an increased grain size is even more critical and alloying elements are needed to stabilize the structure and retain sufficient strength without affecting the ductility required to form the wirebond.

The use of Cu as the wirebond material requires significant process changes because Cu is harder than Au and oxidizes much more quickly, requiring specialized copper wirebond process parameters (e.g., a reducing atmosphere at wirebond or higher pressure/energy at wirebond). Cu is harder and has lower ductility than Au so the bonding process window is more narrow and requires more effort to optimize the process so damage to the Si under the bond pad is minimized. The metallurgical reaction between the Cu wire and the Al bond pad is not as extensive as the Au-Sn intermetallic that forms in Au wirebonding. The thinner intermetallic is more stable and results in a more robust bond. The electrical performance of Cu is better than Au wirebonds because copper enables better heat dissipation and can carry more power with thinner wire diameters.

53.4.2 Wirebond for RF

At RF frequencies the wirebonds affect electrical performance. At sub-RF frequencies, the wirebonds can be neglected as their resistance and inductance are in the noise with respect to performance. In RF applications, the wirebonds experience parasitic losses due to inductance with adjacent wirebonds resulting in signal disturbance. RF circuit designers typically add at least 1 nH inductance per wirebond, but the effect can be variable and must be physically compensated by tuning the circuit. In effect, the wirebonds act as discrete inductors. The materials issues for RF wirebond are the same as described above for digital, but the effect of the wirebonds themselves is significant in RF compared to digital and must be accounted for in the design of the device.

53.5 Solder Interconnects

For surface mount and area array applications, the role of solder in the package is significant. In these advanced designs, the solder is an electrical interconnect, a mechanical bond and must often serve as a thermal conduit to remove heat from the joined device. The interconnects become more critical as chip size, chip carrier size, and the number of I/Os increase, while the solder joint size and cost decreases. Furthermore, some of the use environments are becoming increasingly severe. For example, some automotive electronics are being placed in locations under the hood with temperature extremes that could range from −55 to 180 °C. Portable devices, such as cellular telephones are expected to withstand severe shock environments caused by dropping the phone.

A solder interconnect consists of the solder alloy and the pads to which it is joined. The solder alloy is a low-temperature-melting metal that wets and reacts with metal pads or leads to form a metallurgical bond. During the wetting process the solder reacts with the pad metalization forming an intermetallic compound (IC) on the pad surface that continues to grow when the solder is in the solid state.

The most commonly used solder alloy for electronic interconnects is near-eutectic Sn-Pb with a composition of 63Sn-37Pb (by wt%). The microstructure of this alloy is shown in the optical micrograph in Fig. 53.6 and consists of Sn- and Pb-rich lamella. The lamella are oriented as cells after solidification with the slightly coarsened regions that separate the individual cells as the last part of the solder to solidify. This alloy melts at 183 °C. Pb-rich Sn-Pb alloys (such as 95Pb-5Sn or 97.5Pb-2.5Sn) are used for soldering temperature hierarchy as these alloys melt at temperatures in excess of 300 °C. The microstructure of Pb-rich alloys consists of a matrix of large Pb grains decorated with Sn precipitates. In flip chip applications die are soldered to substrates with high-Pb solder. The substrates are soldered to a board with near eutectic Sn-Pb. The Sn is the active component of these solder alloys and reacts

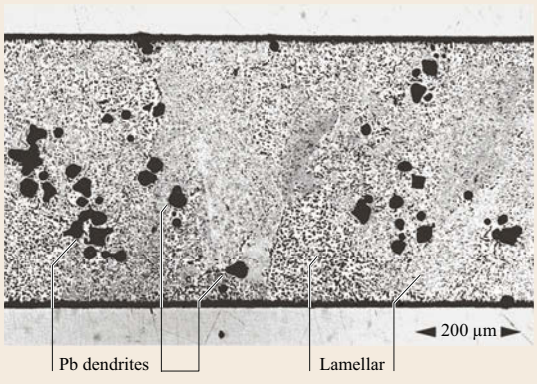

Fig. 53.6 Optical micrograph of the near-eutectic Sn–37Pb solder microstructure with the lamellar Sn- and Pb-rich phases and dendrites indicated

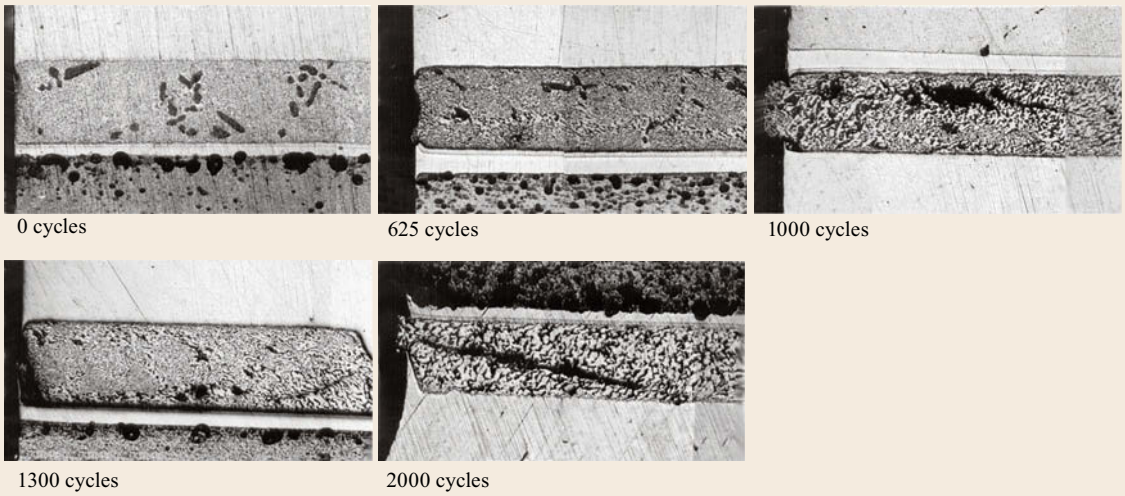

Fig. 53.7 Optical micrographs that show heterogeneous coarsening of the eutectic Sn-Pb microstructure at colony boundaries after thermomechanical fatigue

with metalizations such as Cu or Ni to form intermetallic compounds.

Other solder alloys have found some use in electronic packaging, including Sn-Ag, Pb-In, Sn-Sb, etc. These alloys are used for a variety of applications including creating a soldering temperature hierarchy (higher or lower than Sn-Pb) or slowing the reaction rate with the metalization (e.g., In), or changing the mechanical properties of the joint. These alloys either form as a single-phase matrix with precipitates or as two-phase structures similar to eutectic Sn-Pb. The focus of this section, however, is on the most commonly used solder alloy, eutectic Sn-Pb.

The microstructure of the solder influences the mechanical behavior and reliability of the interconnects by governing the deformation and failure process. Typical deformation depends on the motion of dislocations and the growth and reconfiguration of grains and this is more sensitive to the structure of the solder than its chemistry. Therefore, depending upon processing conditions, the same solder alloy can respond differently to imposed stress and strain. Additionally, solders are low-melting-temperature materials that are used at a significant fraction of their melting point and are thermodynamically unstable. As the joint ages (at temperature and under strain) the microstructure changes and the mechanical properties, and reliability, change. The microstructure changes by grain (or phase) coarsening that may be heterogeneous or homogeneous. Furthermore, the interfacial intermetallic grows in thickness and coarsens with time at temperature. All of this must be comprehended to determine the reliability of solder interconnects.

Thermomechanical fatigue occurs when materials with different CTEs are joined and used in an environment that experiences cyclic temperature fluctuations resulting in imposed cycling strain. Thermomechanical fatigue is a major deformation mechanism concerning solder interconnects in electronic packages. Even small temperature fluctuations can have a large effect, depending upon the joint thickness and CTE difference of the joined materials. The strain imposed on the solder joints follows the relation

$$\Delta\gamma = \frac{\Delta\alpha\Delta Ta}{h} ,$$

where $\Delta\gamma$ is the shear strain imposed, $\Delta\alpha$ is the difference in coefficient of expansion between the joined materials, ΔT is the temperature change, a is the distance from the neutral expansion point of the joined materials, and h is the thickness of the interconnect.

After a critical number of thermal excursions, such as machine on/off cycles, solder joints experience fatigue failure. The type and magnitude of strains in solder joints under conditions of thermomechanical fatigue are often quite complex. For surface mount applications, the strain is nominally in shear. However, tensile and mixed-mode strains can occur due to bending of the chip carrier or board.

The combination of strain and temperature during thermomechanical fatigue has a large effect on the microstructure and microstructural evolution of eutectic Sn-Pb solder joints. The microstructural evolution of 60Sn-40Pb solder as a function of the number of thermal cycles (−55−125 °C) is shown in Fig. 53.7. The

microstructure evolves through deformation that concentrates at the colony boundaries closely parallel to the direction of imposed shear strain, causing the cells to slide or rotate relative to one another. The structure within the cell boundaries becomes slightly coarsened relative to the remaining solder-joint microstructure and, thus are the *weak links* of the joint. Damage (in the form of defects or dislocations) is created at the cell boundaries at the low-temperature portion of a thermal cycle. As the temperature rises, the deformation is annealed by recrystallization or stress-assisted diffusion where material diffuses to regions of high stress. This results in coarsening the Sn-rich and Pb-rich grains and phases in colony boundaries. The heterogeneously coarsened colony boundaries are weaker than the rest of the joint and any further deformation concentrates in the coarsened regions resulting in further coarsening. Failure eventually occurs due to cracks that form in the coarsened regions of a joint. The first indications of impending failure are associated with cracking of coarsened Sn-rich grains in the heterogeneous region whose initial as-solidified grain size is in the submicron range. When cracks initiate during thermomechanical fatigue, the Sn-grain size grows to a range of about $5-10\,\mu m$. Failure occurs when grains can no longer slide and rotate to accommodate the imposed strain resulting in intergranular separation.

Lead-rich Pb-Sn alloys undergo thermomechanical fatigue but show little evidence of microstructural evolution. These solders undergo intergranular failure caused by void coalescence and growth at Pb grain boundaries. The strain imposed during thermomechanical fatigue cannot be accommodated by large Pb grains, resulting in intergranular failure. However, Pb loses the work-hardening effect quickly so that damage in the form of cracks does not propagate easily.

Other solder alloys, such as the Pb-free Sn-3.5Ag eutectic-based solders, experience thermomechanical fatigue damage and failure at Sn grain boundaries. The microstructural evolution in these alloys tends to be phase coarsening with minimal grain size coarsening. Sn-Ag-X alloys tend to have longer thermomechanical fatigue lifetimes than near-eutectic Sn-Pb solders.

Intermetallic compounds form between pad metallization and the active components of the molten solder (typically Sn). For a Cu metalization, the Sn reacts to form Cu_3Sn and Cu_6Sn_5 intermetallics. For Ni, the Sn reacts to form Ni_3Sn_4. After solidification, the intermetallic compounds continue to grow by solid-state diffusion. Over long periods of time, the intermetallic layers can grow to significant thicknesses ($> 20\,\mu m$) and the solder–intermetallic interfaces may constitute easy sites for crack initiation and propagation. Excessive growth also consumes the base metal, or finish, that can result in the loss of adhesion to the underlying metal that is not solder wettable or create a plane of weakness owing to the stress generated from an intermetallic layer that is too thick. The metalized pad thickness generally must be greater than that consumed by the solder.

The transformation of solder-wettable coatings into intermetallics by solid-state reactions can also result in excessive intermetallic growth that degrades mechanical properties. The interfacial intermetallics are brittle and may fracture when strain is imposed, especially if the strain is tensile in nature. Solder-joint interfacial intermetallics are brittle because they typically have complex crystal structures with few crystallographic planes available to accommodate stress by strain relief, i. e., plastic deformation via a slip mechanism. The failures are characteristically brittle and occur through the intermetallic or at the intermetallic/solder interface under low-load conditions.

53.5.1 Flip Chip Interconnects

Recent developments in the under bump metallurgy (UBM) and solder joints have resulted in lower cost and higher performance flip chip interconnects. The UBM serves as an electrical, thermal, and mechanical interface between the silicon bond pads and the package substrate. The structure of the UBM is designed to adhere to the Al on the Si, act as a diffusion barrier between the solder and Si, and be a wettable surface to join to the solder. The most common UBM is the evaporated Cr/Cr-Cu/Cu/Au developed by IBM [53.14] for use with an evaporated high-Pb-content Pb-Sn alloy joined to a ceramic substrate. This UBM is expensive and new UBM systems with sputtered or plated metalizations have been developed. Plated metalizations are the lowest cost UBM.

A significant change in flip chip interconnects is the move toward a lower-melting-point solder alloy, such as eutectic 63Sn-37Pb (wt%) that can be processed below 220 °C as opposed to 350 °C for high-Pb solder. New materials on the die (low-κ dielectric) and substrate (organic materials) require this lower processing temperature. The change in solder alloy also requires a change in UBM. Traditional UBM systems are based on a thin Cu layer that dissolves into high-Sn solders resulting in spalling and dewetting. Eutectic solder UBM systems utilize a layer of Ni for solder wetting. The Ni is wet by Sn-Pb solder but reacts much slower than Cu. The addition of $\approx 9\%$ V to Ni reduces the ferromagnetic behavior of the Ni and enables the use of sputtering of the Ni. Electroless plating of Ni-9%P is the lowest cost UBM and has the advantage that plating occurs only where desired on the metal pads on the silicon. To plate onto Al, the pads are zincated then

immediately plated with Ni. One issue with Ni-based UBMs is the intermetallic layer between the solder and Ni (Ni_3Sn_4). Although very thin, this intermetallic layer can be brittle and the long-term reliability must be fully characterized and understood.

There are three solder deposition techniques available for flip chip. Traditionally, high-Pb solder is evaporated onto the UBM then reflowed to form metallurgical bonds. Evaporation is expensive because the masks must be regularly cleaned and there is excessive scrap solder. The composition of evaporated solder is difficult to control outside the high-Pb regime. Solder paste is a lower cost alternative to evaporation and involves screening the paste onto the UBM then reflowing. Solder paste reduces waste, cleaning is inexpensive, and the paste comes in a variety of compositions, including eutectic Sn-Pb. The difficulty with paste arises at fine pitch applications where the rheology of the paste makes it difficult to force into the required small holes in the screen. Solder may also be plated, which is inexpensive (no waste and easy cleaning) and has excellent fine pitch coverage. Solder bumps of a pitch of 25 mm have been achieved by plating. The difficulty with plating is achieving ball and compositional uniformity.

The trend in flip chip interconnect pitch is that the current 250 μm pitch will continue to shrink. The driving force for this pitch shrink is to satisfy the requirements for high-performance silicon devices. These requirements include a dramatic increase in the number of I/Os due to increases in the number of signal lines and power requirements. Higher power devices require more signal and ground lines and, to limit point sources of heat, the power and ground interconnects should be spread evenly across the area array.

There are a number of materials and processing challenges associated with finer pitches. As the pitch shrinks, the methods to deposit the solder become more limited. Solder paste is very difficult to deposit using a silk-screen method at pitches below 150 μm due to rheological limitations of forcing a semisolid (the paste) into small holes (the silk screen). Evaporation is difficult because developing a metal screen mask with the required tolerances is prohibitively expensive. Solder plating is still a good option but the solder must be very uniform across each die. Solder ball uniformity is critical because large variations between die could result in electrical opens, for small balls, and shorts, for large balls. At 250 μm, ball uniformity across a die is 10%, at 150 μm this decreases to 5% and the change in dimension tolerance is 12.5 μm down to 3.75 μm. An additional issue with a decrease in ball size is the joint gap between the substrate and the die decreases to the point that it may become very difficult to flow underfill completely under the die. At 100 μm pitch the gap between the die and substrate could be significantly less than 25 μm, below the limit of underfill flow. For these very fine pitch applications an alternative underfill technique will need to be developed because flow under the chip will not be possible. One alternative would be to deposit the underfill material on the wafer immediately after flip chip solder bumping then underfill cure would simultaneously occur during solder relfow. New underfill materials and processes must be developed to implement this process.

53.5.2 Flip Chip for RF

Flip chip provides substantial improvements in off-circuit RF performance because the inductance is decreased as the ball height and shape is very consistent and predictable. Wirebond lengths can vary (typically $+/-100\,\mu m$) resulting in parasitic variations not observed in flip chip interconnects. The number of I/Os on an RF circuit is generally small so the pitch of the interconnects is generally quite large.

The die interconnects on GaAs are typically Au whereas on Si they are Al. A UBM is required for Si applications because solder does not wet Al. The solder would wet the Au of the GaAs but the Au layer is very thin and would dissolve the entire Au layer very quickly so a UBM is also required for GaAs. The UBMs available for Si can also be applied to GaAs but can be simpler because the adhesion of other metals to Au is easier to achieve than it is on Al.

The solder alloys for GaAs flip chip bumps tend to be similar to that for Si but with a greater emphasis on Au-based alloys because of the desire to use a highly conductive material such as Au for very-high-speed applications. Eutectic Au-Sn, Ag and In alloys have been commonly used but the wetting of these solders is typically poor. For finer pitch applications on GaAs (due to small die size, not large numbers of I/Os) other materials with good wetting are needed. Conductive adhesives have been explored for GaAs bumps. Work by *Lin* et al. [53.15] found no significant difference in electrical performance up to 2 GHz between a conductive adhesive and Au-Sn solder. The use of underfill for flip chip packages can cause a major loss in RF energy because the high dielectric constant of the underfill polymer is greater than that of air. With a conductive adhesive localized to just the bond pads, not the entire surface of the die, this RF loss will not be observed.

53.5.3 Pb-Free

The electronics industry extensively uses Pb-Sn solder alloys in flip chip applications as well as in many

other interconnects in the electronic package. However, medical studies have shown that Pb is a heavy metal toxin that can damage the kidneys, liver, blood, and central nervous system. Less than one percent per year of the global Pb consumption is used in solder alloys for electronic products but electronics and electrical systems make up an increasingly larger fraction of landfills [53.16]. The issue of Pb leaching from landfills into the water table has raised alarm as a potential source of long-term contamination of soil and ground water. Concerns about the presence of Pb in the environment and potential exposure scenarios that could result in the ingestion of Pb by humans and wildlife has prompted a concerted effort to limit the use of Pb in manufactured products (notably gasoline, plumbing solders, and paint). International laws have recently been proposed to expand Pb control laws to limit or ban the use of Pb in manufactured electronics products. The most aggressive and well-known effort is the European Union's Waste in Electrical and Electronic Equipment (WEEE) directive that proposed a ban on Pb in electronics by 2006. The Japanese Environmental Agency has proposed that Pb-containing scrap must be disposed of in sealed landfills to prevent Pb leaching. Electronics manufacturers have responded to these proposed bans in a variety of ways. Many companies have not taken a stance hoping that legislation will not be enacted. Other companies have aggressively pursued solutions to the proposed bans and are using Pb-free products as a *green* marketing strategy. Extensive research on Pb-free solders has been published. A comprehensive review of the status of Pb-free solders can be found in the literature that is primarily focused on carrier-to-board (surface mount and through-hole) interconnects [53.17–21]. A growing requirement is Pb-free solders for flip chip interconnects.

One benefit of a Pb-free flip chip interconnect is the reduction of Pb^{210}-created alpha particle radiation. All mined Pb contains a small amount of radioactive Pb^{210} that decays and emits alpha particles. When an alpha particle enters an active element of the Si (such as a memory cell) it has sufficient energy to cause the stored charge to be released with the result of changing stored memory from a 1 to a 0 state. There is no permanent damage to the Si itself so this radiation induced fault is termed a *soft error*. The alpha particles have a low energy that is dissipated over relatively short distances. However, due to their proximity to active elements, the flip chip solder interconnects have sufficient levels of alpha particle radiation to induce soft errors in CMOS technology that becomes more critical as cell size on the die is reduced [53.22, 23]. For Pb-Sn solders, one solution to alpha particle radiation is to use elemental Pb that was mined many, many years ago where the majority of Pb^{210} has decayed. The source of this Pb is typically found as the ballast of shipping vessels that sank almost 2000 years ago and is relatively expensive. The elemental constituents of Pb-free solders (Sn, Cu, Ag, Bi, In, Sb), however, do not radioactively decompose so alpha particle radiation is minimal.

Flip chip interconnects are the electrical and mechanical connections between the semiconductor integrated circuit and the package (or board for direct chip attach DCA). These interconnects are formed on the periphery or in an area array on the top surface of an active die. Flip chip interconnects are formed by depositing solder onto a metalized Si wafer in the form of discrete balls, solder paste or by directly plating onto the pads on the wafer. The solder must wet and join to the pads on the Si devices so an under bump metallurgy (UBM) is typically deposited on the Al or Cu pads on the Si. The UBM typically consists of a barrier metal (e.g., Ti or W) followed by a solder wettable layer (e.g., Cu or Ni). The top layer of the Ni metalization is covered with a noble metal, such as Au, to prevent oxidation that inhibits solder wetting. The UBM also acts as a diffusion barrier between the Si and the solder and must be thick enough to withstand interactions (intermetallic formation) between the solder and UBM. Flip chip interconnects are smaller (on the order of 100 μm diameter) than surface mount joints and are projected to have pitches that shrink below 150 μm. Flip chip interconnects have a unique set of requirements. These joints must be able to withstand a potentially high level of strain mismatch between Si and an organic substrate. Flip chip technology has moved from ceramic packaging with high-Pb solder (97.5Pb-2.5Sn) to an organic package that requires lower-temperature reflow ($< 260\,^{\circ}C$). This can be accomplished by bumping the die with high-Pb solder then joining it to an organic board with eutectic Sn-Pb but this is a cost adder that is eliminated with a monolithic solder. The joints must withstand board-level reflow environments compatible with joining to organic substrates that, again, have a maximum reflow temperature of $260\,^{\circ}C$. The Pb-free solder must meet these requirements and perform at, or above, the level of performance of the Sn-Pb solder it is intended to replace. The flip chip solder alloy is typically deposited on Si wafers either as solder paste stencil printed on the defined UBM pads or direct plating on the UBMs. The simplicity and low cost of plating the solder for flip chip interconnects makes electrochemical deposition the most attractive choice for flip chip bumping.

53.6 Substrates

The move to an organic substrate is the focus of an extensive development effort worldwide by both printed circuit board manufacturers and traditional suppliers that requires significant amounts of capital. Cost savings are expected by replacing ceramic substrate with organic substrates. One stated reason for moving to an organic substrate is based on the belief that, in volume production, organic materials are less expensive than ceramics due to the nature of printed circuit board processing. The organic substrate also offers an increase in electrical performance due to a lower dielectric constant (therefore, less capacitance and better speed) of 3.5 for organic versus 5.0 for ceramics.

Advanced substrates for flip chip must also provide increased wireability while delivering improved electrical performance with reliability levels at least equivalent to current surface mount applications. The board interconnect density for flip chip substrates must accommodate the increasing density of off-chip interconnects, and cost-effective substrate capability that combines the necessary fine line and microvia features must be developed. Microvias are the metal-filled holes that provide a conduction path between copper lines in the multiple layers of an organic substrate. Microvia capability must also scale with line width/spacing in order to provide the *via in line* structures that will be necessary to support bump pitch densification. At 250 µm pitch, microvias can be created using a photolithographic process. At a finer pitch, laser drilling techniques are used to create the required small via size to support the smaller capture pads and facilitate the dense routing required for flip chip.

Materials with dielectric constants approaching 2.0 with coefficients of thermal expansion approaching 6.0 ppm/°C are necessary to meet fine pitch requirements. Furthermore, uniformity and flatness requirements must be improved on organic substrates to ensure uniform joint size and bonding across each die as the interconnect pitch decreases.

The change in substrate materials drives the need for a lower-melting-temperature solder to replace the high-Pb-content Sn-Pb alloys that are processed in excess of 300 °C for ceramic substrates. The organic materials in a substrate are typically epoxy-based and char or burn at temperatures in excess of 250 °C. The most common solder alloy candidate is near-eutectic Sn-Pb that can be processed well below 250 °C ($T_{mp} = 183$ °C). However, this could result in a situation where the flip chip interconnect melts every time a subsequent solder reflow occurs. Multiple reflows of the solder interconnects accelerates intermetallic growth between the tin of the solder and the metalized pads for the UBM and substrate. One way to circumvent this issue is to deposit low-melting-temperature eutectic Sn-Pb solder on the substrate lands, or on the high-melting-temperature solder bump. Reflow to the substrate can be performed at eutectic Sn-Pb soldering temperatures but the mixing between the high-Pb content and eutectic solder results in a higher melting temperature composition. Subsequent reflows, at eutectic Sn-Pb processing temperatures, will not remelt the *composite alloy* flip chip joint. This addresses the low-temperature processing requirements for organic substrates but does not address the low-κ dielectric low-temperature processing requirements because the high-Pb-content solder must still be reflowed on the silicon.

53.6.1 RF Substrate Materials

Optimum electrical performance is achieved in an RF module when the signal-carrying conductor is adjacent to the ground plane to contain the electric field. In microstrip designs the conductor is above the ground plane and in coplanar designs the conductor is sandwiched between ground plans as shown schematically in Fig. 53.8. These designs affect the materials in the package. The impedance of the lines is desired to be 50 Ω (which matches the radiation impedance of the antenna to air). The impedance is affected by the conductor material, typically Au, and the dielectric material (Si, SiGe, GaAs, for the die and LTCC, Al_2O_3 or epoxy (organic) for the substrate).

Like its digital counterpart, RF packaging is moving away from the Al_2O_3 ceramic substrates used in RF

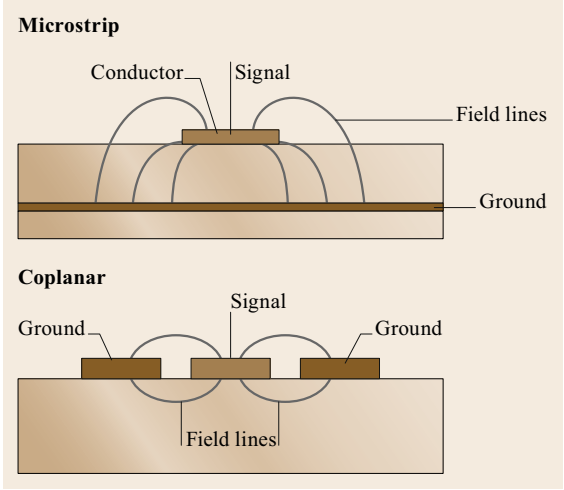

Fig. 53.8 Schematic illustration of RF electric field lines in the microstrip and coplanar designs

applications to the lower-cost solution of LTCC and organic. The metalizations used are Cu on the interior of the substrates and Au as the top layer metalization to improve RF performance.

Organic substrates offer a lower-cost solution. This substrate is built in a laminate structure with punched or laser drilled holes that are subsequently plated for interlayer via interconnects. The laminant layers are variations of epoxy and glass optimized for low dielectric constants. LTCC substrates are also laminant structures of sheets of LTCC with laser drilled and plated vias. Recently, LTCC materials have been optimized to not shrink in the *x*-*y* plane during the sintering process (*z*-direction shrinkage, however, is significant). The LTCC laminants are extremely thin compared to organic, and offer the opportunity to build complex RF substrates.

An additional trend in RF substrate technology is to move the discrete functions of RF module circuits from surface-mounted components to embedding them in the substrate. These embedded functions are typically capacitors and inductors and occasionally resistors. This can be done because the substrate material is dielectric and metal; the basic components of passive devices. The advantages of embedding components are reduced size, reduced cost and improved performance. Size can be reduced because surface-mounted components take up a great deal of the surface of the substrate. By embedding these components, they are thinner and area is reduced. Cost is reduced because the embedded passives are formed as part of the laminant layers by patterning the metal/dielectric and is essentially *free* because the patterning would be done regardless. Performance can be increased through the smaller size of the module. The embedding of components in substrates does offer opportunity for improved materials. Performance could be improved by finding means to alter the material properties of regions of the laminant layers to optimize the electrical performance of discrete components that are to be embedded (i. e., *seed* regions of the substrate for optimal capacitance, inductance and resistance).

53.7 Underfill and Encapsulants

53.7.1 Underfill

Flip chip technology demands that the space between the chip and the substrate be filled with a dielectric organic material to help mechanically interlock the chip to the substrate. The majority of underfill material available is a silica-filled anhydride resin polymer. The filler provides the strength in the composite polymer and the resin bonds with the die and substrate. Without the underfill the difference in coefficient of thermal expansion between the chip (3 ppm/°C) and the substrate ($\approx$ 17 ppm/°C) would quickly result in fracture of the solder interconnects when variations in temperature occurred. New underfills must be developed to accommodate increased bump density and shrinking bump height. As bump density increases and pitch decreases, the underfill must flow into smaller and smaller spaces. A 250 μm pitch requires an underfill with a thickness of 110 μm. At a 150 μm pitch, the dimension between the chip and substrate will be less than 50 μm but 100% fill of underfill is still required. Traditional flow dispensing and cure may not be suitable in these thin spaces due to a lack of capillary driving force (current underfill materials flow through a minimum thickness of 75 μm). For very thin fill spaces, wafer level deposition of the underfill needs to be developed. This wafer level deposition involves spin-on of an uncured polymer to a uniform thickness slightly less than the bump height. The wafer would then be diced and die-mounted on substrates. Reflow would form the solder joints and cure the underfill simultaneously. The filled polymer must be spun to a uniform thickness of 25 μm or less, bond well with silicon and substrate materials, and be compliant.

53.7.2 Encapsulation

Encapsulation of electronic packages is required to protect the electronic components from environmental degradation such as moisture contamination and mechanical damage, and provide electrical isolation. The encapsulation material is a polymer that flows over and covers the electronic components then cures into a solid. For electronic packaging, the most common method to apply the encapsulation is transfer molding. Figure 53.9 is a schematic illustration of the transfer mold process. The transfer mold compound material is typically a thermoset cross-linking polymer. The polymer resin portion consists of 25–35% of the total mold compound (by weight) and consists of epoxy resin, a hardener and a curing agent. The mold compound material is filled with powders of silica (SiO_2), alumina (Al_2O_3) or glass (65–75% of the total weight) to reduce the thermal expansion coefficient of the polymer and add strength. Amorphous silica is used for a minimum thermal expansion coefficient but results

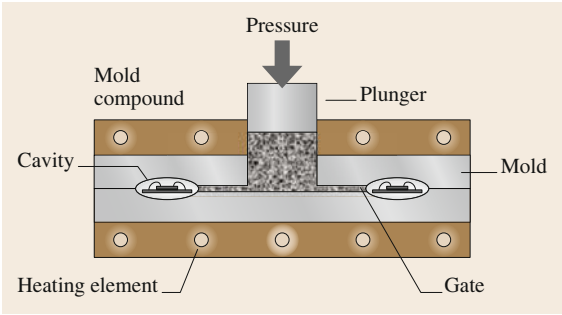

Fig. 53.9 Schematic illustration of the transfer mold process

in a decrease in thermal conductivity. Crystalline silica improves thermal conductivity but is abrasive to the molds. Small amounts of pigments (to color the mold compound), accelerants, flame retardants, mold release agents, getterers, and antioxidants are also added to the final mold compound. Pellets of the mold compound are placed into a heated cavity at the top of the mold and pressure is applied by a ram that pushes the liquefying materials into the mold. The material is forced through channels and through a constriction (called the gate) that provides back pressure and regulates the flow rate of the molten mold compound. After passing through the gate, the mold material flows across the component being encapsulated. The heat is turned off and upon cooling the polymer cross-links, with the use of a curing agent (typically an amine) that is present in the mold compound. The mold compound material has good adhesion, good stability with regards to temperature, chemicals, and the environment. They cure rapidly, have low permeability to moisture and high dielectric strength.

The transfer mold process has the advantage that part dimensions are very well controlled. The process and materials are low cost and high-volume manufacturing is possible.

An issue with mold compound encapsulation processing is wire sweep where the force of the viscous encapsulant can push bond wires to short with one another. This has been addressed with optimized filler size and shape and the mold temperature and pressure. After molding, the difference in thermal expansion between the cured mold compound and the rest of the package (the substrate, leadframe, semiconductor device, etc.) can result in considerable stresses at the interfaces. Furthermore, the CTE of mold compounds changes when the material goes above the glass transition temperature, T_g. T_g is the temperature at which the polymer changes from a rigid structure to a softer more glass-like structure. Below T_g, the CTE of typical mold compounds is $20\times10^{-6}\,(^{\circ}\mathrm{C})^{-1}$ but above T_g this can increase to $60\times10^{-6}\,(^{\circ}\mathrm{C})^{-1}$ or $70\times10^{-6}\,(^{\circ}\mathrm{C})^{-1}$. The T_g of mold compounds varies but is usually 175–200 °C, below the solder processing temperatures that are typically in excess of 220 °C. After cooling from mold processing, the mold compound forms a compression seal with the lower expanding materials (leadframe, substrate, semiconductor). However, upon heating to solder process temperatures the stress is reversed to tensile and can result in interfacial cracking, or delamination. The interfacial cracks provide a conduit for the ingress of water or ionic contaminants that could result in corrosion of metals in the package (particularly Al bond pads). This issue must be addressed by optimizing the mold compound to the package application (materials and size) to minimize strain and to maximize interlocking mechanisms between the mold compound and the substrate/leadframe.

Mold compound encapsulation is generally detrimental to RF device performance. The encapsulant materials are nonuniform and degrade performance because the electric field generated by the RF circuit in the encapsulant is nonuniform resulting in lossy behavior. Many high-performance RF packages are designed with a cavity and are made out of ceramic with a metal lid to form the cavity. However, plastic encapsulation is required for suitable, low-cost, reliable packages, so a trade-off must be made for performance, reliability and cost.

53.8 Electrically Conductive Adhesives (ECAs)

Electrically conductive adhesives (ECAs) are composite materials consisting of a dielectric curable polymer and metallic conductive particles. ECAs are low-process temperature alternatives to solder alloys. The polymer is an adhesive material that chemically reacts with metals to form a bond. The metallic particles in the adhesive form a network in the cured joint that forms a conduction path in area-array applications.

53.8.1 Adhesive Polymers

The polymer portion of the adhesive is available in two forms: thermoplastic and thermosetting. A schematic illustration of these two types of polymers is shown in Fig. 53.10. A thermoplastic polymer is a linear chain of linked monomers (nominally, hydrogen-carbon bonds). After curing, thermoplastic polymers become

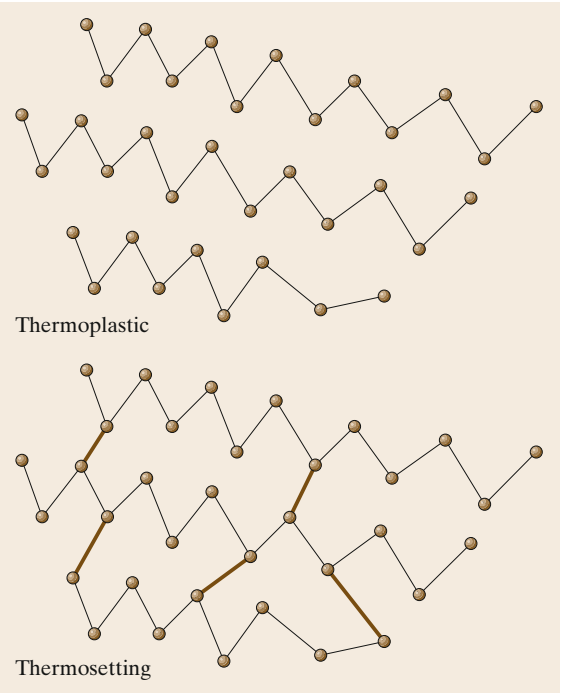

Fig. 53.10 Schematic illustration of polymer bonds for thermoplastic (linear bonds) and thermosetting (cross-linked bonds) electrically conductive adhesives

more rigid, but remain flexible. As temperature is increased, these polymers essentially become molten. This provides a method to repair or replace components with thermoplastic joint area-array joints. Thermosetting materials are similar to thermoplastic, except that monomer chains become cross-linked in three dimensions during the curing stage. The number of cross-links determines the rigidity and the glass transition temperature (T_g) of a thermoset polymer. In general, the more cross-links, the higher the T_g. A curing agent (e.g., a hardener) can be added to thermoplastic polymers to cause the cross-linking reaction in these materials as well. Curing can be performed using UV light, heat, or catalysts. Thermosetting materials are harder than thermoplastic, but can be processed and cured below their T_g and do not become *molten* above the T_g. However, the curing operation is not reversible, making repair difficult. Examples of thermosetting materials include epoxies and acrylics. ECAs are typically made using either thermosetting or thermoplastic polymers, or a combination of the two.

53.8.2 Metal Fillers

A number of metals have been used to provide the electrical conductivity of ECAs. The metals typically are in the form of flakes, plates, rods, fibers, or spheres. The size of the metal particles ranges between 5 and 20 μm. For the ECA to have suitable strength and electrical conduction requires a trade-off in metal filler content. The greater the metal content, the better the electrical conduction, but the poorer the strength of the adhesive. The metal content depends upon whether the adhesive is an isotropic or anisotropic conductor (described below), but does not usually exceed 40% by volume.

The metals most often used in ECAs are silver, gold, nickel, copper or variations of these (such as gold on nickel, silver on glass, or nickel on polymers). Silver-filled ECAs are the most common, because the cost of the metal is moderate and has good electrical conductivity and low reactivity with oxygen. Gold has better physical properties than silver but the cost is prohibitive for most applications. Nickel is less expensive, but also has lower conductivity than either Au or Ag and has been found to corrode when aged in a humid environment resulting in poor adhesion between the nickel and the epoxy matrix. Copper fillers oxidize rapidly and also delaminate from the polymer matrix.

53.8.3 Conduction Mechanisms

The mechanism of conduction in ECAs is hypothesized to occur via percolation where current travels through a three-dimensional matrix of contacting particles. There must be a sufficient quantity of particles present in the adhesive to provide a suitable conduction path. The bulk resistivity of 60Sn-40Pb solder is 15×10^{-6} Ωcm, while that of ECAs range from 7×10^{-5} to 5×10^{-4} Ωcm [53.24]. Therefore, the conduction of solder is 5–33 times better than ECAs. This difference in conductivity is due to the fact that only a portion of the joint cross-section is available to provide the percolation path in ECAs whereas the entire cross-section of solder joints conducts electricity. The loss of electrical conductivity does not severely affect second-level interconnects but could be an issue for first-level interconnects where good conductivity and switching speed may be required. For the current to pass from one metal particle to another, it must pass through, at a minimum, the oxide that forms on the metals or, at worst, some distance through the polymer matrix. It has been proposed that contact resistance is overcome by tunneling or bulk conduction through the semiconducting metal oxide layer. However, measured electrical conduction has been determined to be better than any of the mechanisms described above [53.25]. It is possible that, in silver-loaded ECAs, silver diffuses out of the particles into microcracks in the polymer matrix, thereby creating additional conduction paths. To date, the details of the conduction mechanisms remain unresolved.

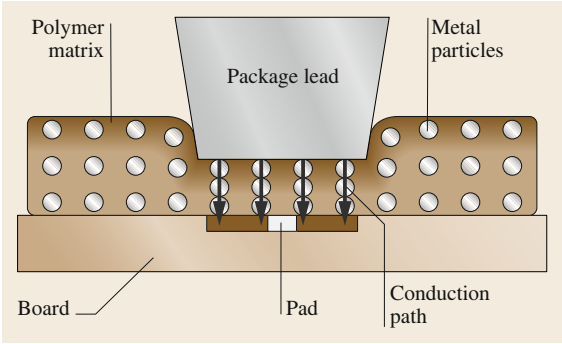

Fig. 53.11 Schematic illustration of an anisotropic electrically conductive adhesive. The adhesive is compressed causing the conductive particles to contact one another in the *z*-axis forming an electrical path between terminal pads. Outside the pad region, the metal particles are separated by the polymer and the AECA acts as a dielectric

53.8.4 Isotropic Versus Anisotropic Conduction

ECAs are available in two types of conductors, isotropic and anisotropic. In isotropic adhesives, the conduction path is uniform in all directions with a filler metal content sufficiently high to create a percolation path for the conductor. Anisotropic ECAs (AECAs, also called a *z*-axis conductors) only have one direction of conduction, useful for fine-pitched applications. In general, anisotropic ECAs are prepared by dispensing metal particles in the polymer matrix at a level far below the percolation threshold. Pressure is imposed on the contact so that the particles come into contact with one another in one direction (parallel to the direction of imposed pressure). In the areas where no pressure is imposed, there is no conduction path and the adhesive is electrically insulated. This is illustrated in Figure 53.11. In area-array applications, anisotropic ECAs can be applied to the board but conduction will only take place between package and mating board pads due to the compression resulting from the cured adhesive causing particle-to-particle contact between mating pads. No metal particle contact is made beyond the terminal pads, thus the adhesive is an insulator in those areas.

The terminal pad surface to which ECAs or AECAs are to be joined must be oxide free for the adhesive to form a cohesive joint. Bare copper typically provides very poor adhesion [53.26] because adhesives do not wet or react well with metal oxides, and in this way adhesives are similar to solder alloys. To overcome this problem, copper can be plated with nickel ($\approx 0.5\,\mu m$) and a thin layer of gold ($\approx 500\,Å$). Gold is an excellent bonding surface because it is virtually free of surface oxide and provides a diffusion barrier for nickel. Unlike solders, ECAs do not allow the luxury of using flux to remove oxides during processing so oxide removal surface treatments must precede dispensing the adhesive. The stability of ECA joints is directly related to the quality of the bond interface with terminal pad metalizations. In general, the less surface oxide present, the better the electrical stability. If surface oxide is present, there can be de-adhesion at the interface resulting in a reduced ability to carry electrical signals. The bonding of ECAs to other polymers, such as printed wiring board surfaces (FR-4 or polyimide) is excellent. Area-array component requirements are more stringent in the case of ECA joints compared with solder bumps. Solders only wet metal surfaces, so special processing steps are not needed to define solder-joint locations. For ECAs, the method of depositing the ECA must be precise (or use an anisotropic ECA) so that electrical shorts do not occur and this is exasperated in area-array fine pitch applications and the interconnects not easily inspected because they are hidden beneath the joined component.

53.8.5 Rework

The ability to perform rework on conductive adhesive interconnects may limit the use of these materials for many applications. Thermoplastic adhesives can be reworked by heating and *melting* the joint allowing components to be separated from the assembly. Thermosetting bonds are not reversible but can be softened by heating well above T_g and then removed. Some acrylic adhesives can be cleaved at room temperature and physically removed, although the brittle nature of the acrylics that allows for removal may also represent too great a joint reliability risk.

53.9 Thermal Issues

53.9.1 Thermal Issues in Digital Packaging

Increasing circuit and component density creates thermal complications that must be resolved by the packaging solution. Excessive temperatures in the devices result in degraded circuit performance or reliability issues. The thermal performance can be improved by using packaging materials with high thermal conductivity.

The operating temperature of Si directly impacts switching speed and timing. In the operating temper-

ature range of 50–100 °C, a 5 °C drop in operating temperature results in a 1% increase in CMOS switching speed. From a reliability perspective, each 10 °C increase in operating temperature results in a 2× increase in the die failure rate. Therefore, packaging materials and processes that improve thermal performance are very important.

New materials are the area where the most significant improvements in thermal performance are possible. Improved thermal interface materials (greases, adhesives, tapes, phase change materials) will improve the heat flow out of the package. Improved adhesives and compliant sheets inside the package will improve heat dissipation from the die and can better accommodate CTE mismatch strains within the package.

Composite materials for package lids, heat spreaders and heat sinks are needed. Currently, these components face a dilemma of conflicting material properties of good thermal conduction materials (e.g., Al) have very high CTE (e.g., Al = 25×10^{-6} /°C) that can result in poor reliability. Furthermore, most low-cost thermal conductors are also electrical conductors making their use in dielectric packages problematic. The development of composite materials with anisotropic conductivities can provide excellent thermal conduction with matched CTE and the potential for a good electrical isolation. At the die level, the use of low-cost thin-film diamond must increase. Diamond has excellent thermal conductivity and isolation but is currently too expensive for extensive use in microelectronic packaging.

53.9.2 Thermal Issues in RF Packaging

RF die can generate a great deal of heat in operating at high frequencies. This is particularly an issue with GaAs die because it has poor thermal conductivity (30W/mK). The generated heat must be dissipated through the package. The preferred method to remove heat from wirebonded GaAs die is to thin the GaAs wafer by back-grinding to 100–125 μm. The thinner the die, the easier it is to transmit heat through the GaAs. Through-die vias are also used to help dissipate heat. The vias are formed by laser drilling holes through the GaAs then plating the side walls with Au and thinning the wafer. Thinning the wafer not only benefits heat dissipation but also reduces the distance from the conducting layer on the surface of the die to the ground plane on the die backside that improves impedance match in microstrip designs.

The problems with through-die vias and wafer thinning are cost and die breakage. Laser drilling and thinning processes increase the cost of the die. Furthermore, GaAs is a very brittle material, so that the presence of vias and thinning exacerbates potential cracking.

One method to reduce the thermal and mechanical problems associated with thermal issues on GaAs is to use flip chip interconnects. For flip chip, the bumps act as electrical, mechanical and thermal interconnects. The bumps are on the front side of the die so full thickness die can be used. The challenge with flip chip as a thermal conductor is to put sufficient numbers of bumps on the die to dissipate the heat.

53.10 Summary

Materials are one of the most important aspects of microelectronic packaging. There is a need for new materials to be developed to meet the ever-changing requirements for high-speed digital and RF applications. Considerable resources are required to develop and characterize these materials. These materials must also be tested to determine their compatibility with assembly processes and device performance and meet industry standards. The fundamental material characteristics that must be understood, depending upon the material, include: dielectric constant, dielectric loss, conductivity, resistivity, moisture absorption, glass transition temperature, strength, time dependent deformation (creep), and fracture toughness.

54. Organic Solar Cells

Masahiro Hiramoto, Yusuke Shinmura

One of the responsibilities of scientists is to help develop new ways in which we can generate energy, since gaining control over energy resources such as petroleum has been one of the main reasons for conflict between nations. Renewable energy generated by solar cells is one of the potential solutions to the problem of maintaining our energy supply and these have been studied intensively for about half-century. Today, silicon solar cells have already been commercialized and have become an indispensable source of electricity. However, the price of electricity produced by silicon solar cells is still higher than that produced by petroleum. In order to increase the production of energy by solar cells, the price of electricity produced by solar cells needs to be lower than that produced by petroleum. Organic solar cells have the potential to be part of the next generation of low-cost solar cells. There was a steep increase in the power-conversion efficiency of organic solar cells around the year 2000, indicating that the technology needed to bring them to a commercial level would be established by around 2020, taking into consideration the example of organic electroluminescent devices for which scientific breakthroughs were made in 1987 and commercialization occurred around 2010. Now, in 2015, the power-conversion efficiency of organic solar cells has reached 12%.

Organic solar cells have many advantages; they are flexible, printable, light weight, and low cost, can be fashionably designed, and can be fabricated by roll-to-roll production, etc. Printed organic solar cells can be attached to the roofs, windows, and walls of houses and buildings. Automobiles wrapped with colorfully printed organic solar cells can be fabricated. Moreover, they are suitable for constructing solar power plants in space, since their light weight allows them to be easily put into orbit. In this section, the history, fundamental principles, and recent progress in organic solar cells are summarized.

The most essential factor for organic solar cells is the existence of excitons, that is, strongly bound electron–hole pairs. To efficiently generate photocarriers from excitons, donor–acceptor sensitization is used. Fullerenes acting as acceptors are used in present organic solar cells. Since the diffusion length of excitons is extremely small, blended junctions are used. Route formation both for photogenerated electrons and holes to the respective electrodes by phase separation is required for organic blended junctions. The magnitude of the photovoltage that can be obtained is determined by the difference between the lowest unoccupied molecular orbital (LUMO) of the acceptor molecules and the highest occupied molecular orbital (HOMO) of the donor molecules. Utilization of tandem cells has been effective in increasing the power-conversion efficiency. Today, the power-conversion efficiency of organic solar cells has reached 12%. For the organic semiconductor films used in organic solar cells, both small molecule films deposited by the dry process of vacuum evaporation and polymer films deposited by the wet process of spin coating are used.

54.1 History

The first organic solar cell was fabricated by *Calvin* in 1958 (Fig. 54.1) [54.1]. For a long while, single films of small molecule organic semiconductors deposited by vacuum evaporation were used. Typical organic semiconductors were phthalocyanines (Fig. 54.2) [54.2] and merocyanine [54.3]. Most organic semiconductor films had p-type characteristics since oxygen molecules from the ambient air, acting as acceptors, inevitably doped the films. A photocurrent could be generated at the Schottky junction between the p-type organic film and a low-work function metal, such as Al. However, in the early stages of development, organic solar cells had little photocurrent, typically less than several microamperes [54.4, 5].

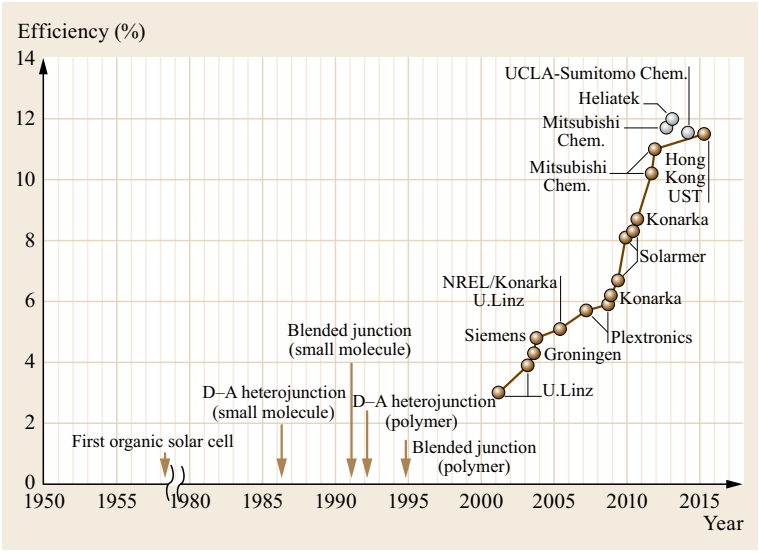

Fig. 54.1 The history of organic solar cells. The main breakthroughs are indicated by *arrows*. The efficiencies after 2000 (*dots*) are plotted according to the NREL chart. *Grey dots* are plotted according to the recent press releases

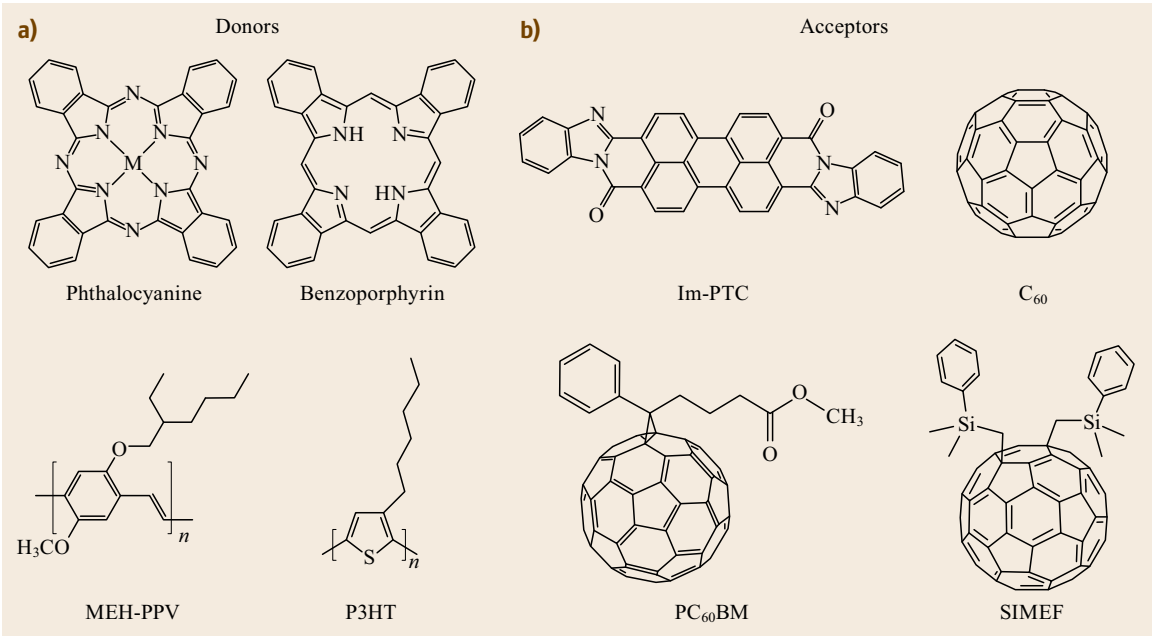

Fig. 54.2a,b Chemical structures of typical organic semiconductors acting as donors (**a**) and acceptors (**b**)

A breakthrough occurred in 1986, namely, the development of a two-layer organic photovoltaic cell, which had a large photocurrent density, of the order of mA/cm^2, and an efficiency of 1% (Fig. 54.1). This was as a result of the donor–acceptor sensitization reported by *Tang* [54.6], which has had a big impact on the field of organic solar cells. A blended junction for small molecule cells was proposed in 1991 by *Hiramoto* [54.7, 8]. In 1992, *Sariciftci* [54.9] reported a polymer heterojunction cell composed of C_{60} and MEH-PPV (poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene]) (Fig. 54.2), which was followed in 1995 by a bulk polymer heterojunction cell reported by *Yu* [54.10]. Typical combinations of donors and acceptors both for small molecular systems and polymer systems are shown in Fig. 54.2. Based on these fundamental studies, after 2000, the efficiency rose from 1% and started to increase rapidly and reached 12% by 2013. Nowadays, the photocurrent density of organic solar cells produced by solar radiation is approaching $20\,mA/cm^2$, which is comparable to the values produced by inorganic solar cells.

The main contributory factors to the increase in efficiency of organic solar cells can be summarized as follows:

1. Donor–acceptor sensitization
2. The use of blended junctions
3. Phase separation in the blended junctions
4. The use of tandem cells
5. The use of fullerenes acting as acceptors
6. Syntheses of new organic semiconductors.

54.2 Excitons

The dissociation of photogenerated electron–hole pairs (excitons) is a key factor for generating carriers in organic semiconductors. Exciton dissociation is affected by the relative permittivity of the solid (ε). The attractive force between an electron–hole pair is given by Coulomb's law

$$F = \left(\frac{1}{4\pi\varepsilon\varepsilon_0}\right)\left(\frac{q_1 q_2}{r_2}\right). \tag{54.1}$$

Here, ε_0, q_1, q_2, and r are the absolute permittivity, the elementary charges on the electron and the hole, and the distance between them, respectively. In a solid with a small value of ε, the positive and negative charges experience a strong attractive force, whereas, in a solid with a large value of ε, the positive and negative charges experience a relatively weak attractive force. Inorganic semiconductors have large values for ε. For example, the value for Si is 11.9 and the exciton has a large diameter of 9.0 nm and is localized over about 10^4 Si atoms (Fig. 54.3a). The thermal energy at room temperature is sufficient for this Wannier-type exciton to dissociate immediately into a free electron and a hole, thereby generating photocurrent. On the other hand, organic semiconductors have small values for ε. For example, the value for C_{60} is 4.4 and the exciton diameter is just 0.50 nm and is localized over a single C_{60} molecule (Fig. 54.3b). The thermal energy at room temperature is hardly sufficient for these Frenkel-type excitons to dissociate into free electrons and holes and they can easily relax into the ground state (Fig. 54.4a). Therefore, organic semiconductors generate few photocarriers. This is the reason why organic solar cells fabricated before the work of *Tang* [54.6] had extremely low photocurrents, of the order of less than a microampere.

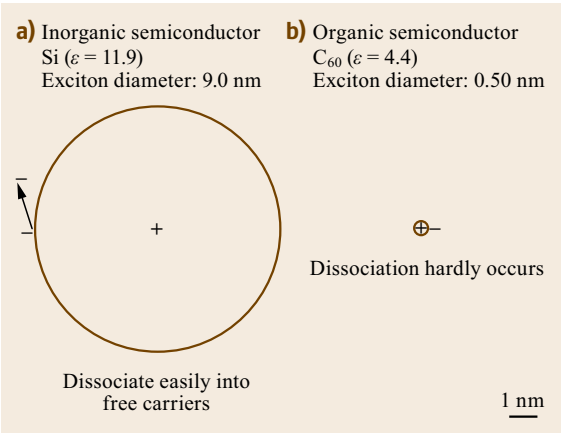

Fig. 54.3a,b Size of excitons for **(a)** an inorganic semiconductor (Si) and **(b)** an organic semiconductor (C_{60}). The former is a Wannier type and easily dissociates into free carriers. The latter is a Frenkel type and dissociates into free carriers with difficulty

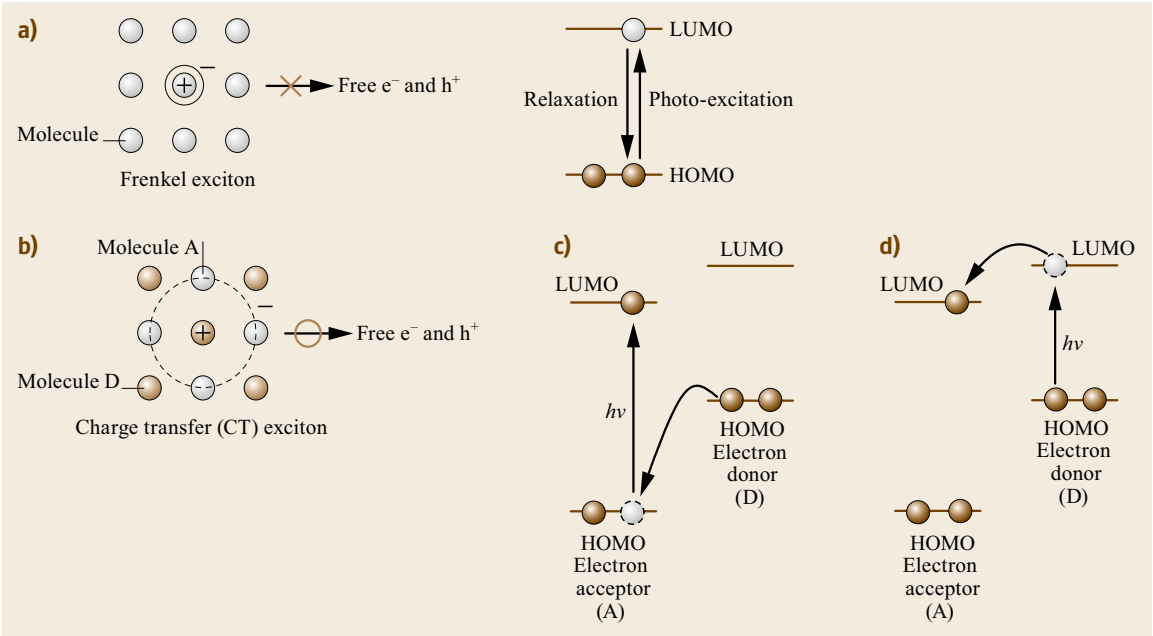

Fig. 54.4a–d Carrier generation in organic semiconductors. **(a)** Single molecule solids. **(b)** Donor(D)/acceptor(A) sensitization for carrier generation by mixing two kinds of organic semiconductor molecules. Efficient free carrier generation occurs from the charge transfer (CT) exciton. **(c)** Photoinduced electron transfer from the HOMO of the donor molecule (D) to the HOMO of the acceptor molecule (A). **(d)** Photoinduced electron transfer from the LUMO of the donor molecule (D) to the LUMO of the acceptor molecule (A)

54.3 Donor–Acceptor Sensitization

Today's organic solar cells have overcome the above problem by combining two kinds of organic semiconductor. An electron-donating molecule (D) and an electron-accepting molecule (A) for which the energetic relationship of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) are brought together in contact or blended. When the electron-accepting molecule (A) is excited, electron transfer from the HOMO of the electron-donating molecule (D) to the HOMO of the electron-accepting molecule (A) occurs, and as a result, the A molecule charges negatively (A^-) and the D molecule charges positively (D^+) (Fig. 54.4c). On the other hand, when the electron-donating molecule (D) is excited, electron transfer from the LUMO of the electron-donating molecule (D) to the LUMO of the electron-accepting molecule (A) occurs, and as a result, the A and D molecules charge negatively (A^-) and positively (D^+), respectively (Fig. 54.4d). Irrespective of the excitation of molecules (A) and (D), the charge transferred states (D^+A^-) obtained are the same. Thus, a CT exciton is formed in which the positive and negative charges are separated on neighboring D and A molecules due to photoinduced electron transfer (Fig. 54.4b). This CT exciton can dissociate to a free electron and a hole due to the thermal energy at room temperature. By utilizing this donor–acceptor (D–A) sensitization, organic semiconductors have become capable of generating photocurrents of significant magnitude; of the order of milliamperes, by solar radiation.

54.4 Exciton Diffusion

A two-layer organic solar cell (Fig. 54.5) [54.6] utilizes D–A sensitization at the heterojunction. The width of the photoactive region (*shaded brown*) is, however, limited to around 10 nm in the vicinity of the heterojunction

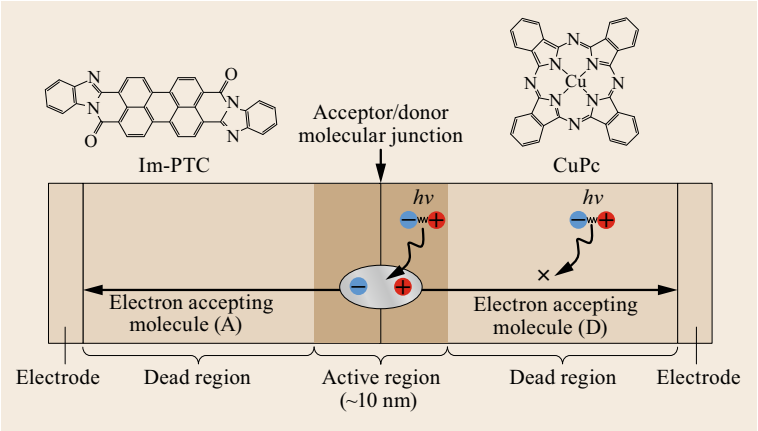

Fig. 54.5 Schematic illustration of a two-layer cell composed of perylene pigment (Im-PTC) acting as an acceptor molecule (A) and copper phthalocyanine (CuPc) acting as a donor molecule (D). Photocurrent is generated only in the active region (*shaded brown*) close to the heterojunction and all other parts of the organic films act as dead regions

due to the extremely small exciton diffusion length of just several nanometers [54.11, 12]. So, when the thicknesses of the organic layers are increased, the so-called *masking effect* occurs, namely, a dead region develops in front of the active region in which the incident solar light is absorbed and no photocurrent is generated, and as a result, the magnitude of the photocurrent is severely suppressed. A 10 nm-thick organic film can only absorb a small part of the incident solar light. However, in order to increase the efficiency of organic solar cells, it is necessary for the whole of the incident solar light to be absorbed in the 10 nm-thick active layer.

54.5 Blended Junctions

In order to overcome this problem, blended junctions in organic semiconductors, which contain both donors and acceptors, were fabricated using the codeposition technique for small molecule organic solar cells (Fig. 54.6a) [54.7, 8]. From the standpoint of photocarrier generation occurring at the molecular level, there are donor–acceptor molecule contacts acting as photocarrier generation sites due to donor–acceptor sensitization in the bulk of the codeposited layer. Blended junctions, usually called *bulk heterojunctions*, have become crucial for polymer organic solar cells [54.10].

Blended junctions are fundamentally physically the same as the porous TiO_2 in the dye-sensitized solar cells proposed by *Grätzel* in 1991 [54.13]. For both solid–solid and solid–electrolyte junctions, by transmitting the incident light through a vast number of heterointerfaces, the whole of the incident solar light can be absorbed in extremely thin active layers.

Figure 54.6b shows the energetic structure of the blended junction in a small molecule cell. Photogenerated electrons in donor molecules transfer from the LUMO of the donor molecule to that of the acceptor molecule and photogenerated holes in acceptor molecules transfer from the HOMO of the acceptor molecule to that of the donor molecule. This D–A sensitization promotes photocurrent generation. The original concept is that the positive and negative charges from ionized donors and acceptors in n- and p-type organic semiconductors, respectively, are compensated by each

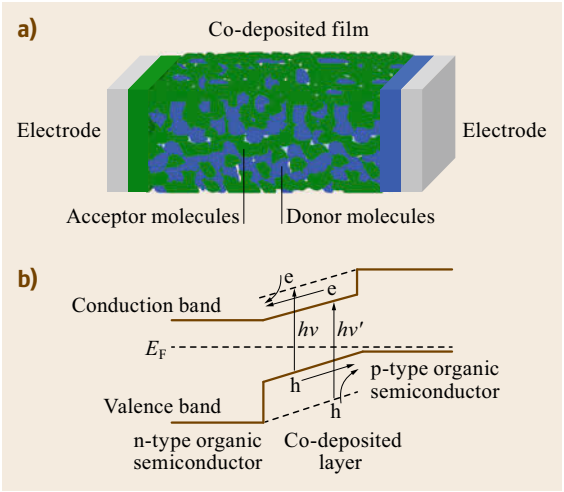

Fig. 54.6 **(a)** A small molecule cell consisting of blended junctions in an organic semiconductor, containing both donor and acceptor molecules. The entire bulk of the blended layer acts as an active layer for photocarrier generation. **(b)** Energetic structure of a blended junction in a small molecule cell

other, and the resulting codeposited interlayer behaves like an intrinsic semiconductor. With regard to the formation of the built-in potential in a molecular solid, the built-in electric field is distributed across an i-interlayer sandwiched between n- and p-layers, similar to the case of amorphous silicon incorporating a p-i-n junction.

54.6 Route Formation

Even if exciton dissociation occurs, nanostructure control of the codeposited films, that is, route formation for electrons and holes generated by exciton dissociation, is crucial in order to extract a significant portion of the photogenerated charge to the external circuit. Once the two kinds of organic semiconductors acting as donor and acceptor layers are blended, extraction of photogenerated holes and electrons inevitably becomes a tough problem, since they can only move through the electron-donating molecules (D) and the electron-accepting molecules (A):

1. *Molecular mixture*: When the two kinds of organic molecules are blended by the codeposition technique at room temperature, the codeposited films usually have an amorphous molecularly blended structure (Fig. 54.6a). Only a small number of carriers can be extracted since there are few routes for electron and hole transport.
2. *Phase-separated structure*: Routes for the electrons and holes are formed by percolation due to self-assembly promoted by annealing, while maintaining D–A molecular contacts in the bulk of the organic film (Fig. 54.7a) [54.15, 16].
3. *Vertical superlattice structure*: An ideal nanostructure is the *vertical superlattice* structure (Fig. 54.7b). This structure enables the efficient dissociation of photogenerated excitons at the D–A interfaces within the exciton diffusion length (5−10 nm) and the transport of electrons and holes

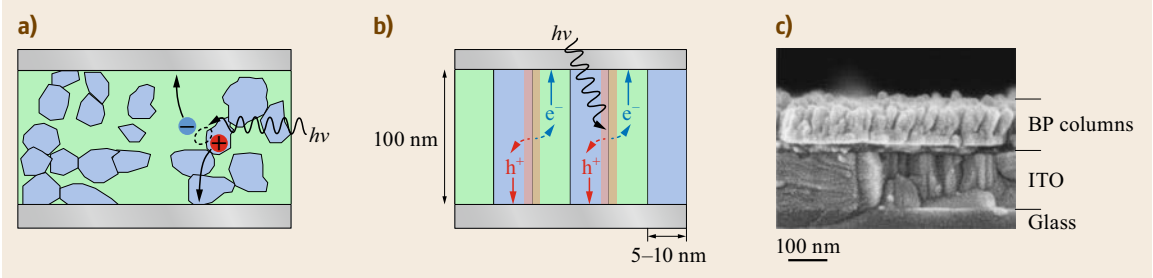

Fig. 54.7 (a) Phase-separated structure. (b) Vertical superlattice structure. to the respective electrodes. By changing the layer width, we can determine the exciton diffusion length to several nanometers [54.12]. It is a difficult task to construct such a structure by artificial design over a large area.

There are reports of the successful construction of such ideal nanostructures. A pseudo-vertical superlattice structure was fabricated by combining a new type of C_{60} derivative (bis(dimethylphenylsilylmethyl)[60]fullerene (SIMEF)), Fig. 54.2) with benzoporphyrin (BP, Fig. 54.2) [54.14]. BP is formed by thermal conversion from a precursor. Fabrication by wet processing was adopted, that is, the blended structure (Fig. 54.6a) was fabricated by a spin-coating technique. After removal of the C_{60} derivative (SIMEF) by washing in toluene, the desired interdigitated structure is made clearly visible (Fig. 54.7c). The round columns of crystalline BP with diameters of around 20 nm stand almost vertically. This structure allows excitons to dissociate within their diffusion length and ostensibly inhibits the recombination of photogenerated electrons and holes. In 2013, Mitsubishi Chemical Co. Ltd. succeeded in obtaining a power-conversion efficiency of 12% with this system. A commercial version using this system is shown in Fig. 54.8a,b, which shows a flexible see-through organic solar cell module and a demonstration building using these modules as exterior walls and windows [54.17]. This is a clear demonstration of the ideal vertical structure (Fig. 54.7c) showing practical conversion efficiency.

54.7 π–π Stacking

For efficient hole transport in blended junctions, π–π stacking of the organic semiconductor is necessary. The formation of π–π stacking of poly(3-hexylthiophene) (P3HT) in a [6,6]-Phenyl-C61 butyric acid methyl ester (PCBM):P3HT (Fig. 54.2) blend by means of a regular arrangement of long-chain substituents allowed the fabrication of highly efficient polymer solar cells [54.18].

Since the organic films are sandwiched between two electrodes, perpendicular orientation of the π–π stack to the substrate is more favorable to hole transport in the blended junctions. That is, face-on orientation (Fig. 54.9a) is more suitable than edge-on orientation (Fig. 54.9b). Blended cells using polymers with face-on orientation enabled high photocurrents to be obtained with thicker active layers without reducing the fill factor, resulting in an increase in efficiency [54.19].

54.8 HOMO–LUMO Gap

The maximum open-circuit voltage (V_{oc}) of photovoltaic cells consisting of a combination of donor–acceptor organic semiconductors is determined by the energetic difference between the LUMO of the acceptor molecule and the HOMO of the donor molecule ($V_{LUMO–HOMO}$) (Fig. 54.10a) [54.20]. In order to accomplish efficient exciton dissociation, about 0.3 eV is reported to be necessary, that is, the observed V_{oc} is around 0.3 V smaller than $V_{LUMO–HOMO}$.

In other words, in order to obtain high V_{oc}, a combination of donor–acceptor organic semiconductors having a larger $V_{LUMO–HOMO}$ difference is necessary (Fig. 54.10). One of the main reasons for the recent increase in power-conversion efficiency is the increase in V_{oc} due to the newly synthesized donor molecules having deeper HOMO levels (Fig.54.10b) [54.20] and the acceptor molecules having shallower LUMO levels (Fig. 54.10c) [54.21].

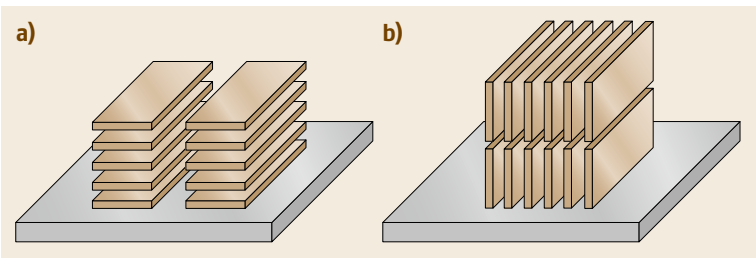

Fig. 54.9 (**a**) Face-on and (**b**) edge-on orientations of π–π stacking. Molecular planes are indicated in the figure. π–π stackings are formed perpendicular to the molecular planes

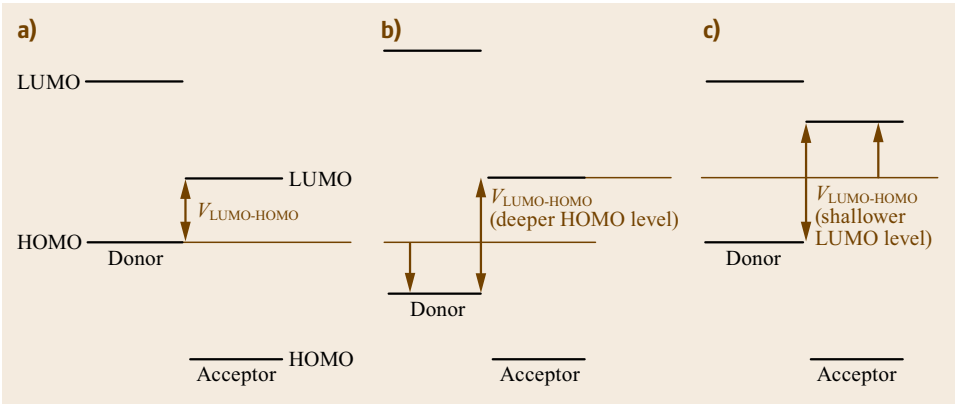

Fig. 54.10 **(a)** $V_{LUMO–HOMO}$ difference of donor and acceptor molecules. **(b)** $V_{LUMO–HOMO}$ difference using a donor molecule having a deeper HOMO level. **(c)** $V_{LUMO–HOMO}$ difference using an acceptor molecule having shallower LUMO level

54.9 Tandem Cells

The first organic tandem cell in which two unit cells were connected by metal nanoparticles was reported in 1990 (Fig. 54.11a) [54.22]. V_{oc} can be doubled by connecting two unit cells. Due to the very small diffusion length of excitons, even two very thin donor–acceptor heterojunction cells with identical absorption spectra joined together can increase the total effective thickness of the cells (Fig. 54.11b) [54.23]. Moreover, an efficiency of 5.3% was obtained with a tandem cell comprising two thin blended cells with identical absorption spectra (Fig. 54.11c) [54.24].

However, a more essential target of cells is to utilize the whole of the solar spectrum by combining cells that absorb light from different parts of the spectrum. Polymer tandem cells having double junctions [54.25] and triple junctions [54.26] utilizing the wide wavelength region from 300 to 900 nm had a V_{oc} of 2.28 V and an efficiency of 11.55%.

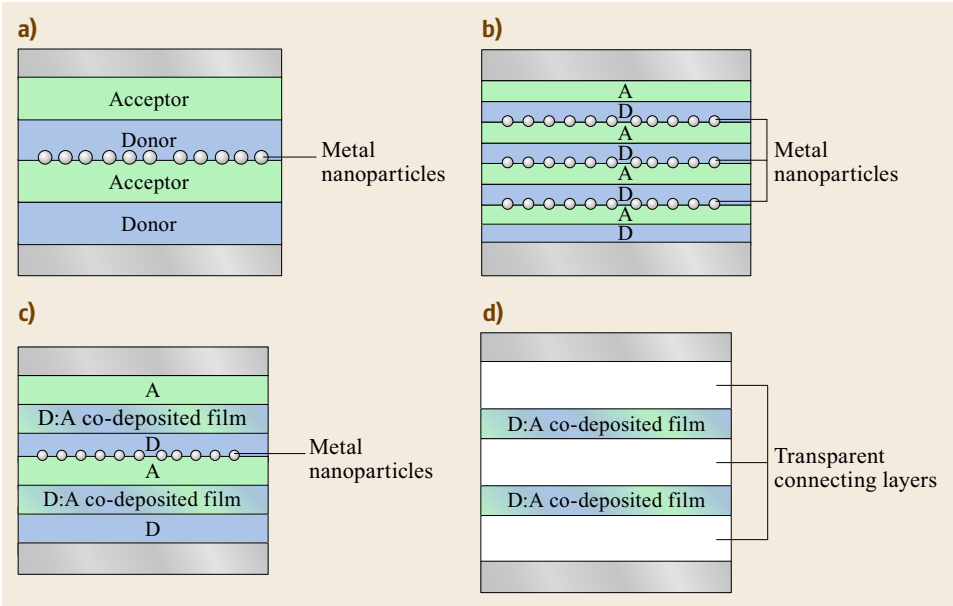

Fig. 54.11a–d Structures of organic tandem cells. **(a)** Two heterojunction cells connected together. **(b)** A series of many extremely thin heterojunction cells with identical absorption spectra. **(c)** Two thin blended cells with identical absorption spectra connected together. **(d)** Transparent connection layers with the optimum thicknesses

More sophisticated small molecule tandem solar cells (Fig. 54.11d) using transparent connecting layers of optimum thickness in which the electric field of light inside the cell is maximized in the photoactive layers of the codeposited films had an efficiency of 12% [54.27].

54.10 Conclusions

The basic components of organic solar cells, that is, excitons, D–A sensitization, exciton diffusion, blended junctions, route formation, π–π stacking, the HOMO–LUMO gap, and tandem cells, are summarized in this section. These components will help us in our search for further breakthroughs in the performance of organic solar cells. For example, (i) if we can utilize organic semiconductors with high ε values, exciton dissociation would no longer be a limiting factor for organic solar cells. (ii) If we can find organic semiconductors with significantly longer exciton diffusion lengths, exciton diffusion would no longer be a limiting factor for organic solar cells. On the other hand, the p-n-control of organic semiconductors by doping has become significant in the fabrication of organic solar cells [54.27–29].

Organic solar cells have the potential to provide the next generation of low-cost solar cells following on from silicon solar cells. Organic solar cells are representative of the organic electronics industry, which includes organic electroluminescent devices and organic transistors, and is set to dominate in the twenty-first century, following on from the dominance of the inorganic electronics industry in the twentieth century. The field of organic solar cells is closely related to many other research fields such as device physics, electronics, and synthetic chemistry, in which there are a vast number of researchers. The author fervently hopes that young researchers will take up the challenge of working in the interdisciplinary field of organic solar cells to help develop the next generation of cells for renewable energy. Some suggested books [54.30–33] are indicated in the references for new and young researchers entering the field of organic solar cells.

55. Materials for Terahertz Engineering

Roger Lewis

Metals reflect, plastics transmit, and water absorbs terahertz-frequency electromagnetic radiation. Such diverse responses open up a vast range of applications for terahertz materials spanning art, science, engineering, and medicine. The three main components of terahertz devices are sources, detectors, and the intervening optics. Sources include solid-state emitters, typically involving in their operation either the lattice (nonlinear optics) or the charge carriers (transient dipoles). Quantum cascade lasers, built of multiple semiconductor layers, represent a rapidly developing solid-state terahertz source. Detectors typically depend on either the crystal lattice (electro-optical detection) or the charge carrier reservoir (electronic detection) being sensitive to terahertz radiation. Terahertz components encompass metal-coated mirrors, plastic (machined, molded, or three-dimensional (3-D) printed) lenses, and waveguides, filters, and polarizers of many different materials and designs. An emerging class of components are the terahertz metamaterials.

55.1 Overview

Most materials have properties in the terahertz range of the electromagnetic spectrum quite different to the properties they possess in the visible range. Many organic materials, such as plastic, paper and cardboard, which are opaque to visible light, transmit light in the terahertz range. This makes terahertz techniques ideal for the testing of packaged materials, *seeing through* envelopes and wrapping. On the other hand water, often thought of as transparent to visible light, absorbs terahertz radiation strongly. This equips terahertz-frequency electromagnetic radiation for a variety of uses that involve detecting water in such areas as agriculture, biology, food processing, and medicine. Metals, which reflect well in the visible, reflect even better at terahertz frequencies. In combination, more exotic applications of terahertz frequencies are possible. For example, terahertz radiation can penetrate the plastic coating of an electrical cable, bounce back from the copper core, and give an idea of the integrity of the cable – even while it is in-service and live. Similarly, terahertz radiation can penetrate layers of paint on an automobile panel, reflect off the metal below, and provide information about the type and thickness of paint as well as of incipient corrosion of the hidden metal before it becomes visible. All these applications are nondestructive: the material being probed by the terahertz radiation remains intact and in situ throughout.

In brief, the physical mechanisms in play at terahertz frequencies may be classified into two broad categories. Conductors, such as metals, tend to reflect

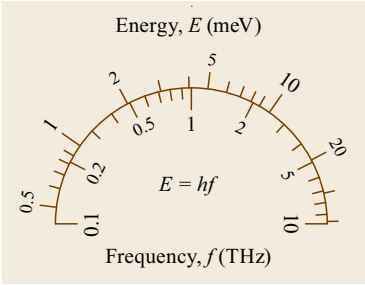

Fig. 55.1 Photon energies in the terahertz range. Roughly speaking, terahertz frequencies correspond to meV energies. The precise relationship is $E = hf$, where h is the Planck constant. To obtain the energy (in meV), multiply the frequency (in THz) by 4.135667516. To obtain the frequency (in THz), multiply the energy (in meV) by 0.2417989348. These numerical conversion factors are approximate but correct to the number of digits given

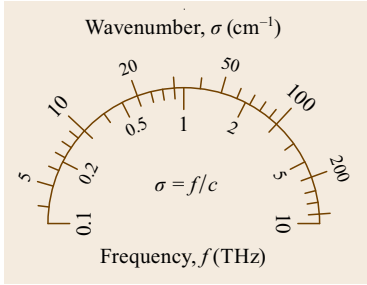

Fig. 55.2 Spatial frequencies (that is, numbers of waves per unit length, abbreviated as wavenumbers) in the terahertz range. Roughly speaking, terahertz frequencies correspond to spatial frequencies of tens per centimeter (or tens of inverse centimeters). The precise relationship is $\sigma = f/c$, where c is the speed of light. The figure is prepared for light in a vacuum. To obtain the spatial frequency (in cm^{-1}), divide the frequency (in THz) by 0.0299792458. To obtain the frequency (in THz), multiply the spatial frequency (in cm^{-1}) by 0.0299792458. These conversion factors are exact for light in a vacuum

terahertz-frequency radiation. Insulators, such as ionic crystals and many organic solids, tend to transmit terahertz radiation of many frequencies, but absorb strongly at certain frequencies, corresponding to allowed oscillations in the material. These characteristic oscillations – differing in frequency from material to material – serve as a spectral signature, and allow identification of the material under inspection.

55.1.1 Bridging Electronics and Photonics

Electronic devices conventionally operate at Hz, kHz, MHz – and even GHz frequencies – but struggle when it comes to THz frequencies. Visible light, on the other hand, is found at much higher frequencies still, of the order or 10^{14}–10^{15} Hz (0.1–1 PHz). It is difficult to extend conventional optical techniques to lower frequencies of 10^{13}, 10^{12}, or 10^{11} Hz. The terahertz region, for convenience here taken to span 10^{11} to 10^{13} Hz, thus lies in-between electronics and photonics. This fascinating frequency space, rich in science but impecunious in technology, is often referred to as the *terahertz gap*.

As set out in Fig. 55.1, terahertz-frequency photons have energies of the order of milli-electron volts. This corresponds, for light in empty space, to spatial frequencies of the order of tens of inverse centimeters, and to wavelengths of hundreds of micrometers, as illustrated in Figs. 55.2 and 55.3 respectively.

55.1.2 Focus on Frequency

Electromagnetic radiation is naturally characterized by its frequency, rather than by its wavelength [55.1, 2]. The frequency is directly proportional to the photon energy, the constant of proportionality being the

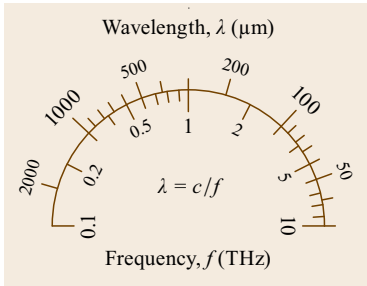

Fig. 55.3 Wavelengths of photons in the terahertz range. Roughly speaking, terahertz frequencies correspond to submillimeter wavelengths. The precise relationship is $\lambda = c/f$, where c is the speed of light. The figure is prepared for light in a vacuum and the conversion factors given are exact for a vacuum. To obtain the wavelength (in μm), divide 299.792458 by the frequency (in THz). To obtain the frequency (in THz), divide 299.792458 by the wavelength (in μm)

Planck constant, that is, $E = hf$. This is a fundamental relationship. Proportionality constant aside, energy *is* frequency. Likewise, photon frequency, considered as twice the thermal energy per degree of freedom, may be directly related to the thermodynamic temperature, T, by $T = [h/k_B]f$. In vacuum, the photon spatial frequency (or wavenumber) is a third quantity that depends directly on frequency: $\sigma = [1/c]f$, where c is the speed of light. In a medium, this relation needs to be modified by the material's properties, expressed by the refractive index. In contrast to the other quantities mentioned so far, the wavelength varies not directly,

Table 55.1 Conversion of units for terahertz photons. The quantities are related by $f = E/h$, $E = hf$; $f = k_B T/h$, $T = hf/k_B$; $f = c\sigma$, $\sigma = f/c$; $f = c/\lambda$, $\lambda = c/f$. Here c is the speed of light, h the Planck constant, and k_B the Boltzmann constant

	f Frequency (THz)	E Energy (meV)	T Temperature (K)	σ Wavenumber (in vacuum) (cm^{-1})	λ Wavelength (in vacuum)

but inversely, with frequency: $\lambda = c/f$. Table 55.1 provides representative conversions between the various photon properties for some round numbers for each variable and for some technically important temperatures. The focus is on the two decades of frequency around 1 THz.

55.1.3 Physical Phenomena at Terahertz Frequencies

Terahertz frequencies offer a cornucopia of physical phenomena. Table 55.2 lists some of these. Representative numerical values are given for an illustrative material, the donor-doped III-V semiconductor, *n*-GaAs. Being crystalline, it exhibits distinct lattice modes; being polar, these modes readily interact with oscillating electromagnetic fields; being doped with charge carriers, it is in addition a platform for electronic phenomena.

Vibrational

Mechanical vibrations in crystalline lattices, or phonons, typically occur at terahertz frequencies. For example, in the common ionic compound NaCl the transverse-optical phonon frequency, f_t, is 4.9 THz and the longitudinal-optical phonon frequency, f_l, is 8.0 THz. These frequencies are related to the low-frequency dielectric constant, $\epsilon(0)$, and the high-frequency dielectric constant, $\epsilon(\infty)$, by $f_l^2\epsilon(\infty) = f_t^2\epsilon(0)$. Lattice properties are thus intimately related to the electric and so to the optical properties of the material.

Electronic

Oscillations of charge carriers often occur at terahertz frequencies. Free electrons oscillate at the plasma frequency, $f_p = (nq^2)/(4\pi^2\varepsilon_0 m^*)$. Here n is the density, m^* the effective mass, q the charge, and ε_0 the electric constant. Surface, interface, magneto-, and gap plasmons all occur at terahertz frequencies.

Charge carriers confined in potential wells also often have characteristic oscillations at terahertz frequencies. Donor or acceptor atoms give rise to one charge carrier moving in the Coulombic potential well of a fixed charge of opposite sign. This produces a hydrogen-like system with the characteristic energy, the Rydberg, scaled for the effective mass of the moving charge and for the dielectric constant of the material.

Table 55.2 Physical phenomena at terahertz frequencies. The numerical values given are based on *n*-GaAs

Phenomena	Equations	Examples
Vibrational		
Lattice–phonons		
– Transverse optical	f_t	$f_t = 8.2\,\text{THz}$
– Longitudinal optical	$f_l^2 = \epsilon(0) f_t^2/\epsilon(\infty)$	$f_l = 8.8\,\text{THz}$
Electronic		
Plasma frequency	$f_p = (nq^2)/(4\pi^2\varepsilon_0 m^*)$	
Electrons confined in Coulomb potential, hydrogenic systems	$Ry^* = (m^*/m_e)(1/\epsilon^2)Ry$	$Ry^* = 5.72\,\text{meV}$
Electrons confined in quantum wells	$E_n = (n^2h^2)/(8ma^2)$	width 10 nm, $E_1 \approx 1.4\,\text{THz}$
Free electrons in a magnetic field – cyclotron resonance	$\hbar\omega_c = \hbar eB/m^*$	$\hbar\omega_c \approx 1.74\,\text{meV/T}$
Bound electrons in a magnetic field – Zeeman effect	$\Delta E = \mu_B g B$	$\Delta E \approx 0.87\,\text{meV/T}$
Combined vibrational and electronic		
Polarons		
Fano resonances		

While optical transitions of hydrogen occur in the ultraviolet and the visible, the scaling means the transitions in the solid-state analogs are at terahertz frequencies. Likewise, electrons or holes confined in quantum wells, such as thin layers containing charge carriers sandwiched between barriers (made by molecular-beam epitaxy), typically have confinement energies corresponding to terahertz photons.

Charge carriers in magnetic fields undergo oscillatory motion and in many practical cases the frequency of this motion is in the terahertz range. For *free* electrons (which may, in fact, be confined to a solid, or to a two-dimensional sheet therein) the result is cyclotron motion. For *bound* electrons, such as those in a Coulombic potential, the effect is named after Zeeman.

Combined Vibrational and Electronic

Furthermore, the vibrations of the lattice may interact with the oscillations of the charge carriers. This gives rise to phenomena such as the polaron, the combination of an electron and the lattice distortion it produces, and Fano resonances, the combination of a phonon and an electronic transition between bound states being resonant with a continuum of electron states.

55.1.4 Terahertz Technology Timeline

The dramatic developments that have taken place in terahertz science and technology in recent times have been based on advances in materials science and materials engineering. Terahertz sources, for example, include vacuum devices (backward-wave oscillator, free-electron laser, synchrotron, and gyrotron) as well as gas lasers; but much of the recent development has been in solid-state sources, such as Gunn oscillators, high-electron mobility transistors, solid-state lasers of various species, and solid sources driven by ultrashort laser pulses, the pulses typically emanating from Ti:sapphire lasers. Likewise, while there exist gas-based terahertz detectors, such as the pneumatic Golay cell, most modern terahertz detectors are based on solid-state devices: Si or Ge bolometers, oxide pyroelectric materials, and, in the case of the detection of ultrafast terahertz pulses by nonlinear optical processes in polar crystals or by photoconductive devices. An overview of the progress of terahertz technologies since 1945 is given in Fig. 55.4.

55.1.5 Entry into the Terahertz Literature

Roughly speaking, the number of terahertz documents in the Scopus database has doubled every three years starting with one document in 1975. More precisely, the number of documents, D, published in any year, Y, from 1975 to 2013 inclusive is expressed well by the equation

$$D = \alpha \exp\left(\frac{Y - 1975}{\tau}\right) \qquad (55.1)$$

with parameters $\alpha = 1.55 \pm 0.42$ and $\tau = 4.66 \pm 0.18$ [55.5].

Review Articles

Overviews of terahertz science and technology appear in three key articles. Each has been cited more than one thousand times:

- *Terahertz technology*, *Siegel* [55.6]
- *Materials for terahertz science and technology*, *Ferguson* and *Zhang* [55.7]
- *Cutting-edge terahertz technology*, *Tonouchi* [55.8].

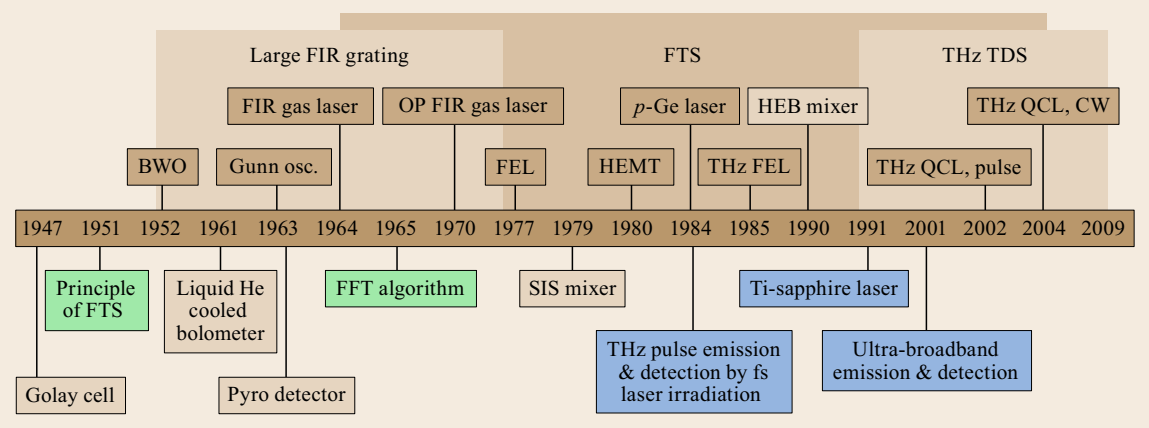

Fig. 55.4 Timeline indicating the emergence of principal terahertz technologies. (After [55.3, 4])

Further reviews cover a range of applications of terahertz science and technology:

- *Terahertz spectroscopy*, *Beard* et al. [55.9]
- *Imaging with terahertz radiation*, *Chan* et al. [55.10]
- *Pulsed terahertz tomography*, *Wang* and *Zhang* [55.11]
- *Biomedical applications of terahertz technology*, *Pickwell* and *Wallace* [55.12]
- *Present and future of terahertz communications*, *Song* and *Nagatsuma* [55.13].

Books

As the field has matured, edited volumes have been succeeded by multi-author monographs and, eventually, single-author monographs:

- 2003 *Sensing with Terahertz Radiation*, *Mittleman* [55.14]
- 2005 *Terahertz Optoelectronics*, *Sakai* [55.15]
- 2006 *Intense Terahertz Excitation of Semiconductors*, *Ganichev* and *Prettl* [55.16]
- 2008 *Terahertz Spectroscopy, Principles and Applications*, *Dexheimer* [55.17]
- 2009 *Principles of Terahertz Science and Technology*, *Lee* [55.18]
- 2010 *Introduction to Terahertz Wave Photonics*, *Zhang* and *Xu* [55.19]
- 2012 *Terahertz Techniques*, *Brundermann* et al. [55.20]
- 2012 *Terahertz Physics*, *Lewis* [55.21].

Conferences

The major conference series in the area is *The International Conference on Infrared, Millimeter, and Terahertz Waves (IRMMW-THz)*. The conference series originated in the USA in 1974 with *The First International Conference on Submillimeter Waves and their Applications*. It was later renamed *The International Conference on Infrared and Millimeter Waves*. In 2004 this stream joined with the *International Conference on Terahertz Electronics*, a series based in Europe and then in its twelfth edition. IRMMW-THz is now held annually, rotating between USA, Europe, and Asia on a three-year cycle. Further information is available at www.irmmw-thz.org.

Journals

- *Journal of Infrared, Millimeter and Terahertz Waves*, previously (until 2009) the *International Journal of Infrared and Millimeter Waves*, was established in 1980. It is closely associated with the IRMMW-THz conference series.
- *IEEE Transactions of Terahertz Science and Technology* has been published since 2011 by the Institute of Electrical and Electronics Engineers.

55.2 Terahertz Sources

Terahertz sources have been reviewed recently [55.5]. A sampling of terahertz sources is presented in Table 55.3. The area is one of rapid current advancement.

55.2.1 Thermal

Thermal sources include emission from gases as in the mercury lamp [55.26], from solid-state sources such as

silicon carbide forming a *globar* [55.23–25], and from the universe itself, via the cosmic background radiation [55.22]. Such sources can be modeled as black (or more accurately, as gray) bodies.

55.2.2 Vacuum Electronic

Charge carriers, typically electrons, accelerated freely, typically in a vacuum, emit terahertz-frequency electromagnetic radiation. Vacuum electronic sources range from relatively small units, such as backward-wave oscillators [55.28–30], to facilities that take up a whole room or building, such as free-electron lasers [55.35, 36] and synchrotrons [55.37]. These yield the highest power of all present terahertz sources, but are accompanied by limitations related to cost, size, and portability.

55.2.3 Solid-State Electronic

Electrons in solids, especially in semiconductors, also may be manipulated to produce terahertz radiation. Diodes [55.38], transistors [55.39], and superconducting elements [55.41] may be adapted for this purpose. Solid-state devices are also the basis of compact and robust terahertz lasers. These fall into two broad categories, bipolar [55.43, 44] and unipolar (the quantum cascade laser) [55.45, 46].

55.2.4 Laser-Pumped

Recent advances in terahertz sources have been associated with laser pumping. Two continuous laser sources of slightly different frequencies may be mixed in a suitable material to yield terahertz radiation at the frequency difference [55.47]. Continuous laser sources may also be used to excite mechanical resonances, which lead in turn to terahertz emission [55.48].

Much work has been done on pulsed laser sources, as these serve as the basis for terahertz time-domain spectroscopy. Pulses of near-infrared radiation can be downconverted to terahertz frequencies by such processes as photoconductive switching [55.49, 50], the ionization of air [55.52], or the reorientation of magnetic dipoles [55.53]. A widely used method is by optical rectification realized in nonlinear (electro-optic) crystals [55.55]. Both bulk [55.56, 57] and surface electric-field-induced [55.58, 59] effects contribute to the terahertz signal. A second widely used method is by the initiation of transient currents by photo-ionization of electron-hole pairs in semiconductors. The two principal mechanisms associated with the development of transient currents are charge-carrier drift [55.67] and diffusion [55.65, 66].

55.2.5 Mechanical Excitation

Terahertz radiation may also be produced by purely mechanical means, much as visible light is produced by friction (triboluminescence) or by the cleavage of surfaces (fractoluminescence). Two examples are charge separation on the peeling of adhesive tape leading to terahertz emission [55.68] and terahertz emission from rapidly-forming surfaces [55.69].

55.3 Terahertz Detectors

The mechanisms of terahertz detection in some sense reflect the mechanisms of terahertz emission: thermal, electronic, and electro-optic physical processes are common to both. A sampling of terahertz detector technologies is given in Table 55.4.

55.3.1 Thermal

Thermal detectors rely on the energy of incoming radiation raising their temperature and this temperature change leading to a change in another physical property. The physical property changed in a thermocouple is the electrical potential generated across it. Thermocouples are conventionally made of alloys of Bi and Sb [55.70, 82] but GaAs [55.83] and CMOS (CMOS) structures [55.84] are other materials employed. Cascading together a number of thermocouples results in a thermopile [55.71]. These also are often based on Bi [55.85] and its alloys [55.86] but other materials, such as Si/Ti, have been used [55.87]. Micromachining is now often utilized [55.88] and arrays of thermopiles are used for imaging [55.89]. Likewise, a voltage is set up across pyroelectric crystals, typically titanates or niobates, when heated [55.72] and these also are now micromachined [55.90] and employed for imaging [55.77] and even holography [55.91]. Rather than measure the change in electric potential on heating, the change in electrical resistance might be employed. This is the principle of operation of the bolometer [55.75, 92, 93]. Bolometers are conventionally made from Si, Ge or alloys such as SiGe on SiN [55.94, 95]. Superconductors, cooled to near the superconducting transition, are also used, but not widely [55.76, 96]. Bolometers are the most sensitive detectors of terahertz radiation.

55.3.2 Electro-Optic

Electro-optical detection relies on having a material whose birefringence is altered on being exposed to terahertz radiation [55.78]. The change in birefringence is then detected by a second light beam, typically a pulse from a Ti:sapphire laser, traversing the same material. This detection method may be described as upconversion; the terahertz response of the material is probed by a higher-frequency beam.

55.3.3 Electronic

Terahertz radiation may induce direct electronic transitions in suitable materials and the change in conductivity, or the change in the electric potential produced, may be used to monitor the intensity of the radiation [55.79, 80]. Alternatively, in an inversion of the photoconductive switch for terahertz emission, a photoconductive material may be used for terahertz detection, typically gated by a Ti:sapphire laser pulse [55.81].

55.4 Terahertz Components

Conventional materials utilized in the transfer of radiation of terahertz frequencies include windows and filters. Windows (of cryostats, for example) are typically made of inorganic crystals, including alkali halides, or plastics, such as polyethylene, polypropylene, or Mylar. Simple filters are based on size effects: for example, transmission filters incorporating diamond or other particles of suitable size, and reflection filters based on metal plates abraded with grits of appropriate grades. Likewise, wire grids, either free standing or supported by a semiconductor or plastic substrate, serve as filters with a cut-on frequency determined by the grid spacing. Other terahertz components include mirrors, lenses, polarizers, and metamaterials, a sampling of which is given in Table 55.5.

55.4.1 Mirrors

Metals are an obvious choice of material for terahertz mirrors. Al is commonly used; Ag has a higher conductivity and so a higher reflectivity; Au, while expensive, is less liable to tarnish. To save expense, and sometimes weight, an Ag or Au coating may be laid over a less expensive or lighter form. Recent innovations in terahertz mirror technology include semiconductor [55.97] and hybrid mirrors [55.98] and mirrors based on the concept of the photonic crystal [55.99].

Modulator	*Chen* et al. [55.107]

55.4.2 Lenses

Terahertz lenses have conventionally been machined on a lathe from a suitable plastic such as polyethylene or TPX. More recently, molding has been employed, allowing for the rapid production of a large number of lenses [55.100]. Other innovations include Fresnel zone plates [55.102] and plasmonic resonances [55.103], variable focal length lenses [55.101], and even terahertz lenses made of paper [55.104].

55.4.3 Polarizers

Polarizers in the terahertz region are based on the same principle as in the visible, for example, by using a material that absorbs differently depending on the direction of the incident electric field. Given the greater wavelengths of terahertz radiation compared to visible radiation, wire-grid polarizers are simpler to realize in the terahertz than in the visible region. Recently, reconfigurable polarizers have been reported [55.105].

55.4.4 Metamaterials

Metamaterials are artificially engineered structures possessing properties not found in natural materials. Metamaterials allow the manipulation of terahertz radiation in various ways. A typical configuration is Au on GaAs forming split-ring resonators [55.108, 109]. Separate control of the electrical permittivity and the magnetic permeability has been achieved in terahertz-absorbing metamaterials [55.106] and terahertz modulators have also been demonstrated [55.107].

55.5 Conclusion

Most materials have properties in the terahertz spectral range significantly different to their properties in the lower-frequency (electronic) and higher-frequency (photonic) frequency ranges that bracket it. Terahertz materials thus form the basis for unique methods that underpin science and technology in this relatively under-explored frequency region. A current and growing area of materials research centers on sources and detectors of terahertz radiation, as well as the components that manipulate terahertz radiation, involving metals, semiconductors and crystalline and amorphous insulators, in a multitude of configurations.

Acknowledgments. K. Sakai is thanked for provision of the diagram on which Fig. 55.4 is based.

56. Metamaterials

Vassili Fedotov

Metamaterials is a new field of interdisciplinary research, which deals with artificial material composites engineered to display physical properties that surpass (or complement) those available in nature. Originally proposed as a way of tailoring media's electromagnetic and optical properties, the metamaterial concept has recently extended its reach to also include elastic, acoustic, and thermal properties. Since 1999, with the emergence of the field, metamaterials has attracted a lot of attention from the scientific community all over the globe, offering immediate applications in antenna and waveguide engineering, imaging, microscopy, sensing, and light manipulation. Metamaterial research has brought together electrical engineers, material and optical scientists, chemists, and mathematicians; it has also advanced our understanding of electrodynamics, pushed the boundaries of nanofabrication, and stimulated the development of novel characterization techniques. Metamaterial research continues to expand quite rapidly, making it almost impossible to faithfully cover the field even with a reasonably sized book. This chapter attempts to give a brief overview of the history of electromagnetic (photonic) metamaterials, important developments, and main concepts in the field. Also, it aims to provide a basic understanding of the principles, design rules, and tricks routinely exploited by the researchers to achieve the desired material behavior. The chapter is divided into two parts, which are devoted to bulk metamaterials and their two-dimensional counterparts, the so-called planar metamaterials or metasurfaces.

56.1 Bulk Metamaterials

Metamaterial is now a well-accepted term for a novel type of optical medium that is artificially engineered to interact with light in ways no natural materials can. Metamaterials gain their unusual properties from the particular design of their elementary building blocks – metamolecules (or meta-atoms), which are built on a subwavelength scale from common constituent materials such as metals and dielectrics. Because of their subwavelength structuring, metamaterials do not diffract light and hence are quite different from photonic crystals, acting as uniform media that can, in principle, be ascribed an effective refractive index.

Interest in the metamaterial research exploded in the year 2001 when scientists experimentally demonstrated a truly exotic effect of negative refraction, a phenomenon in which light rays are refracted or bent in the direction opposite to that which is normally expected [56.1]. Negative refraction became one of the signature effects of the metamaterials physics and its demonstration opened a new exciting chapter in material and electromagnetic research. While subsequent

scientific activity has mainly centered on electromagnetic properties of the metamaterials (most of which will be considered in this chapter), it would be fair to note that one of the first metamaterial definitions given in 2001 by *Valerie Browning* (DARPA, USA) encompassed many more material properties [56.2, 3]:

> *Metamaterials are a new class of ordered composites that exhibit exceptional properties not readily observed in nature. These properties arise from qualitatively new response functions that are: (1) not observed in the constituent materials; (2) result from the inclusion of artificially fabricated, extrinsic, low dimensional inhomogeneities.*

56.1.1 Basic Principle of Metamaterial Operation

The exotic and often dramatic physics exhibited by the metamaterials is in many cases underpinned by the resonant response of their metamolecules. A generic example of the metamolecule, which forms a three-dimensional metamaterial crystal when translated periodically along the x, y, and z-axes, is schematically shown in Fig. 56.1. It typically consists of metallic wires (or patches) embedded in or supported by a dielectric substrate/matrix. An electromagnetic wave incident onto the metamaterial induces oscillating electrical currents $\boldsymbol{j}$ in the conducting elements of each metamolecule, which then scatter (i. e., re-radiate) secondary electromagnetic waves forming the macroscopic response of the metamaterial. Radiation scattered backward is perceived as the metamaterial reflection, while radiation scattered forward contributes to the transmission by adding coherently to the incident wave.

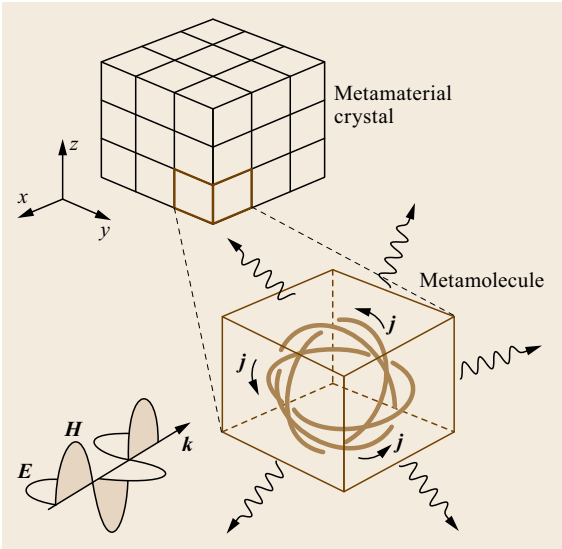

Fig. 56.1 Bulk metamaterial crystal and its elementary building block – the metamolecule (metallic wire resonators embedded into a dielectric cube)

Each metamolecule effectively acts as a very compact antenna that for a certain design and dimensions of its metallic pattern becomes resonantly coupled to the fields of the incident wave, featuring substantially amplified current oscillations and, as a result, strong electromagnetic scattering. The metamolecule can also be considered as a classical analog of an atom, where the frequency of the metamolecule's resonance ω_0 corresponds to the energy of the atom's excited state $E^* = \hbar\omega_0$, while scattering of electromagnetic waves by the induced currents corresponds to the emission of a photon $\hbar\omega_0$ by the atom upon its transition from the excited to ground state.

By tailoring the design of the metamolecules, one can selectively engineer an enhanced effective material response at virtually any wavelength (frequency) and of any origin – be it electric or magnetic, or a combination of the two (yielding optical activity or negative refraction), or even more exotic – toroidal [56.4]. Some examples of the metallic patterns commonly exploited in the metamaterial research are shown in Fig. 56.2, and some of these will be considered in detail below.

The resonant response of a metamolecule is determined by the inductance L and capacitance C of its metallic pattern, which may be viewed as an electrical circuit driven externally by the fields of the incident wave. When the overall size of the metamolecule is smaller than $\approx \lambda_0/20$, such a circuit can be described as a network of lumped electrical components with the resonance frequency given by the well-known expression $\omega_0 = 2\pi f_0 = 1/\sqrt{LC}$. The inductance and capacitance of the pattern in this case must be substantially larger than the self-inductance and self-capacitance of the constituting wire(s), although at present this can be achieved only for some radio and microwave-frequency designs [56.5, 6] due to limitations of existing micro and nanofabrication technologies. In practice, the typical size of metamolecules ranges from about $\lambda_0/6$ to $\lambda_0/2$, which one may slightly reduce (by a factor of 1.5–2) with the help of high-index dielectric substrates. Consequently, the metamolecules do not operate in the *quasi-static* regime and should be regarded as miniature transmission lines with distributed inductance and capacitance. Their resonant behavior results from the excitation of standing waves of electrical currents, which are analogs to the resonant modes of an electromagnetic cavity resonator or a vibrating string (Fig. 56.3). Although an accurate quantitative characterization of the induced current oscillations is cumbersome in this case

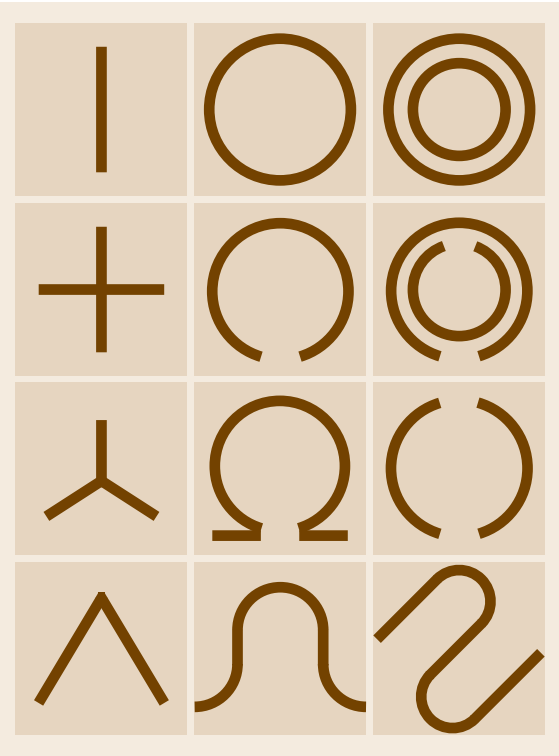

Fig. 56.2 Examples of metamaterial patterns

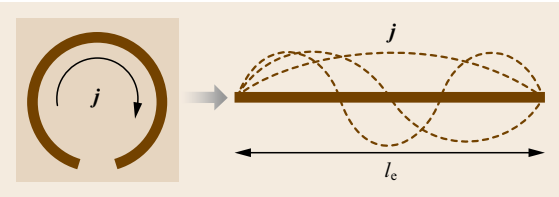

Fig. 56.3 Geometrical resonances of a metamolecule. Conduction currents $\boldsymbol{j}$ oscillating in the metamolecule form standing waves along the length of its metallic pattern (l_e)

and requires the use of the transmission line theory or numerical modeling, the wavelengths of the supported resonances can be estimated using very simple relations,

$$\lambda_0 \approx \sqrt{\varepsilon}\frac{2l_e}{m}\,, \tag{56.1}$$

where l_e is the total electrical length of the metallic pattern that forms the metamolecule, ε is the relative permittivity of the dielectric medium that the pattern is embedded in, and m is a positive integer. Resonances with $m > 4$ are usually not possible to engineer in subwavelength metamolecules (since $l_e > \lambda_0$).

Importantly, by reducing the size of the metamolecule (and hence l_e) such *geometrical* resonances can be moved to shorter wavelengths (higher frequencies) – all the way into the near-IR, where metals are still good conductors and can, therefore, support electrical currents. At visible frequencies, however, the currents are replaced with plasmons, and the linear relation between λ_0 and l_e becomes less accurate and eventually saturates due to the kinetic inductance of the electron plasma [56.7].

56.1.2 The First Metamaterial

Perhaps the first ever metamaterial was constructed and studied by *Bose* more than 100 years ago. In 1898, he wrote [56.8]:

> *In order to imitate the* [optical] *rotation by liquids like sugar solutions, I made elements of molecules of twisted jute, of two varieties, one kind being twisted to the right (positive) and the other twisted to the left (negative) . . . .*

In his experiments, Bose placed the twisted jutes between a spark generator equipped with a polarizer (which acted as a source of linearly polarized millimeter waves) and a detector, and determined the orientation of the polarization plane of the transmitted waves by rotating an analyzer in front of the detector (Fig. 56.4). He confirmed that *the twisted structure* [of the jute] *produces an optical twist of the plane of polarization* [56.8]. It is important to note here that although Bose's structure served merely to reproduce the effect of polarization rotation (i. e., optical activity) encountered in the optical part of the spectrum in sugar solutions and other media lacking reflection symmetry, it did so at millimeter-wave frequencies, where no natural materials are known to exhibit such an effect.

Since then more elaborate designs of optically active metamaterials have been proposed and realized for various operating frequencies, including the optical part of the spectrum, where they easily outperformed the naturally available media in terms of their rotary power (Sect. 56.1.5).

56.1.3 Magnetic Metamaterials (Artificial Magnetism)

Arguably, the most important development in the field of metamaterial research was the demonstration of so-called artificial magnetism, a phenomenon characterized by the appearance of a strong magnetic response (most notably at optical frequencies) in inherently nonmagnetic material composites. Indeed, as will be shown in the following sections, artificial magnetism is the key ingredient of the exotic negative-index response and

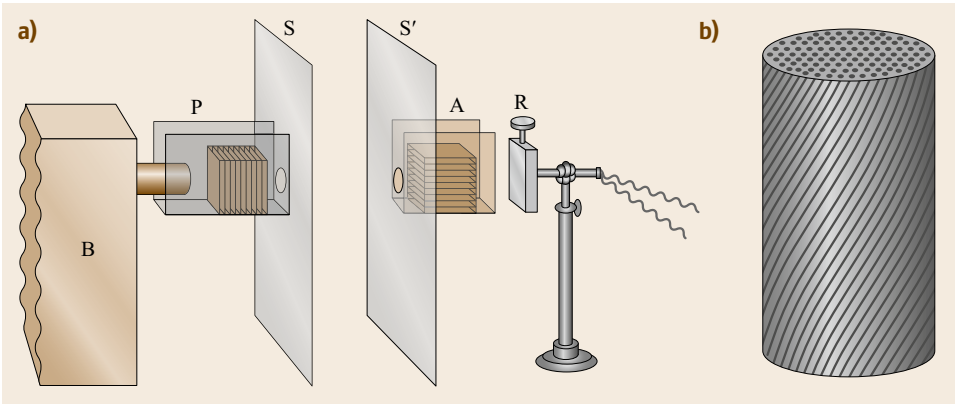

Fig. 56.4a,b Mimicking optical activity with artificially engineered structures. **(a)** Diagram of Bose's experiment: B – source of electromagnetic waves, P – polarizer, S and S′ – screens with apertures, A – analyzer, R – spiral spring receiver. **(b)** Twisted jute, the fist chiral metamolecule. (After [56.8])

a material property essential for the design of three-dimensional electromagnetic cloaks.

The idea of artificial magnetism was conceived in 1999 by *Pendry* et al., who proposed a magnetic analog of an electric conductor with controllable electromagnetic properties [56.9]. Materials exhibiting artificial magnetism were also suggested as a practical solution for manipulating the secondary radio frequency (RF) magnetic fields in an magnetic resonance imaging (MRI) environment, where the use of conventional magnetic materials would perturb the pattern of the primary quasi-static magnetic field [56.5]. Most of all, the interest in artificial magnetism was driven by the fact that strong natural magnetism (exhibited by ferromagnetic materials) is virtually nonexistent at terahertz frequencies and above, where light–matter interactions are mediated exclusively by the electrical component of light (magnetic permeability $\mu \approx 1$).

The existence of strong magnetism in nature is ensured by unpaired electron spins in atoms, which appear to be locally aligned through exchange interaction with one another, forming microscopic domains of uniform spontaneous magnetization (ferromagnetism). At the macroscopic level, the magnetic response results from the re-orientation of all such domains parallel to an externally applied magnetic field each time the field reverses its sign. The re-orientation, however, typically takes a fraction of a microsecond to complete, which means that at terahertz frequencies and above the variations of the applied field are too quick for the domains to follow, and so the ferromagnetic response vanishes. The only mechanism that could yield natural magnetism at optical frequencies is diamagnetism. Classically speaking, diamagnetism is the manifestation of Lenz's law on the atomic scale: when an external magnetic field couples to orbiting electrons, it forces an atom to precess (Larmor precession) and thus induces additional orbital currents, which generate a magnetic field that opposes the external one. Unfortunately, diamagnetic response in natural materials is α^2 times weaker than the electric one (where α is the fine-splitting constant), which is why the interaction of matter with light occurs exclusively via the electric field [56.10].

The metamaterial approach allows for the mimicking of orbital currents with loops of conduction currents that are magnetically induced in metamolecules via Faraday induction (Fig. 56.5a). Although metamolecules are much larger than natural atoms and molecules, they are still smaller than the wavelength of light and thus on the macroscopic scale (i. e., where the effective material response is formed) the above

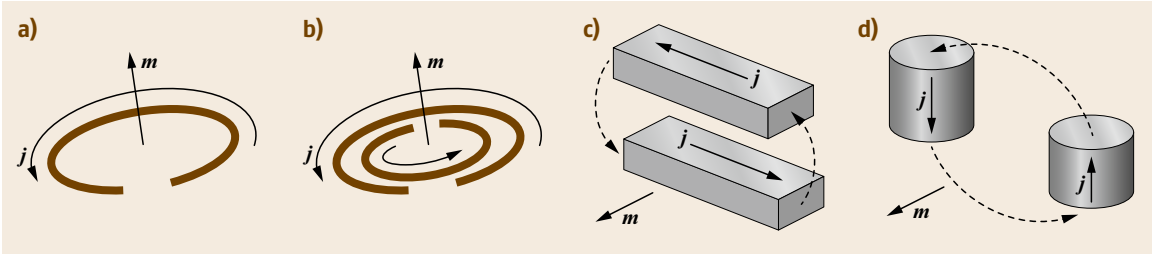

Fig. 56.5a–d Magnetic metamolecules. Orbital currents in atoms and molecules are imitated with loops of electrical currents $\boldsymbol{j}$ induced in **(a)** a split wire ring, **(b)** a double split wire ring, **(c)** a pair of metallic bars, and **(d)** a pair of metallic pillars. Current loops give rise to microscopic magnetic dipole moments $\boldsymbol{m}$

trick will remain unnoticed. Since each metamolecule operates as an *LC*-circuit, the induced conduction currents will be resonantly amplified, yielding artificial magnetic response that is several orders of magnitude stronger than found in natural materials. Note that the sign of the effective magnetic permeability μ^* can be both negative and positive, depending on the detuning from the resonance frequency f_0.

One of the most popular examples of the metamolecule that can exhibit artificial magnetism is a metallic ring with a split (Fig. 56.5a), commonly referred to as a split-ring resonator (SRR). Along with its derivative – a pair of concentric split-rings (Fig. 56.5b), also known as a double split-ring resonator (DSSR), it has been successfully exploited for demonstrating artificial magnetism experimentally within a wide spectral range, spanning from microwave to IR frequencies (see [56.10] and references therein). At near-IR and visible frequencies, however, the split-ring design was rather challenging to implement given the limitations of the fabrication techniques; it was also less effective due to large kinetic inductance of plasmons that replace conduction currents at those frequencies. Instead, magnetic metamolecules were engineered as pairs of parallel metallic bars or pillars (Fig. 56.5c,d). Current loops in those structures were formed by plasmons in the metal and displacement currents in the gaps between the ends of the bars/pillars [56.11, 12].

56.1.4 Negative-Index Metamaterials (Left-Handed Media)

The negative index of refraction ($n < 0$) signifies a peculiar regime of a medium's macroscopic electromagnetic response, when the electric permittivity ε and the magnetic permeability μ become simultaneously negative. Mathematically, negative n is given by the secondary value of the square-root function, which must be chosen to respect the negative signs of ε and μ in such a case

$$n = \sqrt{\varepsilon\mu} = \sqrt{(-1)^2|\varepsilon||\mu|} = -\sqrt{|\varepsilon||\mu|}\,. \qquad (56.2)$$

The negative sign of n is also consistent with the laws of physics and has a clear physical meaning: it indicates that the phase velocity of a wave is antiparallel to its group velocity. This was shown by several scientists in the twentieth century [56.13–15], and in particular, by the Soviet scientist *Veselago* in 1967, who investigated theoretically the electrodynamics of a medium with $\varepsilon < 0$ and $\mu < 0$ in great detail [56.16]. Such a medium (commonly referred to as the *double-negative* or *negative-index medium*) behaves as a peculiar transparent medium supporting the propagation of electromagnetic waves whose wavevectors $\boldsymbol{k}$ form left-handed triplets with the vectors of electric $\boldsymbol{E}$ and magnetic $\boldsymbol{H}$ fields, i. e., $\boldsymbol{k} \propto [\boldsymbol{H} \times \boldsymbol{E}]$. The latter, in fact, gave rise to the original term of the *left-handed medium* suggested by Veselago, which was eventually abandoned by the metamaterial community in order to avoid confusion with an artificial chiral medium (see Sect. 56.1.5). The double-negative medium also features anomalous (i. e., negative) refraction, the reversal of the Doppler shift, Cherenkov radiation, and even radiation pressure.

These exotic effects, however, could not be experimentally verified until recently due to the seeming absence of negative-index materials. Following Veselago's work, a number of attempts were made to find such materials among naturally available magnetic semiconductors, $CdCr_2Se_4$ and alike, which were known to exhibit both electric and magnetic resonances [56.17]. Unfortunately, the task of minimizing the detuning of the resonances so that they could spectrally overlap proved to be impossible. Consequently, the notion of negative-index medium and the associated electromagnetic phenomena were ignored for over 30 years.

It was the demonstration of artificial magnetism in metamaterials (considered in the previous section) that enabled the engineering of a double-negative response artificially, at virtually any frequency. The first double-negative metamaterial operated at around 5 GHz [56.18]. It was realized by structurally combining an array of 7 mm large double split-ring metamolecules with an array of continuous metallic wires (Fig. 56.6a). The former exhibited narrow-band magnetic response, while the latter produced broadband electric response characteristic to that of a bulk metal, which ensured that the bands of negative effective permeability μ^* and permittivity ε^* were spectrally overlapped. Note that while split rings and wires alone behave as opaque media (since the corresponding effective refractive indices $i\sqrt{|\mu^*|}$ and $i\sqrt{|\varepsilon^*|}$ are imaginary), their combination displays the opposite behavior, acting as an electromagnetically transparent medium, as illustrated in Fig. 56.6b. Subsequent efforts by various research groups worldwide were focused on demonstrating double-negative response at higher frequencies and eventually led to the development of negative-index metamaterials for the near-IR part of the spectrum with refractive indices ranging from -0.3 to -4.0 (see [56.10] and references therein). As in the case of magnetic metamolecules, the designs of negative-index metamolecules operating at optical frequencies were substantially modified to take into account the increasing kinetic inductance of electrons in metals and to respect the limitations of nanofabrication techniques existing at that time.

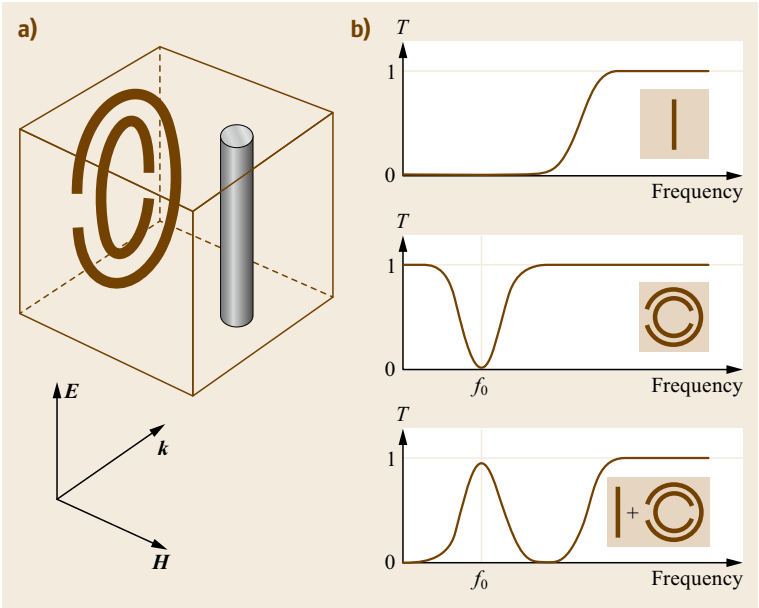

Fig. 56.6a,b Negative-index metamaterial. **(a)** Diagram of the metamolecule – a DSRR combined with a straight wire. **(b)** Transmission spectra schematically shown for metamaterials composed of metallic wires (*top*), DSRRs (*middle*), and their combination (*bottom*)

It is important to note that wave propagation in double-negative media is necessarily complicated by the implicit frequency dependence of ε and μ or, in other words, negative n is *always* strongly dispersive. The latter is dictated by the second law of thermodynamics, which introduces the following constraints valid for nearly transparent media [56.19]

$$\frac{\mathrm{d}(\omega\varepsilon)}{\mathrm{d}\omega} = \omega\frac{\mathrm{d}\varepsilon}{\mathrm{d}\omega} + \varepsilon > 0$$
$$\frac{\mathrm{d}(\omega\mu)}{\mathrm{d}\omega} = \omega\frac{\mathrm{d}\mu}{\mathrm{d}\omega} + \mu > 0\,. \qquad (56.3)$$

Since for negative-index media $\varepsilon < 0$ and $\mu < 0$, it follows that $\mathrm{d}\varepsilon/\mathrm{d}\omega > 0$ and $\mathrm{d}\mu/\mathrm{d}\omega > 0$, which means that both ε and μ cannot be constants.

Negative refraction was the most peculiar (to say the least) effect anticipated in double-negative media. It manifests itself as an anomalous change in the direction of light propagation upon refraction, when a beam of light bends the *wrong* way, while crossing the boundary of double-negative media (Fig. 56.7a). It was the demonstration of negative refraction that shook the scientific community and led to a surge of interest in metamaterial research.

The fact that the incident and refracted waves are on the same side of the normal to the boundary of the negative-index medium follows directly from Snell's law

$$n_2 \sin\theta_2 = n_1 \sin\theta_1\,. \qquad (56.4)$$

Indeed, θ_2 must be negative to satisfy (56.4) when $n_2 < 0$. Negative refraction was first described in reasonable detail by *Mandelshtam*, who concluded that *as unfamiliar as this construction may be, there is, of course, nothing surprising about it* [56.20]. Snell's law, however, does not address the refraction of actual energy carried by the wave. The initial conclusion that in the negative-index medium the energy would flow also in the direction defined by the law of refraction [56.16, 21] was actively contested [56.22–25]. It was eventually shown analytically and numerically that the directions of both phase and group velocities, $\boldsymbol{v}_{\mathrm{ph}}$ and $\boldsymbol{v}_{\mathrm{g}}$, do undergo negative refraction [56.24, 26–29], while the controversy resulted from the fact that in the negative-index medium the wave packets exhibit slanting or *crab-like* motion (Fig. 56.7b). Correspondingly, it was erroneous to interpret the normal to the fronts of the packets as the direction of the group velocity, i. e., energy flow [56.24]. Besides, in isotropic media, the phase and group velocities are always collinear. It was also established that the group velocity of the refracted wave is directed away from the boundary, while its phase velocity was directed toward the boundary (Fig. 56.7b).

Negative refraction was also unambiguously demonstrated by *Smith* et al. [56.1] in an elegant experiment illustrated in Fig. 56.8. A microwave beam was sent onto a prism that had been cut from a double-negative metamaterial (a composite of DSRR and wires), and the deflection of the beam was measured upon its transmission through the prism. The measurements also involved a reference prism made of Teflon, a low-loss dielectric with a refractive index of 1.4. The experimental data indicated that the beam was deflected by the metamaterial prism to negative angles

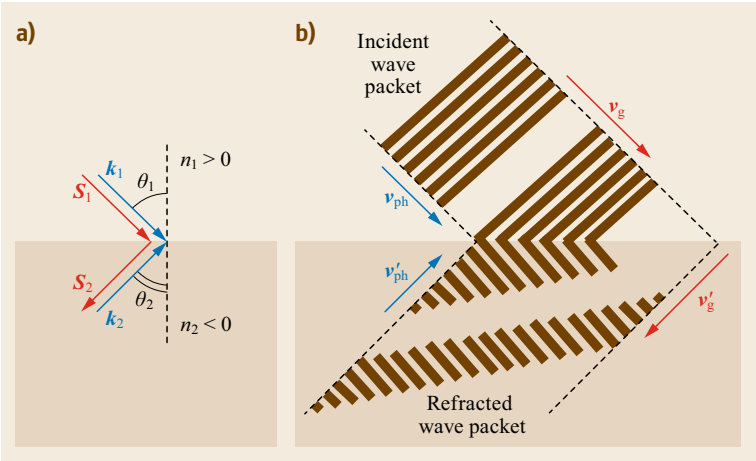

Fig. 56.7a,b Negative refraction. **(a)** Changes in the direction of the wavevector $\boldsymbol{k}$ and energy flow $\boldsymbol{S}$ upon refraction at the interface with a negative-index medium. **(b)** A series of schematically shown wave packets exhibit negative refraction

(compared to the reference case) in the frequency range 10.2 to 10.8 GHz, which had been previously identified as the left-handed propagation region. The deflection angle data were also used to calculate the corresponding index of refraction, which turned out to be negative and highly dispersive (as expected), taking values in the range -2.7 to -0.1. This and subsequent experimental evidence indicated decisively that negative refraction is a reality [56.30].

Perfect lens or superlens

One of the implications of negative refraction noted by Veselago is that a flat slab made of a double-negative material acts as a collecting lens that focuses light rather than disperses it (Fig. 56.9a). Such a lens features no focal plane and, therefore, forms a three-dimensional image of an object (much like a flat metal mirror), provided that its distance from the lens does not exceed the lens' thickness (for $n = -1$). However, unlike a metal mirror, such a *flat lens* produces a real image.

In the special case when $\varepsilon = -1$ and $\mu = -1$, the flat lens reveals additional interesting properties [56.16, 21]. It appears to be perfectly matched to free space exhibiting zero reflection, so that all the energy of the incident wave passes to the refracted wave. Also, light rays arrive at the image plane with zero phase delay, thus preserving the phase information of the object. This can be understood by noting that any ray connecting the object with the image travels half of the distance in air and the other half in the negative-index slab (Fig. 56.9a). Because the phase velocities in the two media have equal magnitudes but opposite signs, the corresponding phase delays compensate each other exactly. However, the most fascinating property of such a lens, perhaps, is that it can produce a sharper image (compared to conventional optical systems) demonstrating resolving power, which exceeds the limit set by the wave nature of light – the so-called diffraction limit. This was shown by *Pendry* in his seminal work *Negative refraction makes a perfect lens* [56.21].

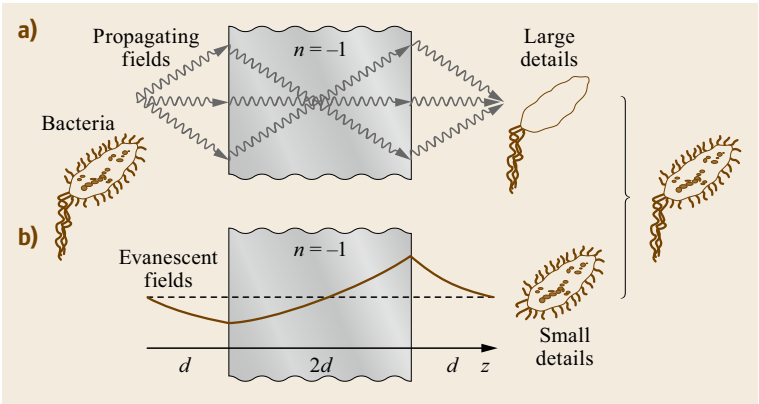

Fig. 56.9a,b Perfect lens. **(a)** The negative-index slab (thickness $2d$) acts as a collecting lens, which focuses *propagating* electromagnetic waves and restores the details of an object that are larger than the wavelength. **(b)** The negative-index slab also acts as an amplifier of *evanescent* waves and restores the details of an object that are smaller than the wavelength

Indeed, the finest details of an object (those that are smaller than the wavelength of light) are carried by the waves with purely imaginary wavevectors. Consequently, these waves decay exponentially as they propagate in air away from the object (*evanescent waves*), and thus cannot be focused by an ordinary lens. In the negative-index slab, the sign of the exponent is reversed and the amplitude of the evanescent waves is bound to increase (Fig. 56.9b). It is easy to see that the decay of the evanescent waves in air is completely negated by the *amplification* occurring inside the slab. The flat lens, therefore, behaves as a *perfect lens* (or *superlens*) – it restores not only the phase but also the amplitude of all light-field components and, as a result, preserves subwavelength features of the object (as illustrated in Fig. 56.9). On the other hand, this optical device should not be regarded as a lens in the usual sense since it cannot focus a parallel beam. The superlens acts as a matching device that transfers light fields between the object and image planes without aberrations; effectively, it *annihilates* the space between the object and the image, so that the image becomes the object.

The superlens, however, has an important drawback. The amplification of the evanescent waves inside the negative-index slab, which at first may seem to violate the conservation of energy, is in fact a transient process. The slab here acts as a resonant cavity that accumulates energy over time for each evanescent-wave component. Correspondingly, imaging (or rather transferring) finer details takes a progressively longer time since the slab must amplify evanescent components with a stronger decay, i. e., smaller input level. Furthermore, the resonant enhancement is limited by inevitable material losses, and although this limitation would not necessarily ruin the super-resolution completely [56.21], the perfect lens will operate efficiently only when the distance to the object z (as well as the thickness of the lens $2d$) is of the order of the wavelength λ_0.

56.1.5 Chiral Metamaterials

While research efforts have mainly been focused on engineering composite media with particular values of permittivity and permeability (or, alternatively, refractive index), the metamaterial approach also enables the enhancement of other, more complex optical properties, such as those governed by chirality [56.31]:

> *I call any geometrical figure, or group of points, chiral, and say it has chirality, if its image in a plane mirror, ideally realized, cannot be brought to coincide with itself.*

In short, any object that cannot be superimposed with its mirror image is chiral. A spring coil (helix), a screw, and a human's hand are the celebrated examples of chiral objects. Chirality is the most fundamental type of asymmetry, which in matter leads to the effect of *optical activity*. It is characterized by a difference between the refractive indices (i. e., phase velocities) experienced by right and left-hand circular polarizations in a chiral medium, $\Delta n = n_+ - n_-$, and leads to a progressive rotation of linear polarization as light propagates through the medium (Fig. 56.10)

$$\Delta\phi = \frac{\Delta n d\pi}{\lambda_0}\,, \tag{56.5}$$

where $\Delta\phi$ is the angle of polarization azimuth rotation, d is the thickness of the medium, and λ_0 is the wavelength of light.

In a lossy medium, the effect is also accompanied by a difference in the absorption of right and left-hand circular polarizations, known as *circular dichroism*. This effect was discovered in quartz by Arago in 1811 and linked to the structural asymmetry of matter by Pasteur in 1848. It is now widely used in analytical chemistry, biology, and crystallography for identifying the spatial structure of molecules and crystals. Chiral materials are always in demand in optoelectronics, life

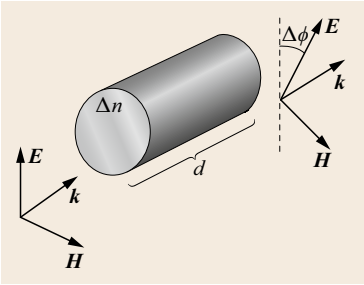

Fig. 56.10 Optical activity: polarization azimuth of linearly polarized light rotates as the latter propagates inside a chiral medium

science microscopy, and display technology providing a means of manipulating the polarization state of light; they are also widely used in photography.

In naturally available chiral media, optical activity is relatively weak and, therefore, slabs with the thickness of hundreds of wavelengths must be used to achieve measurable rotation. For example, the specific rotatory power in quartz, cinnabar, and liquid crystals corresponds to 20°/mm, 600°/mm, and 1000°/mm [56.32] in the visible part of the spectrum. Chiral metamaterials, on the other hand, can exhibit optical activity several orders of magnitude stronger [56.33–35]. The latter is particularly appealing for applications in the terahertz frequency range (and below) where the effect is virtually absent. There are many possible realizations of the chiral metamolecule depending on the application, targeted frequency range, and limits of the fabrication technique, but in all cases its design reveals a structural twist that can be related to either right or left-handed screws (Fig. 56.11).

The first chiral metamolecules, which were experimentally tested in 1898 by *Bose* using millimeter waves [56.8], were made of twisted jutes (Sect. 56.1.2). Two decades later, *Lindman* [56.36] suggested using small (a few centimeters long) randomly oriented copper helices as artificial molecules that would promote polarization azimuth rotation for radio waves. The idea was verified and eventually extended to the case of oriented helices by *Tinoco* and *Freeman* [56.37]. Recent advances in three-dimensional nanofabrication techniques have enabled the realization of such artificial chiral molecules in the optical part of the spectrum [56.38]. The demonstrated array of submicron gold helices formed a uniaxial photonic metamaterial, which operated as a compact and efficient broadband circular polarizer. A very different approach was taken by *Zheludev* et al. [56.39], who proposed the design of chiral metamolecules based on pairs of identical, spatially separated, and mutually twisted planar metallic resonators such as bars, crosses, rosettes, split rings, etc. (Fig. 56.11c–f). The advantage of this approach was that chiral metamaterials could be readily fabricated for any frequency of operation in the range from microwave [56.33] to optical [56.40, 41] frequencies using well-established planar lithography techniques. Moreover, due to the resonant electromagnetic (inductive [56.39]) coupling between the constituent metallic elements of the bi-layered metamolecule, the complete 90° rotation of the polarization can be achieved with just one layer of such metamolecules (with the thickness of the resulting metamaterial slab in the direction of light propagation being less than $\lambda_0/30$) [56.34]. Zheludev's approach also enables the engineering of strong, virtually dispersionless polarization rotation within a wide spectral range [56.42] when the twisted pair is formed by complimentary metallic patterns (Fig. 56.11g). Optical activity may also be observed for bi-layered meta-

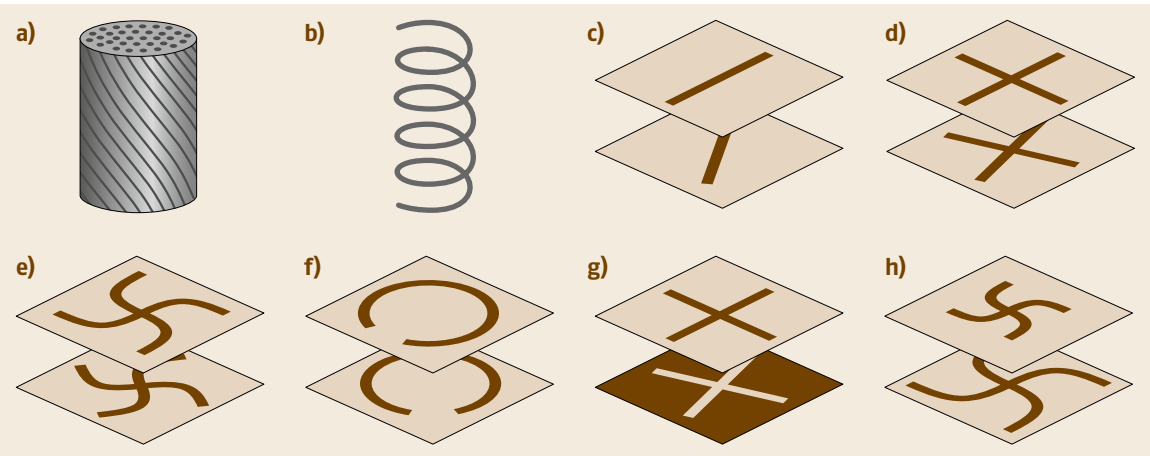

Fig. 56.11a–h Examples of chiral metamolecules: twisted jute (**a**), wire coil (**b**), pairs of mutually twisted metallic bars (**c**), crosses (**d**), rosettes (**e**), split rings (**f**), mutually twisted wire cross and cross-shaped aperture (**g**) and a pair of metallic rosettes of different sizes featuring zero twist (**h**)

molecules that feature zero twist between their layers (Fig. 56.11h). In such a case, the structural twist of the constituent resonators was shown to be sufficient provided that the resonators have different sizes [56.43].

It is easy to see that the designs of chiral metamolecules can be reduced to the combination of two basic elements, a split ring and a cut wire resonator electrically connected together, as shown in Fig. 56.12. This illustrates that chiral metamaterials exhibit simultaneously electric and magnetic responses, which appear to be mixed such that magnetic dipole moments are induced in the split rings by the electric component of light (via cut wires), and vice versa. This cross-coupling between the electric and magnetic fields is described by a dimensionless chirality parameter κ, which in the simplest case of an isotropic chiral medium is a scalar [56.44]

$$\begin{aligned} \boldsymbol{D} &= \varepsilon_0 \varepsilon \boldsymbol{E} - \mathrm{i}\kappa \sqrt{\varepsilon_0 \mu_0} \boldsymbol{H} \\ \boldsymbol{B} &= \mu_0 \mu \boldsymbol{H} + \mathrm{i}\kappa \sqrt{\varepsilon_0 \mu_0} \boldsymbol{E} \,. \end{aligned} \tag{56.6}$$

It is the chirality parameter that gives rise to the difference between the refractive indices for right- and left-hand circular polarizations

$$n_{\pm} = \sqrt{\varepsilon \mu} \pm \kappa \,. \tag{56.7}$$

While the studies of artificial chiral media found applications in many areas of microwave engineering, such as antennas, absorbers, polarizers, and waveguides [56.45, 46], the recent explosive interest in chiral metamaterials was triggered by the opportunity of achieving negative refraction in such media in a relatively simple way. It was identified independently by *Tretyakov* et al. [56.47] and *Pendry* [56.48], who noted that according to (56.7) the index of refraction of a chiral medium becomes negative for one of the circularly polarized waves if $|\kappa| > \sqrt{\varepsilon \mu}$. Also, in that case neither ε nor μ need to be negative, which was in stark contrast to the previously formulated, more complex condition for the negative refraction of linearly polarized waves (Sect. 56.1.4). Thus, the proposed chiral route to negative refraction, although limited to one circular polarization, relies on the engineering of only one resonance – the resonance of optical activity (where κ can become sufficiently large), and is, therefore, expected to improve and simplify the designs of negatively refracting composites [56.48]. The validity of this approach was confirmed experimentally using microwave [56.49] and terahertz [56.50] chiral metamaterials based on stacks of mutually twisted metallic patterns, which enables effective refractive indices as low as -2 and -5, respectively, to be attained.

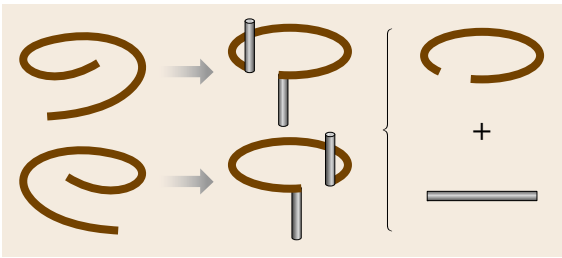

Fig. 56.12 Chiral metamolecule and its two basic structural elements – a split ring and a cut wire

56.1.6 Transformation Optics and Metamaterial Cloaks

One of the successful applications of the metamaterial concept was in the practical implementation of transformation optics, a mathematical technique aimed at designing complex electromagnetic media that can control the flow of light in a desired manner [56.51, 52]. The transformation optics approach enables the recreation of an electromagnetic phenomenon in a warping virtual space as an optical illusion in the physical Euclidean space. For example, the effect of gravitational lensing caused by a massive celestial body (which is treated by the general theory of relativity as the manifestation of a gravity-induced distortion in an abstract spacetime continuum) can be viewed as the ordinary refraction of light by a shell of the dielectric medium enclosing the body in the physical space. This appears possible because Maxwell's equations have exactly the same form in any coordinate system, while the permittivity and permeability are just scaled by a common factor, which absorbs the transformation from one coordinate system into another [56.53]

$$\varepsilon'^{\mathrm{i'j'}} = |\det(\boldsymbol{\Lambda})|^{-1} \boldsymbol{\Lambda}^{\mathrm{i'}}_{\mathrm{i}} \boldsymbol{\Lambda}^{\mathrm{j'}}_{\mathrm{j}} \varepsilon^{\mathrm{ij}} \,, \tag{56.8a}$$

$$\mu'^{\mathrm{i'j'}} = |\det(\boldsymbol{\Lambda})|^{-1} \boldsymbol{\Lambda}^{\mathrm{i'}}_{\mathrm{i}} \boldsymbol{\Lambda}^{\mathrm{j'}}_{\mathrm{j}} \mu^{\mathrm{ij}} \,, \tag{56.8b}$$

where $\boldsymbol{\Lambda}^{\alpha'}_{\alpha} = \partial x'^{\alpha'} / \partial x^{\alpha}$ denotes the Jacobian transformation matrix between the virtual space $\{x^{\alpha}\}$ and the physical space $\{x'^{\alpha'}\}$.

The correspondence between coordinate transformations and the material parameters was noted by *Dolin* more than 50 years ago [56.54], but it was perceived as being merely a mathematic trick because (56.8a) and (56.8b) do not impose physical constraints on the values of the transformed permittivity and permeability. The perception, however, has changed recently with the advent of the metamaterial approach, which in principle enables the engineering of extreme values of ε' and μ', as well as their spatial variation prescribed by the transformations in (56.8). Originally driven by the desire to realize the invisibility cloak, transformation optics has now become a powerful tool for designing a wide range

of new optical effects and devices, including electromagnetic wormholes, hidden gateways, optical black holes, field rotators and concentrators, etc. (see [56.55] and references therein).

The *shell cloak* is the most remarkable example of space distortion; it can steer light around an object making the latter invisible, when imitated in the physical space using metamaterials. The distortion squeezes the space from within a sphere with the radius R_2 to within a shell with the same outer radius and inner radius R_1 (Fig. 56.13). Electromagnetic waves will not interact with or scatter from the core of the shell because it is not a part of the resulting curvilinear space, while the shell itself will neither scatter waves nor cast a shadow in the transmitted field (either of which would allow one to detect the cloak).

In the local spherical coordinate system with the origin placed at the center of the sphere, the transformation rules give the following values of ε' and μ' in the shell ($R_1 < r' < R_2$) [56.52]

$$\begin{aligned}
\varepsilon'_{r'} &= \mu'_{r'} = \frac{R_2}{R_2 - R_1}\frac{(r' - R_1)^2}{r'} , \\
\varepsilon'_{\theta'} &= \mu'_{\theta'} = \frac{R_2}{R_2 - R_1} , \\
\varepsilon'_{\varphi'} &= \mu'_{\varphi'} = \frac{R_2}{R_2 - R_1} .
\end{aligned} \tag{56.9}$$

Correspondingly, ε' and μ' are free to take any values in the core ($r' < R_1$), while $\varepsilon' = \mu' = 1$ outside the shell ($r' > R_2$). It is easy to see that (56.9) correspond to extremely anisotropic distributions of ε' and μ' in the global Euclidean space, while some of the components of the permittivity and permeability tensors, although positive, approach zero near the core. Clearly, no natural material system can offer such complex variations of its parameters.

A proof-of-principle demonstration of a metamaterial shell cloak was performed in 2006 by *Smith* et al. [56.56]. The experiments were conducted in the microwave part of the spectrum, where the fabrication of bulk metamaterial samples and their characterization was generally easier to accomplish. Even in that case, the implementation of a true three-dimensional cloak was not practical, given the limitations of the measurement technique and the complexity of the metamaterial properties [56.56]. The cloaking principle was demonstrated for TE-waves in a parallel-plate waveguide using a two-dimensional cylindrical shell structure (Fig. 56.14). Such a configuration of the experiment enabled substantial simplification of the metamaterial design. Also, additional steps were taken to reduce the set of required material parameters; however, this was at the expense of nonzero reflectance. The metamaterial shell was formed by 10 concentric cylindrical layers of 3.3 mm large magnetic SRR metamolecules, and had the inner and outer radii $R_1 = 27.1$ mm and $R_2 = 58.9$ mm, respectively. The cloak was designed to operate at 8.5 GHz.

Figure 56.15 compares the measured and simulated fields inside and outside the cloak, which show a rather good match. As the waves propagate through the metamaterial shell, the center section of the wavefront starts to slow down when it approaches the core, exhibiting wavelength compression. The wavefront splits to pass around the core and rejoins on the opposite side. Upon exiting the shell, the wavefronts are seen to match those propagating alongside in the empty space. The

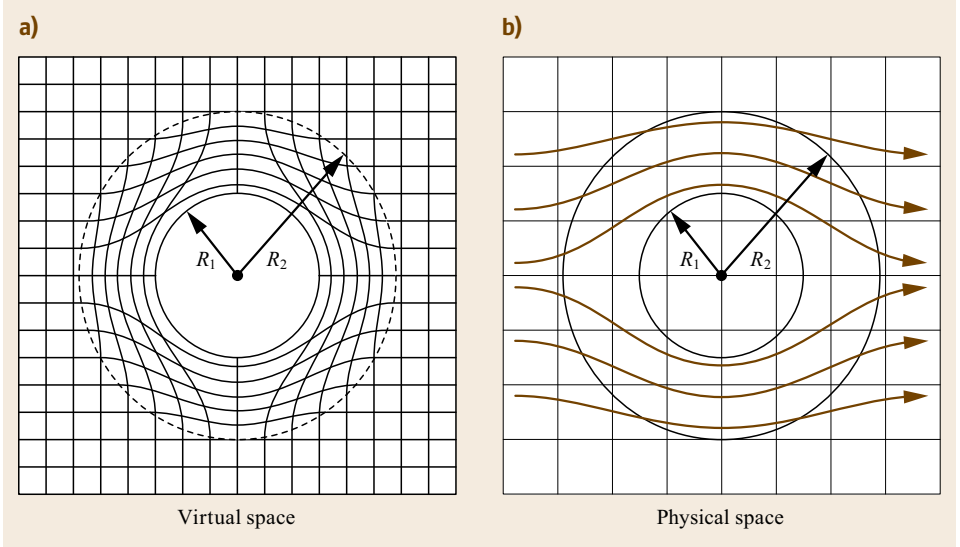

Fig. 56.13a,b Transformation optics. **(a)** Space distortion of a finite extent that results in **(b)** an electromagnetic cloaking shell, when imitated in the physical space through a distribution of material parameters

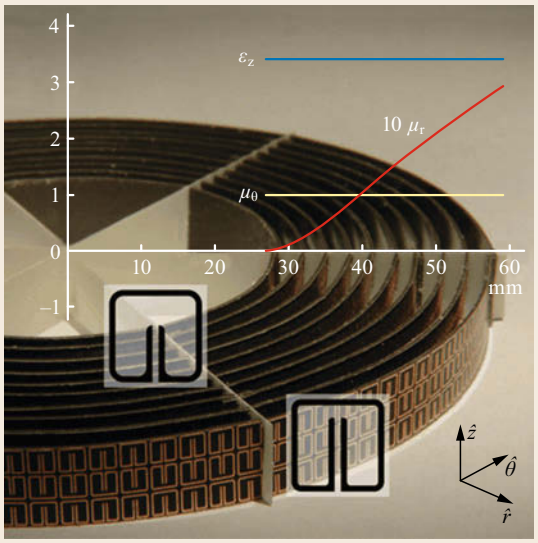

Fig. 56.14 Photograph of a two-dimensional microwave cloaking shell. (Reprinted from [56.56], with permission from AAAS)

fields outside the cloak also feature a small but non-negligible component of scattering (reflection) resulting from the implementation of the reduced parameters set. A pronounced attenuation of the transmitted fields is attributed to resistive losses present in the metamaterial structure.

Although this demonstration illustrates the feasibility of the metamaterial approach in the context of transformation optics, the practical deployment of a shell invisibility cloak is still rather challenging. The main reason is that the required values of the material parameters in this type of cloak are attained via metamaterial resonances, which renders it as an inherently narrow-band device. Also, the resonant nature of metamaterial properties makes cloaking performance highly sensitive to resistive losses in the constituent materials (especially at optical frequencies), while fairly complex design and strong electromagnetic anisotropy of the shell cloak call for the development of sophisticated computation and fabrication techniques.

The *carpet cloak* or ground-plane cloak represents an alternative, easier to implement strategy of concealing an object [56.57]. It employs a reflective bump (a perturbation on a surface of a conducting plane) covered by a layer of metamaterial with a specially tailored variation of the refractive index. The bump provides a cavity for hiding the object, while the metamaterial layer conceals the presence of the bump, creating an illusion of a flawless mirror (see Fig. 56.16a–c). In this case, given the restricted geometry of the cloak, it becomes possible to minimize the anisotropy of the transformed material parameters, while the required values of the refractive index turn out to be merely greater than unity. This allows one to substantially simplify the design of the metamaterial cover and exploit metamolecules off their resonance, which makes the carpet cloak a truly broadband and scalable optical device.

The first metamaterial carpet cloak was experimentally demonstrated in 2009 at microwave frequencies by *Smith* et al. [56.58], who built the device using over 10,000 I-shaped 2 mm large metamolecules. Its functionality was confirmed for the 13−16 GHz range of frequencies and could be extended to up to 18 GHz. Low levels of absorption due to nonresonant operation of carpet cloaks and the relative simplicity of their designs have enabled successful demonstrations of the concept also in the IR [56.59] and visible [56.60] domains (Fig. 56.16d).

56.1.7 Hyperbolic Metamaterials

Hyperbolic metamaterials are perhaps the only class of artificial electromagnetic media that does not rely on resonant interaction with the incident radiation. Instead, the unusual optical properties of the hyperbolic metamaterials result from extreme anisotropy of their *effective* permittivity ε^*, when the sign of ε^* reverses for the electric field parallel ($\|$) and orthog-

onal ($\perp$) to the anisotropy axis of the metamaterial crystals. In other words, depending on the direction of light propagation (and polarization) such metamaterials behave either as metals or as dielectrics (i. e., insulators). This is achieved for material composites typically formed by an array of parallel metallic wires/rods embedded into a dielectric matrix (Fig. 56.17a), or a stack of alternating thin layers of metal and dielectric (Fig. 56.17b). Normally (at visible frequencies and below), in the first case, $\varepsilon^*_{\parallel} < 0$ and $\varepsilon^*_{\perp} > 0$ (type I anisotropy), while in the second case, $\varepsilon^*_{\parallel} > 0$ and $\varepsilon^*_{\perp} < 0$ (type II anisotropy). The anisotropy of both types leads to unusual, hyperbolic dependences for the frequency ω of the allowed TM-polarized modes ($H_{\parallel} = 0$) on their wavevectors $\boldsymbol{k}^* = \{k^*_x, k^*_y, k^*_z\}$, which explains the name given to this class of metamaterials (Fig. 56.17c,d)

$$\frac{k^{*2}_z}{\varepsilon^*_{\perp}} - \frac{k^{*2}_x + k^{*2}_y}{|\varepsilon^*_{\parallel}|} = \frac{\omega^2}{c^2} \quad (\varepsilon^*_{\parallel} < 0, \varepsilon^*_{\perp} > 0) \qquad (56.10a)$$

$$\frac{k^{*2}_x + k^{*2}_y}{\varepsilon^*_{\parallel}} - \frac{k^{*2}_z}{|\varepsilon^*_{\perp}|} = \frac{\omega^2}{c^2} \quad (\varepsilon^*_{\parallel} > 0, \varepsilon^*_{\perp} < 0) \; . \qquad (56.10b)$$

In principle, such relations (known as the dispersion relations) allow, at any given frequency, the propagation of waves with infinitely large wavevectors, which is in stark contrast to spherical or, in the general case, elliptical dispersions characteristic of natural materials. In practice, however, the range of the permitted wavevectors k^* appears to be capped, although at rather large magnitudes, due to the small but finite structural periodicity of the composites at the microscopic level (owing to the effective medium description no longer being valid when the wavelength becomes comparable to the composite's lattice constant).

One of the immediate consequences of the hyperbolic dispersions is that there are no evanescent waves, while for certain light propagation directions, the effective index of refraction can be extremely large. The latter finds applications in miniaturizing photonic devices, subdiffraction photonic funnels, and nanoscale resonators (see [56.61] and references therein). Also, due to strong material dispersion, the hyperbolic media can act as spatial frequency filters [56.62], while the extreme anisotropy of its dielectric permittivity ε^* can be exploited in linear polarizers [56.63].

Negative Refraction

Negative refraction was perhaps the first phenomenon demonstrated in hyperbolic media [56.65, 66]. In particular, the effect can be observed for TM-polarized waves at a facet cut perpendicular to the anisotropy axis of a type I metamaterial crystal (Fig. 56.18a). In this

case, the dielectric permittivity in the direction normal to the vacuum–metamaterial interface is negative and, due to the continuity of the normal component of the electric displacement across the interface ($E_z = \varepsilon^* E_z^*$), the normal component of the wave's electric field inside the metamaterial E_z appears to be reversed. As a result, the component of the Poynting vector propagating in the metamaterial parallel to the interface S_x^* is also reversed, rendering the angle of the beam refraction negative (Fig. 56.18a).

Nevertheless, a hyperbolic metamaterial slab operating in the negative refraction regime can exhibit only partial focusing of light, as illustrated in Fig. 56.18b. This is because the mutual orientation of the Poynting vector and the wavevector (in other words, group and phase velocities) is not always antiparallel or even collinear, as in the case of isotropic negative-index media, but depends on the propagation direction relative to the metamaterial's anisotropy axis.

Subwavelength Imaging

Subwavelength imaging is one of the most promising applications of hyperbolic media. Unlike negative-index metamaterials, which enable the complete restoration of evanescent waves at the image plane (Sect. 56.1.4), the hyperbolic media make it possible to convert evanescent waves in air/vacuum into propagating ones, which then can be collected in the far-field zone and processed by conventional optical microscopes. The device that does such a trick is called the hyperlens [56.67].

A conventional hyperlens has the form of a hollow cylinder made of a type I hyperbolic metamaterial. An example of such a lens designed to operate in the ultraviolet (UV) spectrum is shown in Fig. 56.19a. If an object is placed on the inner surface of the cylinder, the scattered evanescent waves, which carry all the subwavelength information in air/vacuum, can enter the hyperlens where they will propagate radially with no decay (k_r^* is no longer imaginary), as dictated by the hy-

The lens is formed by a stack of curved alternating layers of metal and dielectric, which behaves as a type I hyperbolic metamaterial at UV frequencies. **(b)** Scanning electron microscope image of the cross-sectional view of a lens operating at the wavelength of 410 nm. The scale bar is 500 nm. (After [56.64])

perbolic dispersion. While the waves spread inside the hyperlens, the azimuthal component of their wavevectors k_φ^* gradually becomes smaller due to the conservation of the angular momentum in the cylindrical geometry, $k_\varphi^* r = \text{const}$. Correspondingly, at a certain radius r, the azimuthal component of the wavevectors may become small enough ($k_\varphi^* < \omega/c$) for the radial component to be real even outside the cylinder,

$$k_\mathrm{r} = \sqrt{\frac{\omega^2}{c^2} - k_\varphi^2}\,, \tag{56.11}$$

where $k_\varphi = k_\varphi^*$. It is easy to show that the resolution of such a hyperlens, that is, the smallest separation between two successfully resolved features of the object, is simply proportional to the ratio between the inner and outer radius of the cylinder [56.67]. Hyperlenses have been successfully demonstrated experimentally in the microwave [56.68], visible [56.69, 70], and near-UV [56.64, 71] domains (Fig. 56.19b).

Enhancement of Spontaneous Emission

Enhancement of spontaneous emission (or control of spontaneous emission) is another promising application of hyperbolic metamaterials. It is based on Fermi's golden rule, which states that the lifetime of spontaneous emission is strongly influenced by the density of available electromagnetic modes [56.72]. Given the analogy with the electronic density of states in solid state physics, the latter is proportional to the area of the isofrequency surface defining the dispersion, and is, therefore, finite in dielectrics (where the dispersion is elliptical) but diverges in hyperbolic media. Consequently, when an emitter is brought close to the surface of a hyperbolic metamaterial it starts to couple to the available high-k states [56.73], and the radiative decay rate of the emitter increases compared to that in air/vacuum.

There are, however, several factors that in practice limit the enhancement of spontaneous emission. Most notably these are the finite structural periodicity of a metamaterial composite, which introduces a cut-off for the largest wavevectors permitted by the metamaterial, and the finite separation between the emitter and the metamaterial, which makes it impossible for some of the evanescent harmonics to reach the metamaterial and hence couple to its high-k states.

Although many experiments involving hyperbolic metamaterials of types I and II demonstrated a shortening of the lifetime [56.73–75], the discrimination between the true radiative mechanism involving propagating high-k modes and the nonradiative mechanism (i. e., dissipation due to ohmic resistance of materials) has been challenging [56.75, 76].

56.2 Planar Metamaterials

Planar metamaterials, also known as metafilms or metasurfaces, represent a special class of low-dimensional artificial media. They are formed by metal films periodically patterned on a *subwavelength scale*, which are many times thinner than the wavelength of light. Despite their vanishing thickness, planar metamaterials can strongly interact with electromagnetic waves, which they transmit, absorb, or reflect without diffraction, acting as media of *zero* dimension in the direction of light propagation. As a result, planar metamaterials are able to efficiently mimic (and improve) the functionalities of the existing bulk optical components such as lenses, prisms, polarizers, filters, beam splitters, etc. More importantly, they make accessible a range of new exotic effects including a magnetic mirror, perfect absorption, asymmetric transmission, optical activity without chirality, wavefront rectification, etc.

Importantly, while practical implementation of bulk metamaterials (especially in the optical domain) still very much depends on advances in the development of three-dimensional fabrication techniques, planar photonic metamaterials are fully compatible with the existing micro and nanofabrication techniques exploited by complementary metal–oxide–semiconductor (CMOS) technology. This, in combination with the unusual electromagnetic properties of the planar metamaterials achieved through the nanoscale control of light, renders this type of artificial media an intriguing and viable alternative to various conventional photonic components.

56.2.1 Frequency Selective Surfaces

One of the most basic properties of planar metamaterials is the ability to resonantly transmit, reflect, or absorb electromagnetic radiation within narrow frequency bands that can be engineered on demand. The idea of such metamaterial filters, which were termed frequency selective surfaces (FSS) because of their vanishing thickness, originated in the RF and microwave communities [56.77, 78] and can be traced back to the work on phased antenna arrays done in the 1960s [56.79]. The simplest example of an FSS is the perforated metal screen placed behind the glass window of a microwave oven, which blocks microwave radiation escaping from

the oven but at the same time allows one to see through the window.

An FSS is typically formed by an array of complex-shaped patches of a metal foil arranged on a two-dimensional lattice with a *subwavelength* period, and mechanically supported by a thin dielectric substrate (Fig. 56.20a). The FSS is transparent everywhere apart from a specific range of frequencies, known as the stop band, where the array of patches reflects electromagnetic waves as if it were a continuous sheet of metal (Fig. 56.20b). Such a spectrally selective response is underpinned by the electromagnetic resonances of individual patches, which have the same nature as the *geometrical* resonances in bulk metamaterials (Sect. 56.1.1). They are controlled by the shape and size of the patches (also regarded as metamolecules), and the dielectric permittivity of the immediate surroundings. Consequently, planar metamaterials share most of the design features of their bulk counterparts (Fig. 56.2), and the wavelength of their resonances $\lambda_0 = c/f_0$ is given by the expressions similar to (56.1),

$$\lambda_0 \approx \sqrt{\frac{\varepsilon+1}{2}}\frac{2l_e}{m}\,, \tag{56.12}$$

where l_e is the total electrical length of the metallic pattern that forms the metamolecule, ε is the relative permittivity of the supporting substrate, and m is a positive integer. As with bulk metamaterials, resonances with $m > 4$ are usually not possible to engineer. The only difference between (56.1) and (56.12) is that factor $\sqrt{\varepsilon}$ has been replaced with $\sqrt{(\varepsilon+1)/2}$. Such a modification reflects the fact that an FSS is usually supported by a dielectric on one side, while the other side contacts with air. The effective permittivity in this case can be calculated as the average between the permittivities of the dielectric and air, which happens to be a good approximation that works well for dielectric layers as thin as $0.05\lambda_0$ [56.77]. It is easy to see that when an FSS is sandwiched between two dielectric layers with permittivity ε, (56.12) and (56.1) become identical. As in the case of bulk metamaterials, (56.12) works particularly well for metamaterials operating at near-IR frequencies and below, where metals are still good conductors and can, therefore, support electrical currents.

An FSS can also be formed by an array of complex-shaped subwavelength apertures, rather than patches, made in a thin metal screen (Fig. 56.20c). Such an *inverse* or *negative* type of planar metamaterials does not necessarily require supporting substrates, as mechanical stability here is often ensured by the metal screen itself. A negative FSS behaves as a mirror everywhere apart from in a certain range of frequencies, known as the passband, where electrical currents induced in the perforated screen are resonantly suppressed, rendering the metallic structure electromagnetically transparent (Fig. 56.20d). The spectral selectivity of the negative FSS is shaped by the resonances of individual apertures, which are different in nature from the resonances of conventional (i. e., positive) metamolecules and are usually described with the help of fictitious *magnetic currents* [56.80]. Nevertheless, the passband of a negative FSS can be predicted based on the spectral response of its complementary structure. According to the Babinet principle, the specular reflection coefficient of a perforated metal screen equals the transmission coefficient of a *free-standing* array of metallic patches that have the same shape as the apertures in the screen, and vice versa. Such an approach works particularly well in the RF and microwave domains where metals behave as perfect conductors, while the thickness of the screen can be made as $\lambda_0/10^3$ or less. Thicker screens have the

opposite effects on the bandwidths of the complimentary metamaterial patterns, making the transmission passband narrower and the stopband wider. Also, the two types of FSS will behave differently if the thickness of the dielectric substrates d exceeds $\lambda_0/4$ [56.77].

The shape of the transmission stopband (or passband) and its width can be modified by introducing additional resonant elements in the design of the metamolecules (e.g., asymmetrically split wire rings, Fig. 56.20e) or, alternatively, by cascading several FSS [56.77, 78]. In particular, both methods can be used to engineer a very narrow window of transparency within the stopband of a planar metamaterial (Fig. 56.20f), which mimics the famous effect of electromagnetically induced transparency in cryogenically cooled gases [56.81–83]. The metamaterial transparency window is characterized by a very sharp normal dispersion of the phase of passing electromagnetic waves, which corresponds to a substantial reduction of the group velocity. For example, a $\lambda_0/35$ thick planar structure can delay electromagnetic pulses by more than $1/3$ of their initial width [56.82].

FSSs play a key role in many antenna systems for modern fixed and mobile communication systems [56.77, 78], and can be configured to operate as low-pass, high-pass, and band-pass, or dichroic filters [56.84–87]. Other applications include laser–cavity output couplers [56.88, 89] and narrow-band infrared sources [56.90–92]. Also, owing to their resonant behavior, planar metamaterials are able to enhance light–matter interaction, facilitating optical sensing [56.93, 94], energy harvesting [56.95], and generation of coherent radiation [56.96, 97].

56.2.2 Magnetic Mirrors (High Impedance Surfaces)

If an FSS is placed on top of a continuous metal screen such that the supporting substrate is sandwiched between the metallic pattern of the FSS and the screen, acting as a spacer, the electromagnetic boundary conditions at the surface of the resulting planar metamaterial can be altered in a peculiar way. In contrast to the case of regular metallic mirrors (Fig. 56.21a), the direction of the E-field component of an electromagnetic wave reflected off the structure will not reverse. Instead, the reversal will occur for the H-field component (Fig. 56.21b), and the total magnetic field tangential to the surface will vanish [56.98, 99], as if the metamaterial acts as an *artificial magnetic conductor* (hence the term *magnetic mirror*).

When the change of the phase upon reflection $\Delta\varphi$ is exactly zero and ohmic losses are absent, such a planar metamaterial can be regarded as a perfect magnetic conductor, the counterpart of a perfect electric conductor. In practice, the reflection phase of a magnetic mirror crosses zero only at a certain frequency f_0, corresponding to the resonant mode of the structure (Fig. 56.21c). The useful bandwidth of a magnetic mirror is usually defined by $|\Delta\varphi| < \pi/2$ to either side of f_0, since these changes of the phase would not cause destructive interference between the incident and reflected waves [56.98, 99].

The behavior of the magnetic mirror can be understood by examining a corrugated metal slab, where a series of narrow slots are cut vertically, or a $\lambda/4$ thick dielectric slab backed by a metal plate. In the first case, each slot can be regarded as a parallel-plate transmission line, which runs into the slab and is shorted at the bottom (Fig. 56.22a). If the slots are $\lambda_0/4$ deep, the short circuit at the bottom end is transformed by the length of the slots into an open circuit with zero currents at the top end, and hence exhibits high impedance. In the second case, the total optical path in the dielectric slab upon reflection equals $\lambda/2$, so that the first antinode of the standing wave, where the E-component is at maximum and the H-component is zero, coincides with the top surface of the slab (Fig. 56.22b). A magnetic mirror is the planar analog of the two cases that effectively have been transformed to a much more compact form by virtue of the strong resonant coupling between the top and bottom surfaces – the FSS and metal screen, respectively. Given the analogy, magnetic mirrors act as two-dimensional electric filters that block surface currents and are thus often referred to as high impedance surfaces (HIS) [56.99].

The resonant frequencies of HIS are typically lower than the resonant frequencies of the constituent FSS due to the capacitive coupling of the latter with the metal screen. For many designs of metamolecules, the wavelength of their resonances can be estimated based on the expression for the guided wavelength in a microstrip transmission line [56.100]

$$\lambda_0 \approx \sqrt{\frac{\varepsilon+1}{2} + \frac{\varepsilon-1}{2\sqrt{1+\frac{5d}{w}}}}\,\frac{2l_e}{m}\,, \tag{56.13}$$

where l_e is the total electrical length of the metallic pattern that forms the metamolecule, $2w$ is the width of the metallic strips forming the metamolecule, ε is the relative permittivity of the dielectric spacer, d is the spacer's thickness, and m is a positive integer ($m < 5$). As in the case of (56.1) and (56.12), this formula is practically useful only in the near-IR and lower frequency domains.

HIS have been realized and studied mainly in the RF and microwave domains where, due to their unusual boundary condition, they have been used as a new

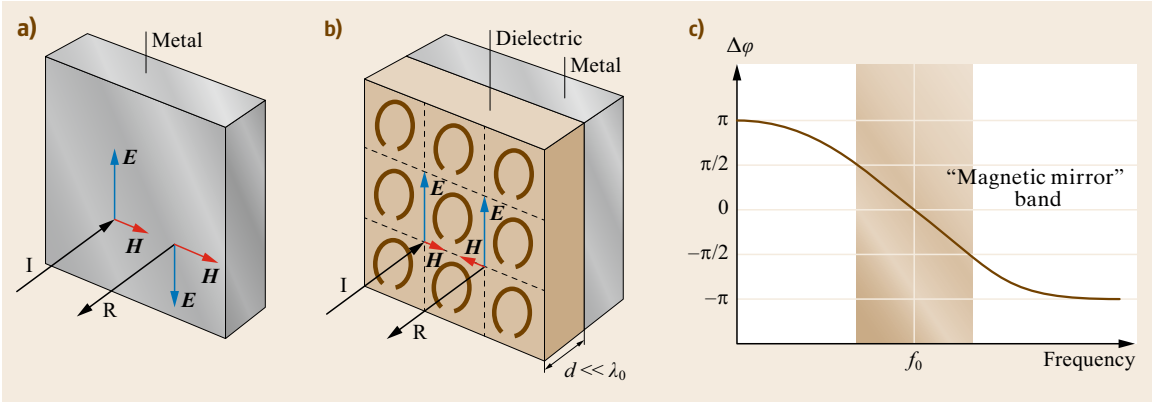

Fig. 56.21 Electromagnetic boundary conditions at the surface of **(a)** a conventional metallic mirror and **(b)** a magnetic mirror. **(c)** Dispersion of the reflection phase schematically shown for a magnetic mirror at its resonance

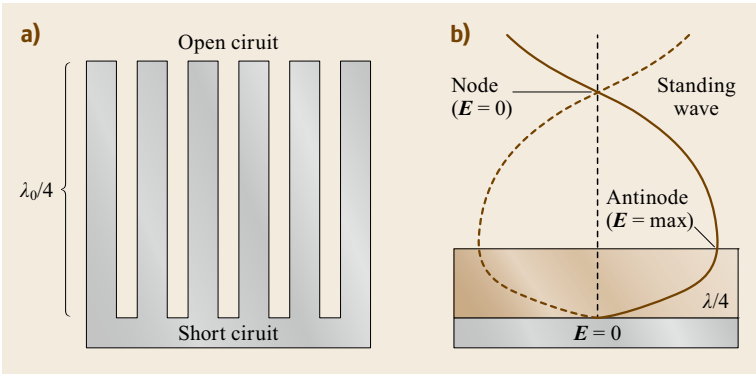

Fig. 56.22a,b Bulk analogs of a magnetic mirror: corrugated metal slab **(a)** and dielectric slab backed by a metal plate **(b)**

type of ground plane for low-profile antennas [56.99, 101, 102]. Indeed, an electric-dipole antenna lying flat against a HIS will not be shorted out (as it happens on a regular metal sheet), while its radiation will appear amplified due to the in-phase oscillations of the antenna's image created by such a mirror. Moreover, since at resonance HIS do not support propagating surface waves, the antenna will radiate efficiently, with a smooth radiation pattern that is free from the effects of multipath interference along the ground plane.

The magnetic mirror effect has been successfully demonstrated also in the visible part of the spectrum [56.103], where one faces challenges in metamaterial fabrication and has to deal with the plasmonic behavior of nanostructured metals and increased ohmic losses. The interest in optical magnetic mirrors is driven by applications in surface-enhanced spectroscopy, and the opportunity to increase the efficiency of optical antennas and nanoemitters, and engineer compact optical cavities. The first metamaterial sample was based on a periodic grid of 40 nm thick meandering aluminum nanowires forming a resonant *fish-scale* pattern, which was placed on top of an aluminum film coated with a 50 nm thick silicon dioxide layer (Fig. 56.23). The resulting nanostructured mirror exhibited high-impedance resonances in the yellow and red spectral bands. In particular, its reflection at 560 and 630 nm was accompanied by changes of the phase as small as $\pi/9$ and $\pi/6$, respectively.

56.2.3 Perfect Metamaterial Absorbers

One of the most promising practical applications of magnetic mirrors has proven to be *resonant loss amplification* (or perfect absorption [56.104]), which benefits from the presence of, otherwise detrimental, resistive losses. This metamaterial functionality exploits the high-impedance resonance where the tangential component of the total electric field on the surface of a magnetic mirror is significant. Consequently, if an electrically resistive sheet (for example, a thin slab of a lossy dielectric) is placed on top of the structure, a part of the incident energy will be dissipated in this slab and, as a result, the reflection coefficient of the system may become significantly reduced. This can be shown quantitatively by using transmission line the-

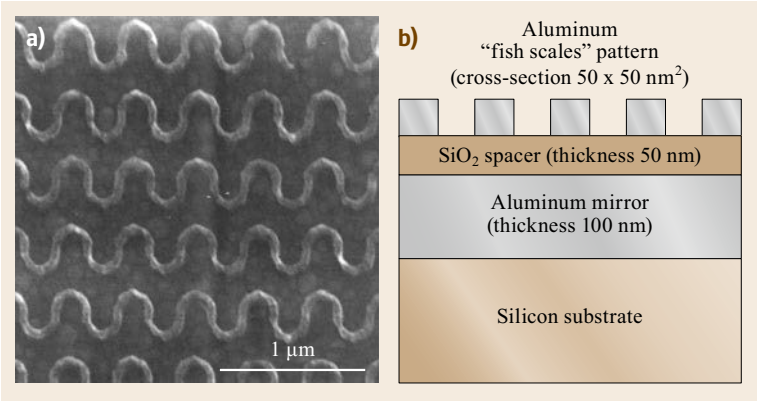

Fig. 56.23a,b First optical magnetic mirror. **(a)** Scanning electron microscope image of the aluminum *fish-scale* nanopattern. (After [56.60, 103]) **(b)** Cross-section of the mirror

ory. In fact, the reflectivity may drop as low as −30 dB ($R = 0.1\%$) [56.105], indicating that the resonant absorption of light by the metamaterial mirror is virtually complete.

The idea of the metamaterial absorbing screen was originally conceived by *Engheta* [56.106] and experimentally demonstrated by *Fedotov* et al. [56.105], who also showed that the source of losses could simply be the dielectric spacer of the magnetic mirror itself. An absorbing magnetic mirror may, therefore, be regarded as an extremely compact electromagnetic cavity, where light bounces back and forth (effectively being trapped between the constituent FSS and metal screen) while passing through the lossy dielectric many times until it is completely absorbed. Such an interpretation is also supported by the results of numerical simulations when presented in the form of field lines of the total Poynting vector, which are often used to visualize the flow of electromagnetic energy near subwavelength scatterers [56.107, 108]. At high-impedance resonance, these lines are seen to wind around the metallic fabric of the metamaterial, going in and out of the dielectric spacer where they eventually terminate (Fig. 56.24). Achieving maximum absorption, however, is possible only for a certain, optimum range of resistive losses (i. e., values of imaginary part of the substrate's permittivity, $\mathrm{Im}\{\varepsilon\}$); the absorption is naturally weak if the losses are too small, and it is also weak if the losses are too high, since large $\mathrm{Im}\{\varepsilon\}$ destroys the magnetic mirror behavior [56.105].

Resonant loss amplification may be used to improve the sensitivity of photodetectors outside their main spectral band by enhancing a small tail of interband absorption. In this case, for example, the photosensitive material could replace the dielectric spacer of the magnetic mirror, while the metamaterial structure itself would act as a light-harvesting device. This approach should be particularly efficient for semiconductor detectors and solar cells, and for increasing the quantum efficiency of photomultipliers.

56.2.4 Designer Metasurfaces and Flat Optics

The resonant response of a planar metamaterial is accompanied by a phase shift of the transmitted wave, which varies between $-\pi/2$ and $+\pi/2$, depending on the detuning from the resonance frequency. Remark-

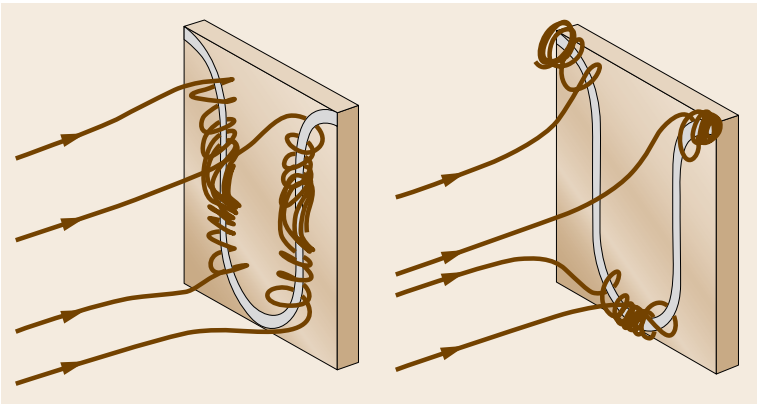

Fig. 56.24 Perfect absorption: lines of the total Poynting vector (*power flow*) calculated for two different absorption resonances of a microwave *fish-scale* magnetic mirror

ably, it occurs on the length scale of one-tenth or even one-hundredth of a wavelength, which renders the phase shift virtually discontinuous. Thus, by varying the size and geometry (and hence the detuning from the resonance frequency) of individual metamolecules along the surface of the metamaterial, one can spatially modulate the phase discontinuity and, in accordance with Huygens's principle, imprint the resulting phase profile on the transmitted beam. The same applies to the reflected beam, which is produced by the coherent superposition of the waves scattered by the individual metamolecules in the backward direction. Given the ever-expanding choice of resonant patterns, metasurfaces with gradient structuring (designer metasurfaces) should enable the shaping of transmitted and reflected wavefronts in nearly arbitrary ways, thus performing as sophisticated but ultimately flat optical devices [56.109]. This is in stark contrast to conventional bulk optical components (e.g., lenses, prisms, wave plates, and curved mirrors), where the phase shifts are accumulated gradually along the optical path, typically over the distance of several wavelengths.

Although the idea of designer metasurfaces can be traced back to earlier works on microwave FSS [56.110, 111], it attracted significant attention only recently following the work of *Capasso* et al. [56.109], who demonstrated wavefront manipulation in the IR and formulated generalized laws of refraction and reflection in the presence of phase discontinuities

$$\sin\theta_2 = \frac{n_1}{n_2}\sin\theta_1 + \frac{\lambda_0}{2\pi\, n_2}\frac{\mathrm{d}\varphi}{\mathrm{d}x}\,, \tag{56.14a}$$

$$\sin\theta_1' = \sin\theta_1 + \frac{\lambda_0}{2\pi\, n_1}\frac{\mathrm{d}\varphi}{\mathrm{d}x}\,, \tag{56.14b}$$

where $\mathrm{d}\varphi/\mathrm{d}x$ is the gradient of the phase discontinuity along the interface (Fig. 56.25). These relations imply that the refracted and reflected beams can have arbitrary directions, provided that suitable $\mathrm{d}\varphi/\mathrm{d}x$ is introduced. In particular, refraction and reflection of light incident at angle θ_1 become negative for phase gradients smaller than $\mathrm{d}\varphi/\mathrm{d}x = -(2\pi/\lambda_0)\, n_1 \sin\theta_1$. While deriving (56.14a)–(56.14b) it was assumed that φ varies continuously along the interface, so that all the incident energy is transferred into the modified reflection and refraction. Since, in practice, a metasurface is a discrete array of scatterers, although with subwavelength separation, there will also be regularly refracted and reflected beams that obey the conventional laws of refraction and reflection [56.112].

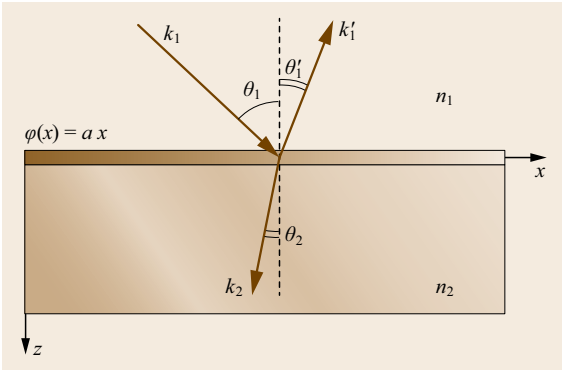

Fig. 56.25 Anomalous refraction and reflection at an interface with linearly varying phase discontinuity $\varphi(x)$

An example of the designer metasurface exhibiting negative refraction and reflection in the IR is presented in Fig. 56.26a. It features a regular array of V-shaped gold metamolecules arranged in the groups of 8, with their shape and size changing gradually in each group in the x-direction. Compared to more simple cut wires, V-shaped metamolecules produce much stronger scattering contributions to modified refraction and reflection for all their permutations and ensure phase shifts in the entire range from 0 to 2π, as required for engineering a continuous phase gradient.

A more complex scattering phenomenon, such as the generation of a vortex beam, is observed when the phase shift varies linearly in the azimuthal direction. This can be achieved with a designer metasurface, for instance, by arranging V-shaped metamolecules of different permutations in eight equal sectors, which imprint constant phase shifts with $\pi/4$ increment counterclockwise (Fig. 56.26b). By re-arranging the metamolecules such that the phase shift is constant in the azimuthal direction but increases hyperbolically in the radial direction, one obtains an aberration-free optical flat lens [56.113].

Very recently, the concept of wavefront manipulation using designer metasurfaces was taken further with the introduction of the so-called Huygens metasurfaces [56.114, 115], planar arrays of metamolecules that react to both E and H components of light. Huygens metasurfaces are expected to have major implications for integrated and transformation optics, as they allow one to control the amplitude and phase of the scattering independently, and hence generate truly arbitrary field patterns for given illumination.

56.2.5 Polarization Manipulation with Planar Metamaterials

Similar to bulk metamaterials, homogeneously patterned planar metamaterials can exhibit complex polarization effects, which lie beyond trivial polarization conversion originating from structural anisotropy [56.116]. These phenomena include, in particular, enhanced con-

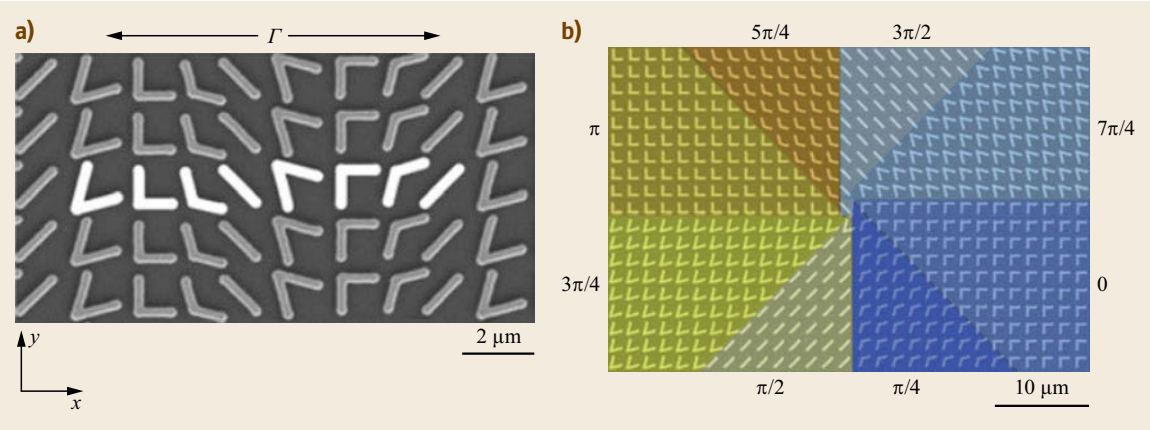

Fig. 56.26 Scanning electron microscope images of IR designer metasurfaces, which exhibit negative refraction and reflection **(a)** and generate vortex beams **(b)**. (After [56.109])

ventional optical activity, optical activity occurring in the absence of structural chirality, and asymmetric transmission [56.117], which, unlike the first two effects, does not seem to have an analog in bulk media.

Natural (Intrinsic) Optical Activity

Natural optical activity manifests itself as the polarization azimuth rotation of linearly polarized light, as well as the preferential absorption of either right or left-hand circularly polarized light in a lossy medium (Sect. 56.1.5). Conventionally, optical activity is attributed to *intrinsic chirality* of matter, a particular type of asymmetry characterized by the presence of a screw-like twist in its very structure (either on molecular or crystal lattice levels). Such a twist exists only in three dimensions and, therefore, cannot be realized in a truly planar structure. Instead, it may be introduced in a bi-layered stack, for example, by rotating metamaterial patterns in the first and second layers with respect to each other, as illustrated in Fig. 56.11c–g. Due to the strong resonant coupling between the mutually twisted patterns, the rotation of the polarization plane of up to 90° can be achieved for interlayer separation of only $\lambda_0/30$ or so [56.33, 34]. Consequently, all bi-layered chiral metamaterials considered in Sect. 56.1.5, although not technically planar, can be regarded as planar metamaterials given their vanishing thickness. Moreover, it is easy to see that even the presence of a supporting substrate makes the structure of a planar metamaterial intrinsically chiral if its pattern features a spiral-like twist. In this case, however, the manifestation of optical activity is usually rather weak [56.33, 40, 118].

Extrinsic Optical Activity

Extrinsic optical activity is a practically unknown instance of the polarization phenomenon, which is very difficult to observe using natural materials but which can be easily engineered in planar metamaterials, offering an efficient and robust polarization control mechanism. It is attributed to the chirality that is drawn extrinsically from the experimental arrangement that includes not only molecules (or metamolecules), which must be *oriented* and can be *structurally achiral*, but also the wave propagation direction. This special condition for observing optical activity was first identified by *Bunn* [56.119] and confirmed in liquid crystals by *Williams* [56.120].

In the context of metamaterial research, the effect was experimentally demonstrated by *Plum* et al. in both the microwave [56.121] and optical [56.122] parts of the spectrum by characterizing the transmission response of specially designed metasurfaces at oblique incidence. The metasurfaces were based on regular arrays of achiral asymmetrically split-ring metamolecules (Fig. 56.27a), although, in principle, any metamaterial pattern that does not possess twofold rotational symmetry could have formed an extrinsically chiral arrangement with an obliquely incident beam (and hence exhibited optical activity). The observed rotation of the polarization azimuth exceeded 80° for microwave and 1° for optical metasurfaces, which in absolute terms surpasses the strength of optical activity achieved in most intrinsically chiral planar metamaterials.

Optical activity of an extrinsically chiral metasurface has the following key features:

1. No effect can be observed at normal incidence.
2. No effect can be observed at oblique incidence if the metamolecules possess twofold rotational symmetry or if the line of their mirror symmetry is parallel to the plane of incidence.

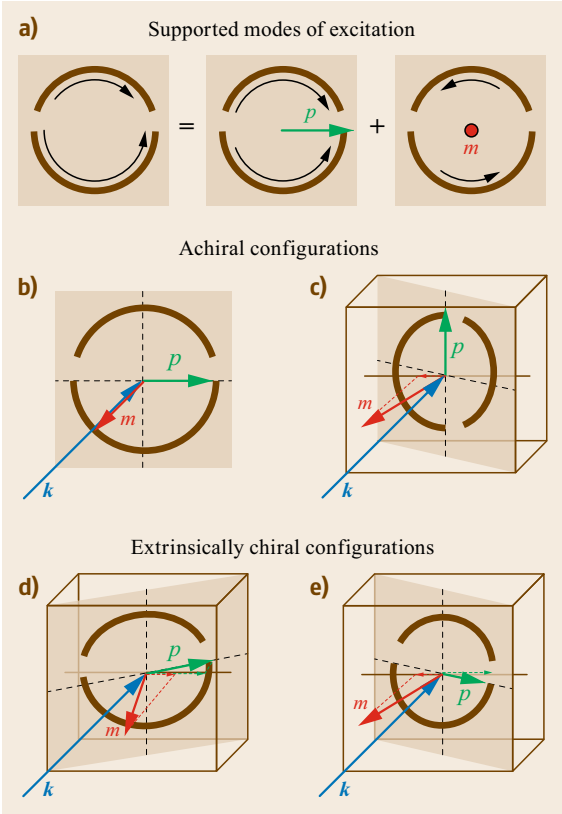

Fig. 56.27a–e Optical activity due to extrinsic chirality. **(a)** Oscillating currents in an asymmetrically split ring can be represented as a sum of symmetric and antisymmetric modes, corresponding to an electric dipole $\boldsymbol{p}$ (*green arrow*) and a magnetic dipole $\boldsymbol{m}$ (*red arrow*). Optical activity is controlled by the projections of $\boldsymbol{p}$ and $\boldsymbol{m}$ onto the plane perpendicular to the incident wavevector $\boldsymbol{k}$ (*green* and *red dashed arrows* correspondingly). The effect is absent either **(b)** at normal incidence, when one of the projections is zero, or **(c)** if the projections are mutually orthogonal. The strongest optical activity of opposite sign occurs if these projections are either **(d)** parallel or **(e)** antiparallel

3. Opposite angles of incidence yield the effects of opposite signs.
4. The magnitude of the polarization rotation and circular dichroism is controlled by the angle of incidence.

Most of the features can be readily understood based on geometrical considerations. Indeed, the first and second features expose mutual orientations of the metasurface and incident beam that result in vanishing extrinsic chirality (Fig. 56.27b,c). The third feature simply reflects the fact that reversing the angle of incidence transforms an experimental arrangement into its mirror form, which gives rise to extrinsic chirality of opposite handedness (see Fig. 56.27d,e). Understanding the fourth feature, however, requires one to revisit the physical mechanism of the effect, as detailed below.

Similar to conventional optical activity, its extrinsic counterpart results from the simultaneous presence of electric and magnetic responses in the metamolecules. The asymmetry of the metamolecules (such as, for example, asymmetrically split rings) plays a key role here: an electromagnetic wave resonantly induces unequal currents oscillating in the upper and lower arcs of the rings. Such a current configuration may be represented as a sum of symmetric and antisymmetric current modes. The symmetric mode yields an electric dipole moment, $\boldsymbol{p}$, oscillating in the plane of the ring and parallel to the split, while the antisymmetric mode gives rise to a magnetic dipole moment, $\boldsymbol{m}$, which oscillates perpendicular to the plane (Fig. 56.27a). At oblique incidence, each dipole moment acquires a component in the plane orthogonal to the wave propagation direction (Fig. 56.27d). When the split is parallel to the plane of incidence (the line of mirror symmetry is orthogonal to the plane of incidence), the projections of $\boldsymbol{m}$ and $\boldsymbol{p}$ become collinear and scatter electromagnetic waves with orthogonal polarizations, so that the polarization of the resulting transmitted wave exhibits maximal rotation. Clearly, by varying the angle of incidence, one changes the difference between the magnitudes of the dipole projections, and hence controls their relative contributions to the polarization state of the transmitted wave. Also, it can be seen that for opposite angles of incidence, the mutual phase difference between the projections of $\boldsymbol{m}$ and $\boldsymbol{p}$ reverses, which directly affects the sign of optical activity (see Fig. 56.27d,e). When the split is perpendicular to the plane of incidence (the line of mirror symmetry is parallel to the plane of incidence), the projections of $\boldsymbol{m}$ and $\boldsymbol{p}$ become orthogonal to each other (Fig. 56.27c). In this case, the electromagnetic waves scattered by the projections have the same polarizations, and so the polarization state of the transmitted wave cannot change. Finally, at normal incidence, the projection of $\boldsymbol{m}$ is zero, which makes the absence of optical activity trivial (Fig. 56.27b).

The mechanism described above equally applies to the reflection off an extrinsically chiral metasurface, where it leads to strong *specular optical activity* (the existence of this effect in bulk media is still being debated) [56.123]. Intriguingly, this reflection effect mimics the longitudinal magneto-optical Kerr effect, but obviously does not require a magnetic field for its observation.

Even though extrinsic chirality can only be ascribed to an *anisotropic* metasurface, its response features a spectral band where the manifestation of the

anisotropy (i. e., linear birefringence) is negligible. For this band the incident polarization state remains linear upon transmission/reflection, exhibiting pure azimuth rotation [56.121, 122]. Importantly, extrinsic optical activity is exhibited by truly planar metamaterials, which are typically much easier to fabricate than the bi-layered stacks. The scalability of the metamaterial designs and inherent tunability of the phenomenon, the magnitude (and sign) of which can be continuously controlled by tilting the metasurface with respect to the incident beam, enables the exploitation of extrinsic optical activity in polarization control applications both in microwave and photonic devices. Examples of the latter may include compact and efficient polarization rotators, circular polarizers, and polarization modulators, as well as vibration sensors.

Asymmetric Transmission

Asymmetric transmission is a new fundamental phenomenon of electromagnetism, which manifests itself as a difference in the overall intensity of circularly polarized waves transmitted by a medium in the opposite directions. In some ways, it resembles the famous nonreciprocity of the Faraday effect in magnetized media but requires no magnetic field for its observation and is fully compliant with the Lorentz reciprocity principle. Asymmetric transmission was discovered in 2006 by *Fedotov* et al. in planar chiral metamaterials [56.124], a new distinct class of metasurfaces that feature *two-dimensional* (2-D) *chirality* in the structure of their metamolecules.

2-D chirality implies that a *planar* object or a pattern cannot be brought into congruence with its mirror image (which is obtained by reflection across a line in the object's plane) unless it is lifted off the plane. The simplest example of a planar chiral object is the Archimedean spiral. 2-D chirality has been rarely acknowledged in the context of optics and materials research simply because natural planar materials were not known to men (at least until 2004, when graphene sheets were physically isolated and studied [56.125]). The study of optical implications of 2-D chirality was pioneered by *Zheludev*, who introduced the notion of 2-D chirality (termed as *planar chirality*) to the field of metamaterials research in 2003 [56.126].

While conventional chirality reveals a structural twist in three dimensions, planar chirality does so in two dimensions. It is convenient to associate the twist of a planar chiral pattern with a special unitary vector, $\boldsymbol{W}$, known as the *twist vector*. It points along the normal to the plane of the pattern, and its direction is governed by the corkscrew law: if the screw rotates in the direction of the structural twist, then it moves along the twist vector. Correspondingly, if $\boldsymbol{W}$ points along the direction of observation, the pattern is perceived as being twisted clockwise and, conversely, if $\boldsymbol{W}$ points toward the observer, the pattern is twisted counter-clockwise (Fig. 56.28). Importantly, the sense of the twist (and hence the direction of $\boldsymbol{W}$) reverses when a planar chiral pattern is observed from opposite sides, and this is exactly what makes the engineering of the asymmetric transmission effect possible.

Phenomenologically, the origin of the effect may be traced to a particular structure of the complex matrix that describes the transmission of circularly polarized waves through a planar chiral metamaterial

$$\boldsymbol{\chi}^{2\mathrm{D}} = \begin{pmatrix} t_{++} & t_{+-} \\ t_{-+} & t_{--} \end{pmatrix} , \tag{56.15}$$

which is a non-Hermitian matrix with equal diagonal elements ($t_{++} = t_{--}$). When expressed in terms of transmission coefficients in the linear (Cartesian) basis, this matrix can be transformed into a sum [56.124]

$$\boldsymbol{\chi}^{2\mathrm{D}} = \boldsymbol{\chi}_0^{2\mathrm{D}} + \mathrm{i}\, t_{xy}\, \mathrm{sgn}\,(\boldsymbol{k}\cdot\boldsymbol{W})\,\hat{\boldsymbol{g}} , \tag{56.16}$$

where $\boldsymbol{k}$ is the wavevector of the incident wave, t_{xy} is the coefficient characterizing the conversion of a lin-

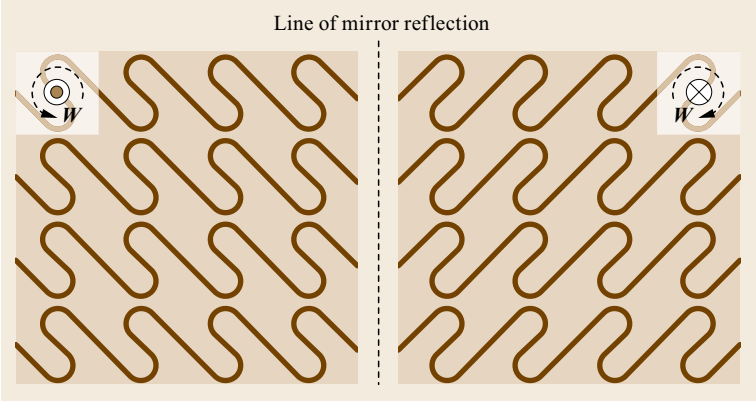

Fig. 56.28 Examples of planar chiral metamaterial patterns featuring clockwise and counter-clockwise twists

early polarized state into its orthogonal counterpart upon transmission,

$$\chi_0^{2D} = \frac{1}{2}\begin{pmatrix} t_{xx}+t_{yy} & t_{xx}-t_{yy} \\ t_{xx}-t_{yy} & t_{xx}+t_{yy} \end{pmatrix} \quad (56.17a)$$

is a symmetric matrix that describes the anisotropy of the chiral pattern, and

$$\hat{\mathbf{g}} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \quad (56.17b)$$

is a unitary antisymmetric matrix. The antisymmetric part of χ^{2D} is proportional to the pseudoscalar combination $(\boldsymbol{k}\cdot\boldsymbol{W})$ and is, therefore, responsible for direction-dependent transmission, as the latter changes sign upon the reversal of the wave propagation direction. The antisymmetric part is also proportional to t_{xy}, which can only exist for anisotropic metamolecules of low-structural symmetry and vanishes for patterns possessing a fourfold symmetry axis. The polarization conversion term t_{xy} cannot be eliminated by the choice of appropriate coordinate systems only in the presence of dissipation. In other words, *the asymmetric transmission effect can be observed in a planar chiral metamaterial if, and only if, it is simultaneously anisotropic and lossy*. It also follows form (56.16) that the asymmetry is reversed for the opposite handedness of (i) incident polarization and (ii) structural twist.

The transmission asymmetry exhibited by planar chiral metamaterials is different from that of the Faraday effect in magnetized media. Indeed, in the case of the Faraday effect, the asymmetry applies to the transmission amplitude and phase of an incident circularly polarized wave itself, whereas planar chiral metamaterials, due to their anisotropy, partially convert the incident wave into one of the opposite handedness, and it is the efficiency of this conversion that is asymmetric with respect to the direction of propagation. The fundamental novelty of the asymmetric transmission effect may also be appreciated by comparing the polarization eigenstates (i. e., the polarizations that are preserved upon transmission) of planar chiral metamaterials with that of the Faraday media. The eigenstates of the transparent Faraday media, in general, are two elliptical polarizations of opposite handedness, while the eigenstates of planar chiral metamaterials are two elliptical polarizations of the same handedness, which differ only in the azimuths of their main axes – they are orthogonal (Fig. 56.29). The eigenstates of planar chiral metama-

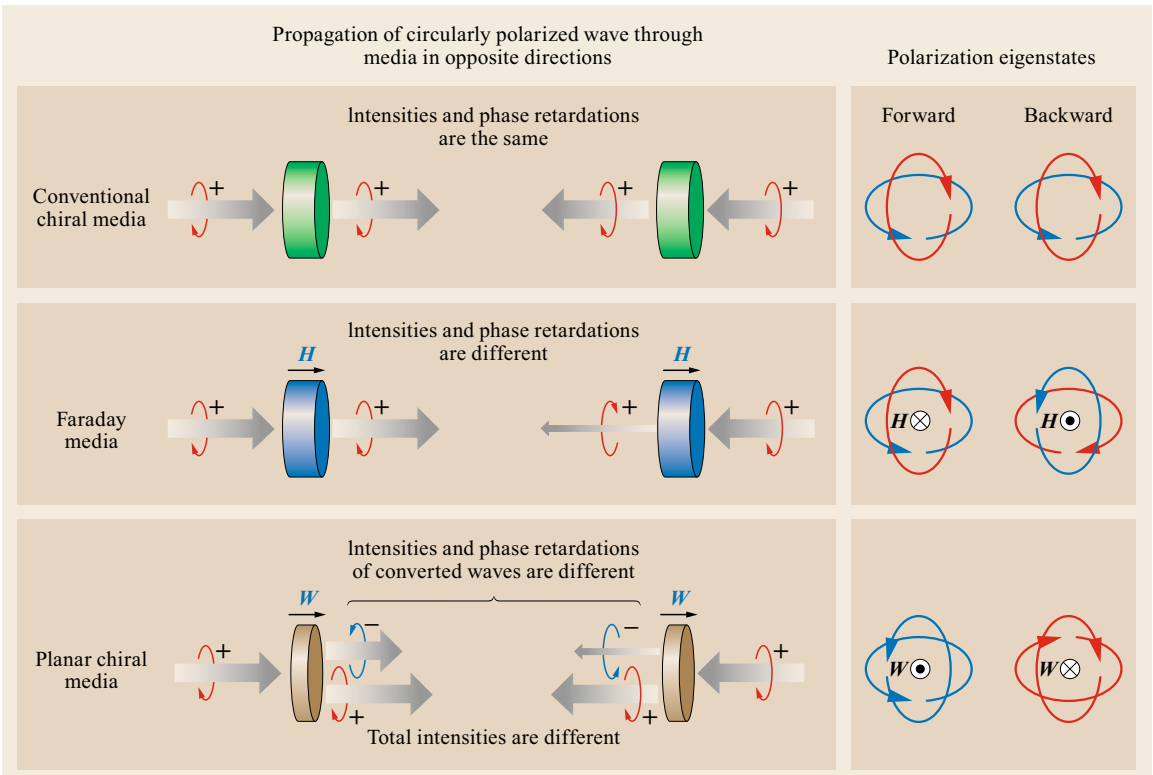

Fig. 56.29 Manifestations of polarization effects and corresponding polarization eigenstates in conventional chiral media, Faraday media, and planar chiral media. Vectors $\boldsymbol{H}$ and $\boldsymbol{W}$ denote magnetization and planar chiral twist, respectively

terials are also different from those of conventionally chiral media (and chiral metamaterials) exhibiting optical activity. The eigenstates of the latter are completely symmetric with respect to the propagation direction, whereas the eigenstates of planar chiral metamaterials reverse their handedness (Fig. 56.29).

At an abstract crystallographic level, it has been shown that a combination of birefringence and circular dichroism (termed *elliptical dichroism*) provides a basis for the optical manifestation of asymmetric transmission and that a hypothetical bi-axial elliptically dichroic bulk medium should exhibit optical properties characteristic to a planar chiral metamaterial [56.127]. More rigorous, quantitative descriptions of asymmetric transmission with a detailed analysis of the effect on a microscopic level and systematic study of planar chiral metamolecules have also been developed [56.128–131].

In practical terms, the asymmetric transmission is a strong and scalable phenomenon, which has been experimentally demonstrated in the microwave [56.124, 132], terahertz [56.133], and optical [56.134, 135] parts of the spectrum, with the observed absolute transmission asymmetry exceeding 15%, 6%, and 4%, respectively. This invites the application of planar chiral metamaterials as novel polarization sensitive components of electromagnetic devices, such as polarization and direction sensitive beam splitters, circulators, and sensor components. For example, when placed into a ring resonator, a planar chiral metamaterial will enforce generation of left and right-handed elliptically polarized waves in the opposite directions of circulation.

57. Thermoelectric Materials

Donald T. Morelli

Thermoelectricity is one of the oldest phenomena to be observed in semiconductors, with discovery of the various thermoelectric effects dating back to the early part of the 19th century. These effects manifest themselves as the appearance of a voltage in a circuit comprised of two different conductors due to a temperature difference (Seebeck effect), or as the absorption and evolution of heat at the junction of two different materials under electrical current excitation (Peltier effect). These effects can be utilized in devices to generate electrical power from waste heat or to provide solid state cooling, respectively.

This chapter reviews the main factors governing thermoelectric effects in solids, and how these factors may be manipulated to produce materials with high thermoelectric figure of merit. The first portion of the chapter covers the main features that determine electrical and thermal transport in crystalline semiconductors, while the latter portion discusses several new approaches to this old problem that hold promise for highly efficient thermoelectric materials in the future.

Thermoelectricity encompasses the collective effects that involve the conversion of a temperature difference to electricity and vice versa. The thermoelectric process is fundamentally a microscopic one involving the transport and exchange of energy by and between electrons and lattice vibrations, or phonons, in a solid. This process can be described in terms of the Seebeck, Peltier, and Thomson coefficients. As such these effects may be implemented to generate electrical power from primary or waste sources of heat, or inversely to provide all-solid-state heat pumping, i. e., climate control, under electrical activation. The extent to which thermoelectricity might impact our utilization of energy in the United States is provided by an examination of the flow and usage of energy in the transportation, industrial, commercial, and residential sectors in the United States, as provided by *Lawrence Livermore Laboratory*, *United States Department of Energy* [57.1]. These data indicate that almost two-thirds of the energy produced is rejected mainly in the form of waste heat. This is not really surprising to us, as we all learn at an early age to keep well away from the exhaust pipe of even an idling automobile and to never open the cap on the radiator of a vehicle whose engine is running; and we all have witnessed the great clouds of bellowing steam emerging from the stack of a nuclear- or coal-burning power plant. This rejected energy represents a tremendous opportunity – in some sense, it is like a new energy source, prodigious in size, available almost for *free* and waiting to be used. To appreciate the size of this energy source, the energy content available in this pathway is equivalent to that in over 400 billion gallons of gasoline [57.2]. It is here, in the recovery of wasted thermal energy, where thermoelectricity can play a pivotal role. Conversion of this heat to electricity, even at modest fractions, can improve significantly the overall efficiency of energy utilization in the US and worldwide, and thereby both reduce dependence on foreign sources of fossil fuels and significantly decrease carbon emissions. It is prin-

cipally for this reason that the field of thermoelectricity, which has always been of interest scientifically if not technologically, has grown substantially in the last ten years.

57.1 Overview of the Field

Thermoelectric energy conversion systems use the thermoelectric effect to convert heat, either from a primary source such as a burner, or waste heat, such as that in the exhaust stream of an automobile or power plant, to useful electricity. The efficiency for conversion of heat to electricity is determined by the dimensionless figure of merit $zT = \alpha^2\sigma T/\kappa$, where α is the Seebeck coefficient, σ the electrical conductivity, κ the thermal conductivity of the materials comprising the thermoelectric device, and T the absolute temperature. For a thermoelectric device operating between a heat source at temperature T_H and a heat sink at temperature T_C, the efficiency is given by [57.3]

$$\varepsilon = \frac{\Delta T}{T_H}\left(\frac{\sqrt{1+zT_{ave}}-1}{\sqrt{1+zT_{ave}}+\frac{T_C}{T_H}}\right), \qquad (57.1)$$

where $T_{ave} = (T_H + T_C)/2$. Figure 57.1 is a surface plot of this relationship for $T_H = 700\,^\circ\mathrm{C}$ (973 K) as a function of T_C and zT. We see that a conversion efficiency exceeding 25% under these conditions can be achieved over a wide range of figures of merit and cold-side temperatures.

Thermoelectric materials research dates back to the time of *Seebeck* himself, who studied the effect that bears his name in a large number of metals and minerals [57.4]. Subsequent studies were carried out by *Haken* [57.5] and *Altenkirch* [57.6] in Germany in the early part of the 20th century. The modern era of thermoelectricity dates back to the work of *Ioffe* (Institute of Semiconductors, USSR) [57.7] and *Goldsmid* (General Electric Research Laboratories, Great Britain) [57.3]. Through combined experimental and theoretical work it was well established by 1970 that the best thermoelectric materials, such as PbTe and Bi_2Te_3 with $zT \approx 0.5-1.0$, were narrow gap semiconductors with large charge carrier effective masses and comprised of heavy-atom elements arranged in high-symmetry crystal structures.

In spite of a plethora of studies, both theoretical and experimental, on new thermoelectric materials, for the next quarter of a century the field remained somewhat quiescent, with no substantial improvements in the figure of merit. It was recognized that the thermoelectric problem was one in which the figure of merit requires a combination of *contraindicated* physical properties: a set of properties which nature is not disposed to provide in a single material, for instance high electrical conductivity and large Seebeck coefficient, or high electrical conductivity and low thermal conductivity.

The situation changed rapidly in the mid-1990s for a number of different reasons. Firstly, due to a greater awareness of the insecurity of our energy future and the impact of energy usage on the precarious state of the environment, the scientific and technical communities began to focus more heavily on the science and technology of energy processes and energy-related materials; secondly, the field began to benefit from the use of more sophisticated synthesis techniques and sensitive characterization methods, especially at the nanoscale; and finally, and perhaps most importantly, the scientific community developed an increased understanding, at a fundamental level, of the nature of electrical and thermal transport processes in solids, two examples being the theoretical treatment of *Hicks* and *Dresselhaus* [57.8, 9] of thermoelectricity in quantum-confined systems and the origination by *Slack* [57.10] of the concept of *phonon-glass-electron-crystal*.

From (57.1), it can been seen that commonly available thermoelectric materials like Bi_2Te_3 and PbTe, with zT values on the order of unity or less, have a conversion efficiency of under 10%. Clearly the most direct means of increasing the efficiency is to improve upon the transport properties that comprise the figure of merit. We now look at this relation in somewhat greater detail

$$z = \frac{\alpha^2\sigma}{\kappa} = \frac{P}{\kappa}\,. \qquad (57.2)$$

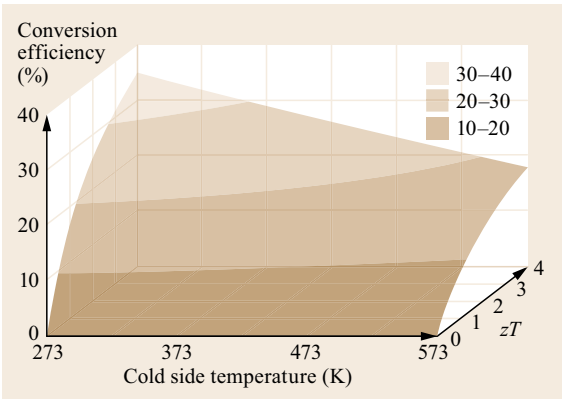

Fig. 57.1 Efficiency of a thermoelectric generator with a hot-side temperature of 700 °C (973 K) as a function of cold-side temperature and figure of merit zT

Here κ is the total thermal conductivity and consists of the sum of the electronic (κ_e) and lattice, or phonon (κ_p) contributions. The numerator term, the *electrical* part of the figure of merit, is called the power factor (P).

One of the oldest [57.7] and most effective ways of increasing z is by alloying to form solid solutions such as $Pb_{1-x}Sn_xTe_{1-y}Se_y$ or $Bi_{2(1-x)}Sb_{2(1-x)}Te_{3(1-y)}Se_{3y}$. The basis for this approach is the strong phonon scattering that occurs due to the mass difference on one or both of the binary compound lattice sites. In this approach the long-range periodicity of the lattice is preserved, but there are intense short-range perturbations. Electrons, with wavelengths many times the interatomic distance, are essentially uninfluenced by these perturbations, while phonons, the characteristic wavelength of which is on the order of the interatomic distance, can be strongly scattered by these local distortions in atom mass and size. The net result is that the ratio σ/κ_p, or more particularly μ/κ_p, where μ is the carrier mobility, is increased substantially, leading to an enhancement of z.

Within the last decade there have been many novel approaches to designing new thermoelectric materials with values of figure of merit beyond those possible using the solid-solution method. These approaches can be broadly grouped into two categories: 1. those that seek to increase the Seebeck coefficient α; and 2. those that seek to increase the ratio of σ/κ. An example of the former includes the use of low-dimensional systems [57.8, 9, 11] in which the altered density of electron states leads to enhanced α; examples of the latter include *phonon-glass electron-crystal* structures such as filled skutterudite [57.12] and clathrate [57.13] compounds with glass-like lattice thermal conductivity, and superlattice structures [57.14] with increased phonon scattering by interfaces.

The main challenge in any methodology seeking to reduce the lattice thermal conductivity is maintaining adequate carrier mobility, and hence electrical conductivity. Magnetic scattering, for instance, using rare earth ions or transition metal ions with partially filled d-shells, can dramatically reduce the lattice conductivity, but is inevitably accompanied by a strong reduction in carrier mobility [57.15]. Even the filled skutterudites, with their notable reduction in κ_p, suffer a strong reduction in mobility upon filling and reach high z only by an alteration of band structure that causes an increase in Seebeck coefficient relative to their unfilled counterparts.

57.2 Semiconductors as Thermoelectric Materials

57.2.1 Electronic Properties of Charge Carriers in Semiconductors

An intrinsic semiconductor is defined as a material in which, at $T = 0$, completely filled electron energy levels (known collectively as the valence band) are separated in energy from energy levels that are empty (known collectively as the conduction band); thus, at zero temperature, a semiconductor is insulating, because there are no empty states nearby in energy into which an electron may move under application of an electric field. As temperature is increased, electrons may be thermally excited across the energy gap to occupy states in the conduction band. Electrons so promoted in energy are then free to move to other nearby states in the conduction band, and thus can contribute to electrical conductivity. At the same time, the empty states left behind in the valence band, called holes (equal in number to electrons promoted), can also contribute to conduction as a positive charge carrier. The two types of charge carriers in an intrinsic semiconductor, electrons (n) and holes (p), move through the lattice with distinct mobilities, μ_e and μ_h respectively, and thus in an intrinsic semiconductor, the total electrical conductivity, σ, is given by the sum of the partial conductivities of electrons (σ_e) and holes (σ_h)

$$\sigma = \sigma_e + \sigma_h = ne\mu_e + pe\mu_h \,. \tag{57.3}$$

Because electrons and holes are fermions, the probability of their occupation of a given energy state is determined by Fermi–Dirac statistics. The Seebeck coefficient of an intrinsic semiconductor, on the other hand, is determined by the partial Seebeck coefficient of the electrons and holes, weighted by their conductivities, according to the relation

$$\alpha = \frac{\alpha_e\sigma_e + \alpha_h\sigma_h}{\sigma_e + \sigma_h} \,. \tag{57.4}$$

In an intrinsic semiconductor, since by definition $n = p$, this relation simplifies to one in which the partial Seebeck coefficients are weighted by the carrier mobilities

$$\alpha = \frac{\alpha_e\mu_e + \alpha_h\mu_h}{\mu_e + \mu_h} \,. \tag{57.5}$$

Once again, the partial Seebeck coefficients of electrons and holes are, as we shall see in a moment, determined

by Fermi–Dirac statistics. Here we note, however, that the *sign* of the Seebeck coefficient is the same as that of the sign of the charge carrier, that is, negative for electrons and positive for holes. Thus in an intrinsic semiconductor, the total Seebeck coefficient is always less than the partial Seebeck coefficient of either the electrons or the holes. For this reason, virtually all useful thermoelectrics are designed using extrinsic doping to produce n- and p-type materials respectively.

Going a step further, the mobility of charge carriers may be written as

$$\mu = \frac{e\tau}{m^*} \,. \tag{57.6}$$

Here τ is the scattering time of the charge carriers and m^* is the carrier effective mass. We make a further assumption that the charge carrier scattering time depends on the carrier energy E as

$$\tau(E) = \tau_o E^{\lambda} \,. \tag{57.7}$$

Returning now to the equation for the figure of merit, using the definition of the conductivity this equation may now be written, for an n-type material

$$z = \frac{\alpha^2\sigma}{\kappa} = \frac{\alpha^2(ne\mu)}{\kappa} = (\alpha^2 ne)\frac{\mu}{\kappa} \,. \tag{57.8}$$

In this form, z depends on one quantity, $\alpha^2 ne$, which is determined by the electronic band structure, and a second quantity μ/κ, which depends on the nature of electron and phonon scattering. To analyze the figure of merit more deeply, we break it into these two pieces and discuss each in turn.

Fermi–Dirac statistics describe the probability of occupation of electron (and hole) states in semiconductors. At temperature $T > 0$, there is finite probability that an electron can occupy the conduction band or a hole can occupy the valence band. In this situation, the electron concentration and Seebeck coefficient are given by the expressions [57.3]

$$\begin{aligned} n &= \frac{4}{\sqrt{\pi}} \left(\frac{2\pi m^* k_B T}{h^2} \right)^{\frac{3}{2}} F_{\frac{1}{2}} \\ \alpha &= \mp \frac{k_B}{e} \left[\frac{\left(\frac{5}{2} + \lambda\right) F_{\frac{3}{4}+\lambda}}{\left(\frac{3}{2} + \lambda\right) F_{\frac{1}{2}+\lambda}} - \eta \right] . \end{aligned} \tag{57.9}$$

Here the Fs are the so-called Fermi integrals of order r

$$\begin{aligned} F_r &= \int_0^{\infty} x_r f(\eta) \mathrm{d}x \quad \text{where} \\ x &= \frac{E}{k_B T} \quad \text{and} \quad \eta = \frac{E_f}{k_B T} \,. \end{aligned} \tag{57.10}$$

The Fermi–Dirac distribution f is given by

$$f = \frac{1}{1 + \exp(x - \eta)} \,. \tag{57.11}$$

As usual h and k_B designate the Planck and Boltzmann constants respectively, and E_f is the charge carrier Fermi energy. The reduced Fermi energy η is the Fermi energy as measured from the edge of the band, i. e., $\eta = 0$ at the bottom of the conduction for electrons and is negative for Fermi energy in the gap, and similarly $\eta = 0$ for holes at the top of the valence band and is negative again for Fermi energy in the gap. The Fermi energy, and thus η, takes on positive values as it moves either into the conduction band for electrons or into the valence band for holes. Using these equations, for a given electron scattering coefficient λ and carrier effective mass m^*, one can calculate the Seebeck coefficient α and the quantity $\alpha^2 n$ that enters directly into the thermoelectric figure of merit.

Figure 57.2 shows the results of such calculations and compares them to the results obtained using classical statistics, i. e., treating the electrons in a solid as if they were like molecules in a gas. Some interesting and important differences emerge. For $\eta < -2$, i. e., for Fermi energy well in the gap, the classical and Fermi–Dirac statistics give identical results. This is the nondegenerate case of a lightly doped semiconductor. For classical statistics the Seebeck coefficient falls more rapidly and actually reaches zero at $\eta = 2$. For Fermi–Dirac statistics, the Seebeck coefficient is diminished as the Fermi level moves into the conduction or valence band, but it never reaches zero. Similarly, the important quantity $\alpha^2 n$ is maximized for Fermi energy right at the band edge for classical statistics, whereas for the more general Fermi–Dirac case, the maximum occurs for Fermi energy one unit of $k_B T$ into the band.

Of course, experimentally, one does not directly control the Fermi energy; rather, one controls the carrier concentration through doping. To see this more clearly, Fig. 57.3 plots the quantity $\alpha^2 n$ versus carrier concentration n, for Fermi–Dirac statistics. Here we clearly see the origin in the peak in the power factor $\alpha^2\sigma$, predominantly arising due to the inverse relationship between α and n.

Thus Fermi–Dirac statistics give a neat interpretation of the quantity $\alpha^2 n$ and in particular what value should be chosen for the Fermi energy and can be used as a guide to approximate what level of doping is required in order to optimize the thermoelectric figure of merit. In practice, because others factors such as the dependence of effective mass on doping level and mixed carrier scattering mechanisms, usually the

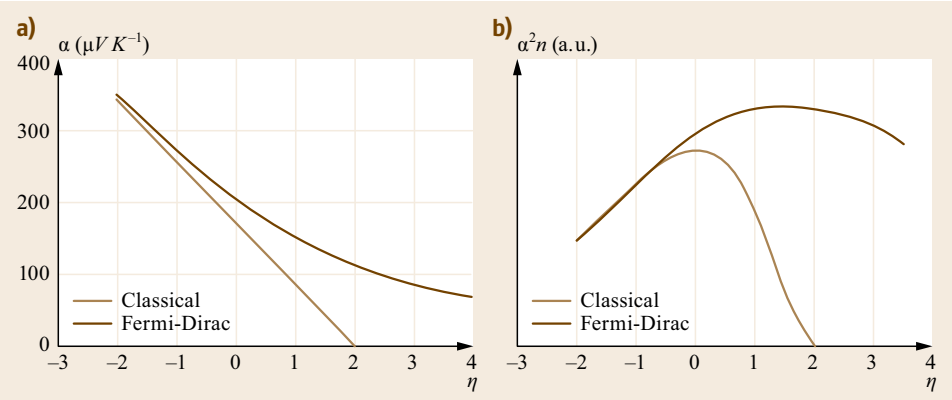

Fig. 57.2 Seebeck coefficient **(a)** α and **(b)** $\alpha^2 n$ as a function of reduced Fermi energy for holes with effective mass $m^* = 0.3$

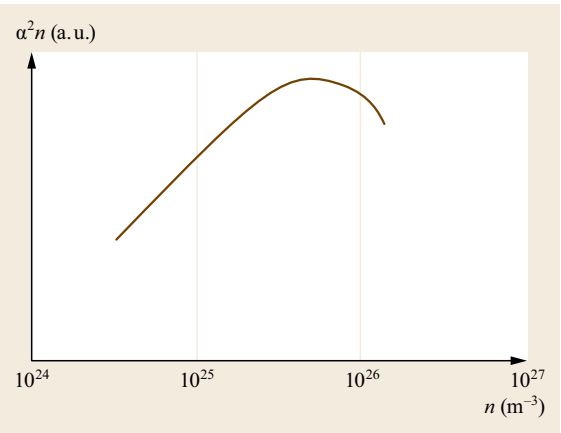

Fig. 57.3 The quantity $\alpha^2 ne$ as a function of carrier concentration at 300 K for a carrier effective mass $m^* = 0.3$

optimum doping level for maximum power factor is determined by trial and error.

57.2.2 Semiconductors with Low Intrinsic Thermal Conductivity

While a reasonably clear understanding of the thermoelectric power factor and the elements that influence it can be obtained with knowledge of the band structure of a material, the dominant carrier scattering mechanism, and the use of carrier statistics, that of course is only part of the thermoelectric problem – we have not yet dealt with the denominator of the figure of merit; the thermal conductivity. While to first order there is much to be learned from *decoupling* the treatment of the power factor from that of the thermal conductivity, in reality all of the transport properties comprising the figure of merit are intertwined and interdependent at some level.

Serious study of the thermal conductivity of crystalline solids was begun before World War II, including the work of *Akhiezer* [57.16], *Leibfried* and *Schloemann* [57.17], and *Lawson* [57.18]. A basic conclusion of all of these studies was that the lattice thermal conductivity of crystals near and above room temperature obeyed the general relation [57.19]

$$\kappa_L \propto \frac{\theta^3}{\gamma^2 T} , \qquad (57.12)$$

where θ is the Debye temperature, γ the Grüneisen constant, and T the absolute temperature. On the basis of this simple relation, one can thus predict that materials with high Debye temperature and/or small Grüneisen parameter will have high thermal conductivity, and vice versa. Since the Debye temperature depends inversely on the average atom mass, this further implies that low thermal conductivity will be favored in materials comprised of heavy mass atoms. Subsequently, *Slack* [57.20] extended this relationship to include a dependence of crystal complexity, i. e., number of atoms in the unit cell, and showed that crystal structures with large unit cells generally possess lower thermal conductivity due to a more complex phonon spectrum. Taken together, this information suggests that the place to look for good thermoelectric materials is amongst semiconductors with low Debye temperature, large numbers of atoms in the unit cell, heavy atom masses, and large Grüneisen coefficients. At the same time, of course, these compounds must possess high thermoelectric power factor, as determined by the equations outlined in Sect. 57.2.1 above.

In practice, there are thousands of possible compounds and dozens of different crystal structure types that must be considered for possible choices for thermoelectric materials, but the power of classifying materials according to their crystal structure and bonding can be illustrated by comparing some results for diamond/zincblende and rock salt structure compounds. It

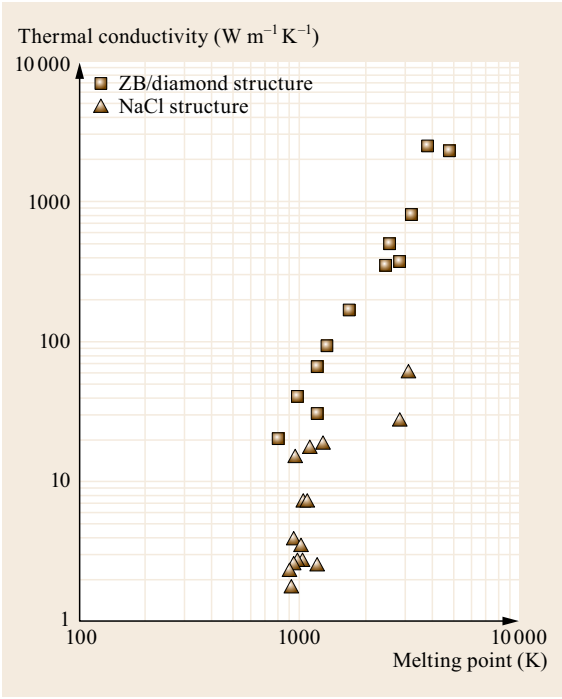

Fig. 57.4 Lattice thermal conductivity versus melting point for a host of diamond, zincblende and rock salt structure compounds

may be noted that the same properties that favor low thermal conductivity (heavy atom masses and low Debye temperature) are also typical of lower melting point compounds, and indeed (Fig. 57.4) there is a strong correlation between lattice thermal conductivity and melting point, at least within families of compounds such as the diamond/zincblende structure and the rock salt structure. The magnitude of the conductivity, however, does depend on the nature of bonding between atoms, as clearly the covalently bonded diamond/zincblende structure compounds and elements have higher thermal conductivity than the ionically bonded rock salt structures. On this basis alone one would naturally be led to choose the rock salt structure compounds over the zincblendes due to the lower thermal conductivity. On the other hand, as mentioned above, we must ultimately find materials that not only have low lattice thermal conductivity, but also high charge carrier mobility, in order that the electrical conductivity may remain high, and this tends to be favored in covalently bonded crystals. It is the hallmark of research on thermoelectric materials that one is constantly confronted, in different forms and guises, an inherent *contraindication* in properties that can frustrate the search for high z.

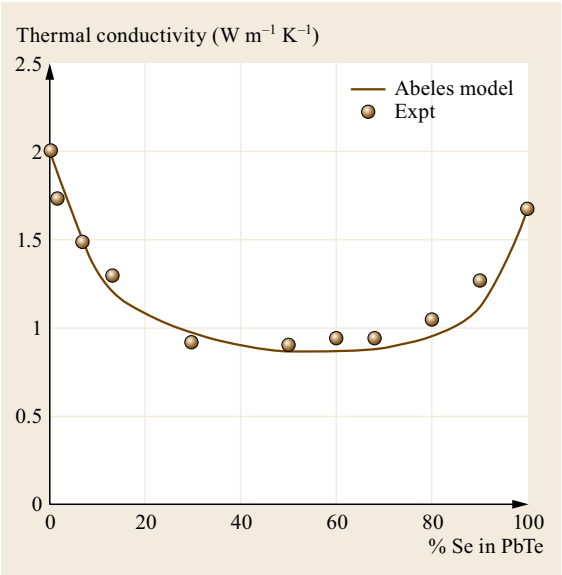

Fig. 57.5 Lattice thermal conductivity of the $PbTe_{1-x}Se_x$ solid solution. The reduction in thermal conductivity is maximized near 50% solute concentration, the point at which mass disorder in the lattice is largest

57.2.3 Semiconductor Solid Solutions

While the above approach for finding compounds with low intrinsic thermal conductivity was very successful, it resulted in very few materials being identified with high z. Researchers quickly noted that z could be increased further, however, by lowering the thermal conductivity using defects or impurities, as long as the electrical properties could be largely maintained. By far the most successful method of achieving this result was by realizing isoelectronic solid solutions of elemental and compound semiconductors. The use of solid solutions to reduce thermal conductivity is rooted in the concept that impurities, when doped into a host lattice, will scatter phonons due to differences in their mass and size with respect to the host atoms. Such behavior was predicted originally by *Pomeranchuk* [57.21], was explored theoretically first by *Klemens* [57.22], and was experimentally demonstrated on a host of materials systems. In the case of thermoelectrics, as we have discussed, it is imperative that when such impurities are introduced into the lattice, they disturb the transport of electrons as little as possible. For example, dopants introduced into a semiconductor to increase the charge carrier concentration can at high concentrations reduce charge carrier mobility due to ionized impurity scattering. Solute atoms that have the same valence electron count as the host atoms in a lattice, on the other hand,

are neutral impurities and interact with charge carriers much less strongly; the resulting reduction in mobility can be quite small. By choosing atoms in the same column of the periodic table (but obviously from a different row), reduction in lattice thermal conductivity can be achieved while largely maintaining the good electrical properties. Moreover, because of the same valence electron count, these atoms can be substituted at large fractions, and in many cases will form a complete solid solution.

The isoelectronic substitution approach was applied very successfully to both PbTe [57.7] ($PbTe_{1-x}Se_x$ and $PbTe_{1-x}S_x$) and Bi_2Te_3 [57.8] ($Bi_2Te_{3-x}Se_x$, $Bi_2Te_{3-x}S_x$, and $Bi_{2-x}Sb_xTe_3$), and was also successfully implemented in the group IV semiconductor system Si-Ge [57.23]. Several theoretical models have been developed to account for the lattice thermal conductivity of alloy solid solutions. Figure 57.5 shows an example of the experimental data for $PbTe_{1-x}Se_x$ in comparison to the model predictions of *Abeles* [57.24]. As expected, the reduction in thermal conductivity, over a factor of two in this case, is maximum near 50% substitution, when the mass disorder in the lattice is at its largest.

57.3 New Concepts in Thermoelectric Materials Design

By the mid-20th century, most of the ideas discussed above on how to optimize the thermoelectric properties of materials were well known and had been successfully implemented to identify PbTe and Bi_2Te_3 solid solutions as good thermoelectric materials. As part of the electronics revolution, thermoelectricity seemed to be on the cusp of explosive discovery and development as a new technology for generating electrical power and providing solid-state heating and cooling.

It seemed that researchers simply had to apply the new concepts and knowledge to find materials even better than the lead and bismuth tellurides. In spite of that promise, however, very little progress was made over the next several decades, and even by 1990 essentially no new thermoelectric materials with properties superior to the heritage materials were discovered. On top of this, the very factors that make these heritage materials such good thermoelectrics, for example heavy masses and weak atomic bonding, also mean that they tend to be mechanically poor, and comprised of elements that are not in great abundance in the Earth's crust. Thus, even these good thermoelectric materials found limited applications and thermoelectricity was a field on the verge of becoming relegated to the backwaters of scientific inquiry.

By the late 20th century, however, a number of factors and influences came together to lead to a refocusing of efforts on discovery of new thermoelectric materials. While indeed over the past several decades few if any new thermoelectric materials of note were discovered, steady progress was made at the level of advancing our fundamental understanding of thermal and electronic transport in solids. At the same time, new ideas, such as quantum confinement and nanoscience, were introduced and explored in a variety of materials systems, and new methods of synthesis of materials were perfected. Thus several tools and fresh approaches could be brought to bear on the field – one just needed the impetus for doing so. That impetus was provided by a new sensitivity toward the utilization of energy and its potential impact on the climate and environment of the Earth. Suddenly, this old idea of converting heat to electricity, mostly viewed upon as a laboratory curiosity, became a new way to generate power, increase efficiency, and decrease emissions of potentially harmful pollutants. When large sources of federal funding became available for research, scientists were quick to bring to bear a host of these new ideas and new approaches to the field of thermoelectricity. Here, in the interest of space and to keep the discussion focused, we consider three new concepts that have emerged over the last two decades and that continue to drive thermoelectric materials research today, and we describe each of these new approaches in terms of model materials systems:

- Phonon-glass-electron crystal (PGEC)
- Bulk nanostructured materials
- Crystals with large anharmonicity.

57.3.1 Phonon-Glass Electron Crystal: Skutterudites

While the solid-solution approach can reduce lattice thermal conductivity strongly, the magnitude of the thermal conductivity typically is still several times larger than that observed in materials with very low thermal conductivity, such as glasses and other amorphous structures. Study of the thermal conductivity of the latter materials has its own long and storied history, dating back to at least the studies of *Zeller* and *Pohl* [57.25], who noted the vast difference in thermal conductivity between crystalline and amorphous SiO_2. A significant amount of work was sub-

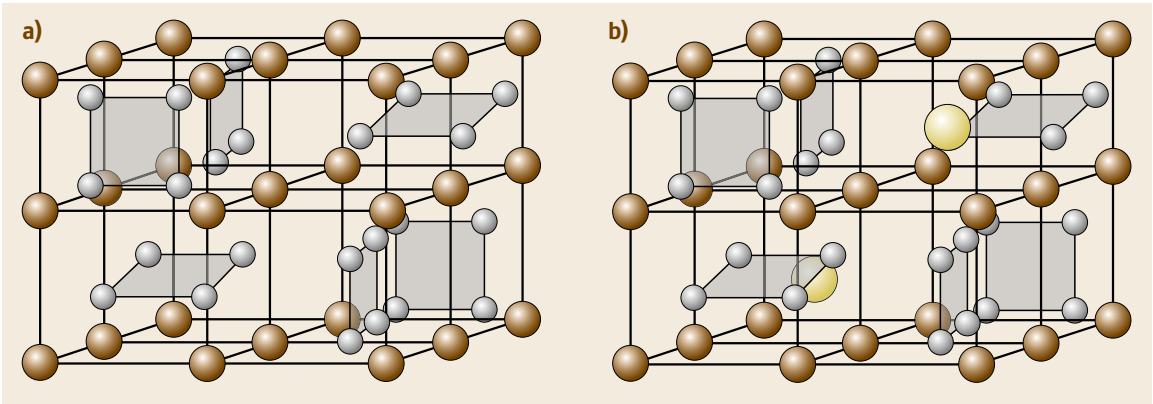

Fig. 57.6a,b The skutterudite crystal structure. A prototypical compound is $CoSb_3$; Co atoms are *brown* and Sb are *gray*. The Sb atoms reside in square planar rings occupying six of the eight quadrants in the unit cell. In the *unfilled* compound the remaining two quadrants are empty **(a)**; in the *filled* version they are occupied by a rare earth or alkaline earth atom **(b)**

sequently performed on such materials that described heat transport by a phonon-tunneling-type mechanism. Eventually, the concept of *minimal thermal conductivity (MTC)* was introduced that described how in such amorphous and highly disordered solids thermal conductivity reaches a theoretically minimum value corresponding to a phonon mean free path on the order of the lattice spacing [57.26].

While the thermal transport properties of glassy systems is an interesting topic in its own right, it did not seem to bear importance relative to the thermoelectric problem; most amorphous solids are poor electrical conductors and are not good candidates for thermoelectrics. Slack, however, noted that there were a few crystalline solids that exhibited glass-like thermal conductivity – a notable example being YB_{66}. This compound displays galleries of boron atoms, between which Y ions can tunnel. In spite of its crystalline character, the thermal conductivity reaches theoretically minimum values. Slack pointed out that perhaps crystalline semiconductors may exist that have not only good thermoelectric properties, but at the same time also exhibit MTC behavior, and suggested that skutterudite compounds could be such a material.

Like many thermoelectric materials, skutterudites were first studied in the Soviet Union by *Dudkin* et al. [57.27–30]. They found that this family of compounds, typified by the composition $CoSb_3$, could be doped both n- and p-type and displayed a good combination of high mobility, large Seebeck coefficient, and large thermoelectric power factor. However, in spite of the rather complex crystal structure (Fig. 57.6) consisting of a cubic lattice Co atoms containing Sb four-membered square rings in six of the eight quadrants of the unit cell, the lattice thermal conductivity of skutterudites was found to be too large to yield high z. This early work did not explore in detail any mechanisms to reduce the thermal conductivity.

More than a decade later, *Jeitschko* [57.31] showed the skutterudite structure could be *filled* by placing lanthanide ions in the two vacant quadrants in the unit cell, and that these ions exhibited large x-ray displacement parameters, indicating that they were loosely bound or *rattled* about their ionic positions. Some 15 years later, with tremendous insight, Slack suggested that these *filled* skutterudites might exhibit minimal thermal conductivity due to the *rattling* phonon mode of the lanthanide ion. A strong reduction in lattice thermal conductivity of the filled skutterudite $CeFe_4Sb_{12}$ relative to its unfilled parent compound, $CoSb_3$, was experimentally demonstrated by *Morelli* and *Meisner* [57.12] shortly thereafter. Skutterudites were the subject of intense scrutiny, both from the point of view of their interesting physics and chemistry, and for their potential thermoelectric applications, and soon it was shown that these compounds could exhibit a figure of merit in excess of unity at high temperature.

Crucial to the performance of skutterudites is the combination of low lattice thermal conductivity in the presence of good semiconducting electrical properties. Because the filling ion (which in addition to an element from the lanthanide series, may also be an alkaline earth ion) donates electrons to the conduction band, its presence can also modify the electrical properties. By simultaneously substituting Fe for Co, the maximum filling fraction can be adjusted and the electrical properties controlled to produce either n- or p-type materials of desired carrier concentration [57.32]. Recognizing that the *rattling* behavior exhibited by the filler atom was a form of resonant scattering of phonons with

a characteristic frequency determined by the mass of the filler atom and the size of the cage, researchers used combinations of fillers (double or even triple filling) to provide different characteristic resonant frequencies, thus producing the ability to scatter wider ranges of the phonon spectrum and reduce the thermal conductivity even further [57.33, 34].

Research and development on skutterudites has continued up to the present day, and impressive zT values in excess of 1.5 for n-type materials and in excess of unity for p-type materials have been achieved. Prototype generators based on skutterudites for exhaust gas-driven power generation on vehicles have been built.

57.3.2 Bulk Nanostructured Thermoelectrics: Pb–Chalcogenide Nanocomposites

About the same time that Slack introduced the PGEC concept, researchers began to contemplate the role that quantum confinement, low-dimensionality, and nanostructuring may play in thermoelectricity. The papers by *Hicks* and *Dresselhaus* [57.8, 9] considered the influence of the modification of the electron density of states that occurs in one-dimensionally (quantum wire) and two-dimensionally (quantum well) confined systems, and these theoretical studies launched intense investigation of these topics. While the promising early results of *Harman* et al. [57.35] and *Venkatasubramanian* et al. [57.14] have not been reproduced, the subsequent studies on nanostructured materials that grew out of these efforts were to bear fruit in the coming years.

An illustration of the positive effects of nanostructuring is provided by the work on so-called LAST materials and hierarchically architectured nanocomposite thermoelectrics. The former is an acronym for compounds based on the PbTe-$AgSbTe_2$ (lead–antimony-silver-telluride) family and was extensively studied by *Kanatzidis* et al. [57.36]. The unusual thermoelectric properties of these materials were noted much earlier by both *Fleischmann* [57.37] and *Irie* et al. [57.38]. As $AgSbTe_2$ is isostructural with PbTe (face-centered cubic rock salt structure) the PbTe-$AgSbTe_2$ compounds were originally thought to form a complete solid solution. The work of the Kanatzidis group showed, however, that small Ag-Sb rich nanoclusters form in these materials, and in fact this morphology is responsible for an enhancement of the thermoelectric properties, primarily through a reduction in thermal conductivity by scattering of phonons at the interface between the host matrix and the secondary phase. Phonon scattering by inclusions on the nanoscale has a long history of study, dating back to at least the work of *Slack* on

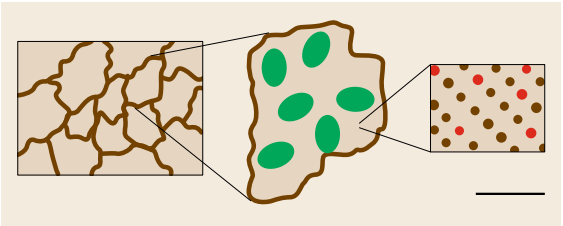

Fig. 57.7 *Hierarchical* structuring of thermoelectric materials. Defects and impurities on different length scales scatter phonons of different wavelengths. Grain boundaries on the mesoscale (*left*; scale bar $\approx 10^3-10^4$ nm) scatter long-wavelength phonons; nanoscale precipitated second phases (*center*; scale bar $\approx 10^1-10^3$ nm) scatter medium-wavelength phonons; and atomic scale impurities (*right*; scale bar $\approx 10^0-10^1$ nm) scatter short-wavelength phonons

$CaCl_2$ precipitates in KCl [57.39], and in fact the use of nanoscale inclusions to reduce the thermal conductivity of Si-Ge thermoelectric alloys was studied as early as 1993 [57.40]. The nanostructured LAST compounds exhibited a thermoelectric figure of merit of $zT = 1.6$.

While nanoscale inclusions can be effective scatterers of medium-wavelength phonons in solids, phonons with frequencies both higher and lower than those that interact strongly with inclusions can still transport heat. On this basis, workers began conceiving of materials systems that could scatter a broader range of phonon frequencies, and thus reduce the thermal conductivity further. It was in this spirit that the concept of *hierarchical structuring* of defects in thermoelectric materials was born (Fig. 57.7). Here the idea is that by combining different types of defects/impurities, each type of which scatter phonons in different frequency ranges, almost all heat transport by phonons can be blocked, just as different optical filters can block different wavelengths of light and when combined can completely block photon transmission. This concept was realized experimentally in the work of *Biswas* et al. [57.41] in which atomic-scale defects, nanostructured second phases, and grain boundaries were combined to scatter high-, medium-, and long-wavelength phonons respectively. The base materials system used to achieve this was once again PbTe, into which was doped SrTe, another rock salt structure compound. The solubility limit of Sr for Pb in PbTe, however, is rather small, on the order of 1%. At first some Sr substitutes for Pb (atomic scale defects), but as the concentration is increased, SrTe nanoclusters form in the material (nanoscale defects). By processing these materials using spark plasma sintering, a fine grain size can be maintained (mesoscale defects). The resulting hierarchy in defect size reduces the thermal conductivity in these materials down to close to

minimal thermal conductivity values. As a result, the thermoelectric figure of merit of optimally doped samples reaches values as high as 2.2.

57.3.3 Crystals with Large Anharmonicity: Tetrahedrites

While impressive results have been obtained using nanostructuring, there are some potential drawbacks with this approach. The composition, distribution of second phases, and grain sizes must be carefully controlled in order to achieve the maximum reduction in thermal conductivity. The processing of these materials is, while straightforward, time consuming. Finally, the stability of these materials with thermal and mechanical cycling is a still-open question.

For these reasons, workers have been looking for other approaches to finding solids with low thermal conductivity. One such approach is to not use any defects or impurities at all – instead, to try to find materials with built-in, intrinsically low thermal conductivity. Of course, as discussed earlier, many of the main drivers of low thermal conductivity, such as complex crystal structures and heavy atom masses, have been known for many decades. Somewhat overlooked, however, has been the nature of phonon scattering, and how it might be maximized intrinsically based on crystal structure and bonding in a solid.

In a simple model of a crystal lattice, atoms are bonded together like masses connected by springs. In a quantum-mechanical picture of the lattice, the vibrations of atoms are quantized and are collective modes known as phonons. For a perfectly harmonic lattice, i. e., one in which the potential energy of each ion is a quadratic function of its displacement, there are no interactions between phonons, and the intrinsic thermal resistance is zero. Lattice thermal resistivity in solids arises due to anharmonicity in the lattice vibrational spectrum – i. e., vibrations for which the potential energy has additional terms of higher order than quadratic. For instance, a cubic term in the potential energy gives rise to anharmonic three-phonon processes, two examples of which are given in Fig. 57.8. Four-phonon and higher-order processes will arise from terms quartic and higher.

A measure of the anharmonicity in a crystal lattice is given by the Grüneisen coefficient γ. The ideally harmonic crystal would have $\gamma = 0$ for all phonon modes and frequencies; this is an ideality that does not exist in nature. The larger the value of γ, the stronger the anharmonicity in the lattice. Thus, a good place to look for crystalline solids with low intrinsic thermal conductivity is in those materials with highly anharmonic phonon spectra.

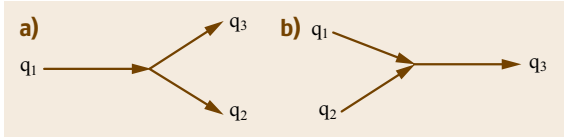

Fig. 57.8a,b Two types of three-phonon anharmonic processes that give rise to intrinsic lattice thermal resistivity in solid. **(a)** A phonon of wavevector q_1 is destroyed and two phonons of wavevectors q_2 and q_3 are created (phonon creation); **(b)** two phonons of wavevector q_1 and q_2 are destroyed and a phonon of wavevector q_3 is created (phonon annihilation)

But what gives rise to anharmonicity? This very fundamental question has been of intense interest to researchers in recent years. One very interesting and fruitful approach is the concept of the effect of lone pair electrons on vibrational modes in solids. The seed of this idea goes back to the work of *Zhuze* [57.42] in the Soviet Union, who noticed the large difference in thermal conductivity between certain compounds depending on their composition and the valence state of the atoms comprising them, and in particular those containing Sb ions. The electronic configuration of Sb is $[Kr]4d^{10}5s^25p^3$. In certain coordinations of Sb in the lattice, all five of the valence electrons participate in bonding; an example is the zincblende-like compounds Cu_3SbSe_4, in which each Sb atom is tetrahedrally coordinated. On the other hand, in other compounds, for instance Cu_3SbSe_3, the Sb is trigonally coordinated, and only three of the valence electrons participate in bonding; the remaining two electrons reside close to the Sb ion in an unbonded configuration. This configuration of unbonded electrons around Sb (or indeed any other ion) is known as the lone pair. Zhuze suggested that the electron clouds of overlapping Sb lone pair electrons gives rise to nonlinear forces in the lattice vibrations, i. e., give rise to anharmonicity. This effect was recently invoked by to explain the low intrinsic thermal conductivity of $AgSbTe_2$ [57.43]. *Skoug* and *Morelli* [57.44] showed that the thermal conductivity of large families of compounds exhibiting pnicogen atom lone pairs could be understood in this context, and were able to relate the degree of thermal resistivity with the distance of the lone pair electrons from the nucleus of the atom, with those configurations in which the lone pair was furthest from the nucleus having the strongest reduction in thermal conductivity. *Ozolins* et al. [57.45] formalized the connection between the presence of the lone pair and the degree of anharmonicity using calculations of the lattice dynamics for several compounds.

A very interesting example of how this effect can manifest itself in enhanced thermoelectric behavior

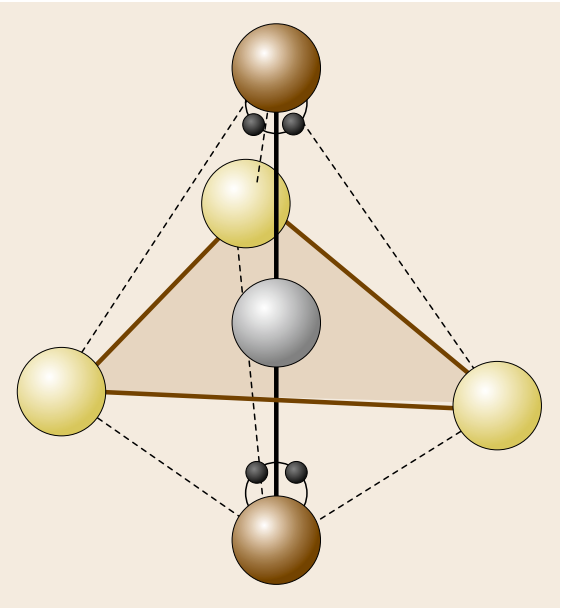

Fig. 57.9 The trigonally coordinated Cu site in tetrahedrite. A copper atom (*gray*) is trigonally surrounded by three sulfur atoms (*yellow*). Two antimony atoms (*brown*) possessing unbonded lone pair electrons (*black dots*) reside above and below the trigonal plane. The Sb lone pairs act to *pull* the copper atom of the trigonal plane. The trigonal bipyramid arrangement is a cage in which the Cu atom rattles, giving rise to PGEC-like behavior

is provided by the family of compounds known as tetrahedrites. The base composition of tetrahedrite is $Cu_{12}Sb_4S_{13}$. Its crystal structure is cubic with 29 atoms in the unit cell. Tetrahedrite possesses several key structural features that have strong implications for its thermoelectric properties. First, the Sb atoms are trigonally coordinated and do indeed display the classic lone pair as described above. Additionally, Cu occupies two distinct crystallographic sites in the lattice; one in which the Cu atom is tetrahedrally coordinated by sulfur, and a second site in which the Cu ion resides in a trigonal plane of sulfur atoms; six Cu atoms are supposed to reside in each site in the lattice. Guided by electronic band structure calculations, *Lu* et al. [57.46] showed that while the base composition $Cu_{12}Sb_4S_{13}$ is metallic, the substitution of divalent Zn for Cu can yield semiconducting behavior. At the same time, the lattice thermal conductivity exhibited values below $0.5\,Wm^{-1}K^{-1}$, i. e., close to the minimal thermal conductivity of a solid. By optimizing the Zn concentration they demonstrated that tetrahedrites can reach zT values close to 0.9. Since then, several other studies [57.47–49] investigating different atoms substitutions and different methods of processing these materials has resulted in zT values in the range of 1.1−1.2. Recently, *Lai* et al. [57.50] combined density functional theory (DFT) calculations with high resolution x-ray scattering studies to show that Sb lone pairs residing above and below the trigonal Cu–S plane (Fig. 57.9) act to displace the Cu away from the plane, causing a buckling-type behavior. In this picture, the three sulfur atoms surrounding the copper ion together with the lone-pair-containing antimony above and below the plane comprise a bipyramidal *cage* in which the copper atom *rattles*. This PGEC-like behavior is thought to be the source of low thermal conductivity in these compounds.

With the growing ability to calculate the properties of materials from first principles, approaches such as that used for tetrahedrite offer the opportunity to use powerful materials-by-design principles to conceive of new structures and compositions with the unusual combination of transport properties required for thermoelectricity directly *built-in* to them. This is a new paradigm in thermoelectric materials research that offers great promise from thermoelectric in the future.

57.4 Summary and Future Outlook

Thermoelectrics are very unique material systems in which the fundamental behavior associated with electrons and phonons in crystalline solids can give rise to interesting thermal and electronic effects, which can be important technologically. The stringent requirements on Seebeck coefficient, electrical conductivity, and thermal conductivity that are necessary to produce good thermoelectric behavior continue to offer challenges and inspiration to myriad researchers. Thermoelectricity has become a proving ground for numerous new and innovative concepts in physics, chemistry, and materials science, including quantum size effects, nanostructuring, phonon-glass-electron crystal behavior, and large anharmonicity. New knowledge uncovered in these and other areas is driving improvements in material performance, and the future holds promise that highly efficient thermoelectric devices for both power generation from waste heat and solid-state climate control will become a reality.

58. Transparent Conductive Oxides

Hideo Hosono, Kazushige Ueda

Transparent conducting oxides (TCOs) such as doped ZnO, In_2O_3 and SnO_2 play important roles as transparent electrodes in commercial applications such as display and lighting devices. Although transparency and electrical conductivity are inherently conflicting, TCOs possess both properties simultaneously. To understand the fundamentals of TCOs, the essetials of the transparency and electrical conductivity are reviewed simply. Comprehension of the essentials enables us to develop novel TCOs following the principles of the materials design that carrier conduction paths should be constructed in wide-gap oxides. Because the electronic structure of oxides is considerably different between the conduction band and the valence band, procedures to form the conduction paths for electrons are in contrast to those for holes. In n-type TCOs, only isotropically spread ns^0 orbitals of heavy cations such as Zn^{2+}, In^{3+} and Sn^{4+} are necessary to form conduction paths for electrons at the bottom of the conduction band. In p-type TCOs, however, hybridization of orbitals between oxygen $2p^6$ orbitals and other orbitals such as Cu $3d^{10}$, Sn $5s^2$ and S $3p^6$ orbitals is essential to shape conduction paths for holes at the top of the valence band.

58.1 Overview

Transparent conducting oxides (TCOs) are known as materials that show both transparent and conducting properties, and their films are utilized in flat panel displays, solar cells and electroluminescent devices as transparent electrodes as reviewed in [58.1–7]. The transparent properties mean TCOs show high optical transmission in the visible range, which requires an energy gap larger than 3.3 eV. The conducting properties signify that TCOs show high electrical conductivity in the range from 1 to $10^4\,S\,cm^{-1}$.

Although TCOs are common in industry nowadays, transparency and electrical conductivity are basically incompatible. Transparent materials are usually insulators such as SiO_2 glasses. If they are used in powder or polycrystalline bodies, they look white. On the other hand, highly conductive materials usually show metallic luster or deep dark color. For instance, Ag and Al metals show metallic color with high reflectivity, which are utilized in mirrors. Oxide high-temperature superconductors such as $YBa_2Cu_3O_7$ show black color. Therefore, to obtain TCOs, it is necessary to convert transparent insulators to highly conducting semiconductors by increasing electrical conductivity without coloration.

58.1.1 Electrical Conduction

Electrical current I in materials is expressed by Ohm's law as $I = V/R$, where V and R are potential difference and resistance respectively. When the equation is normalized by the sizes of materials, Ohm's law can be expressed as $\boldsymbol{J} = \sigma \boldsymbol{E}$, where $\boldsymbol{J}$, σ, $\boldsymbol{E}$ are current density, conductivity, and electric field strength. The conductivity σ is generally dependent on materials themselves and a useful parameter, which varies by a factor of over 10^{20}, to categorize materials into metals, semiconductors and insulators. Figure 58.1 shows the electrical conductivities of some materials. Metals

[a] Conductivity, [b] Carrier concentration, [c] Mobility

such as Ag and Al possess high electrical conductivities of the order of 10^5 S cm^{-1}. Semiconductors such as Si and Ge have medium conductivities. Although pure semiconductors are almost insulating, impurity doping markedly increases the conductivities up to the order of 10^2 S cm^{-1}. The typical conductivities of TCOs are located in the middle of metals and doped semiconductors. This would be natural because TCOs are originally doped transparent oxide semiconductors (TOSs).

To understand the nature of the conductivities of TCOs, it is necessary to compare carrier concentration and mobility between some materials. The electrical conductivity is a product of carrier concentration n, elementary electric charge e, and mobility μ as shown in Fig. 58.2 and in (58.1).

$$\sigma = ne\mu \tag{58.1}$$

These parameters straightforwardly characterize conducting materials of metal, semiconductor and TCO. The parameters of typical materials are listed in Table 58.1 [58.17, 18]. Ag metal is found to show high electrical conductivity because of high carrier concentration in the order of approximately 10^{23} cm^{-3}. The mobility of Ag metal is not markedly high among these conductors. P-doped Si shows the lowest electrical conductivity among them because the carrier concentration is fairly low. It can become an electrical conductor simply because the carrier mobility of Si is much higher than that of Ag metal. Even if Si is heavily doped with the carrier concentration up to 10^{19} cm^{-3}, the mobility decreases by carrier scattering and the conductivity does not increase as high as Ag metal. Sn-doped In_2O_3 (ITO) shows the conductivity that is approxmately one-tenth of the Ag value. Because the carrier mobility of ITO is not largely different from that of Ag metal, the carrier concentration of ITO, which is one-tenth of the Ag value, is responsible for its smaller conductivity. These features can be extended to other conducting materials and their carrier

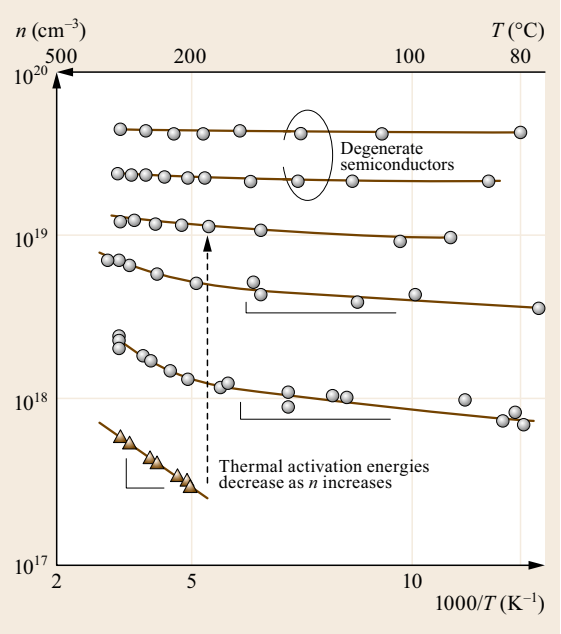

Fig. 58.5 Carrier concentration as a function of inversed temperature in ITO

concentrations and mobilities are plotted in Fig. 58.3. Metals are located in the *top-left* region in Fig. 58.3, which indicates the metals have extremely high carrier concentration but their mobilities are not so high. In contrast, doped semiconductors are located in the *bottom-right* region because of low carrier concentration and high mobility. Figure 58.3 clearly illustrates TCOs are located between metals and doped semiconductors. Because the mobilities of TCOs are not largely different from those of typical metals such as Ag, each TCO can be regarded as a metal with small carrier concentration, which is called as a degenerate semiconductor. The schematic electronic structure of a degenerate semiconductor is shown in Fig. 58.4. Although the thermal activation energy is necessary for semiconductors to generate carriers, it is unnecessary for metals and degenerate semiconductors. This

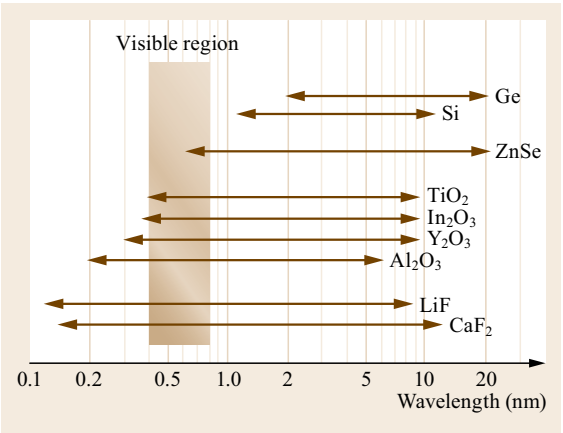

Fig. 58.6 Optically transparent regions in some materials

feature is experimentally observed as absence of thermal activation energy as shown in Fig. 58.5. Figure 58.5 shows the carrier concentration n as a function of reciprocal temperatures [58.19]. At increasing doping concentration, namely carrier concentration, the slope of the lines, which is derived from the activation energy for thermal ionization of dopant, becomes shallow and the conductivity finally becomes almost independent of temperatures.

58.1.2 Transparency

The main group metal oxides such as MgO and Al_2O_3 are electrically insulating but optically transparent in the wavelength range from 380 to 780 nm, namely the visible region. Therefore, oxide single crystals or glasses are frequently used as windows in optical applications. Figure 58.6 shows optical transparent ranges of several materials [58.20]. Typical oxides are transparent in the range approximately from 300 to 10 μm including the visible region. Typical fluorides such as LiF and CaF_2 show a much wider window range than oxides, especially in deep ultraviolet or vacuum ultraviolet regions [58.21]. On the other hand, conventional semiconductors such as Si and Ge have a window range only in the infrared region. Therefore, it is not surprising that TCOs are transparent in the visible region. Figure 58.7 shows a typical transmission spectrum of an oxide single crystal. As shown in Fig. 58.7, the absorption edge is controlled by the lattice vibration in the infrared region, and by the fundamental absorption caused by the electron transition from the valence band to the conduction band in the ultraviolet region.

When carriers are introduced into the parent material (undoped) of TCOs, optical absorption and reflection by the carriers newly appears. The collective motion of the conducting carriers behave as a kind

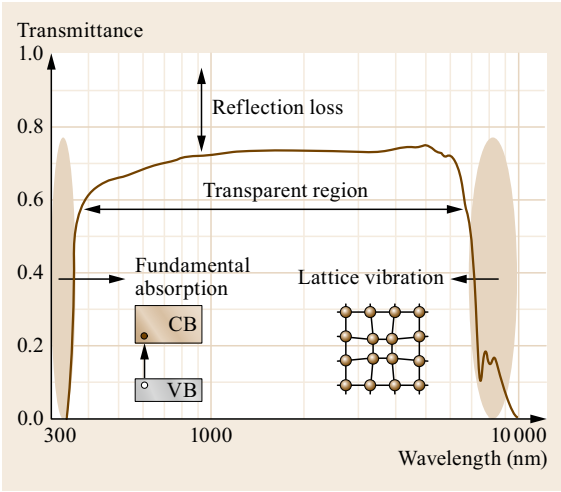

Fig. 58.7 Transmission spectrum of a typical oxide

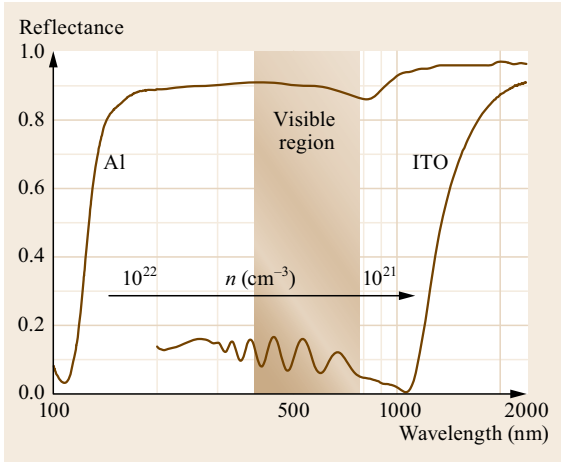

Fig. 58.8 Reflection spectra of Al and ITO

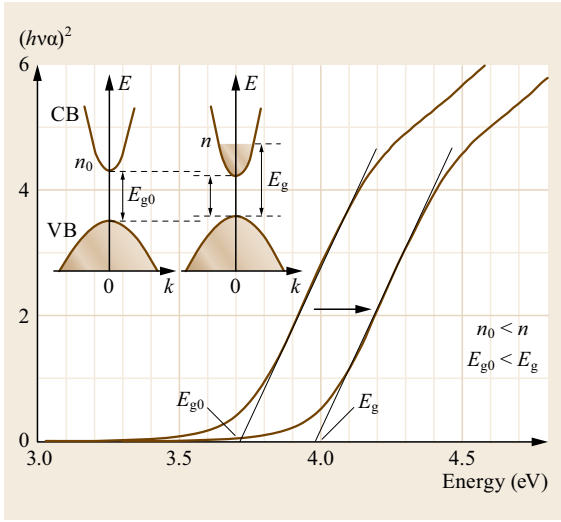

Fig. 58.9 Blue shift of fundamental absorption by band filling

of plasma in conductors. When light, namely an electromagnetic wave, is irradiated to the conductors, the carriers oscillate at the frequency of the light, which is called plasma oscillation. This results in the reflection of the light at the surface of the conductors. However, against light with higher frequency, the carriers cannot catch up with the fast electric field oscillation of the light. The light is transmitted through the conductors without causing the plasma oscillation or reflection at the surface. The maximum threshold frequency that enables the plasma oscillation is called the plasma frequency ω_p and can be expressed by (58.2) [58.17]. The plasma frequency ω_p can be converted to the wavelength λ_p as shown in

$$\omega_p = \frac{ne^2}{\varepsilon_0 m}\,, \tag{58.2}$$

$$\lambda_p = \frac{2\pi c}{e}\sqrt{\frac{\varepsilon_0 m}{n}}\,, \tag{58.3}$$

where n, m, ε_0 and c denote carrier concentration, electron rest mass, permittivity and speed of light in vacuum respectively. In Al metal with high carrier concentration, over $10^{22}\,\mathrm{cm}^{-3}$, the threshold λ_p is located in the vacuum ultraviolet region as shown in Fig. 58.8, and visible light is totally reflected at the surface [58.22]. This is the origin of the metallic luster of the Al metal, and why the wide-ranged reflection of Al is often used as a mirror. On the other hand, since ITO has a carrier concentration one order of magnitude smaller than Al metal, the λ_p moves to the infrared region, which results in the transparency in the visible region because ITO has a sufficient bandgap ($> 3.5\,\mathrm{eV}$) to transmit visible light. Consequently, the maximum carrier concentration of TCOs should be less than $10^{21}\,\mathrm{cm}^{-3}$ because the carriers make the optical windows of oxides narrower in the infrared region.

The carriers influence the optical windows of oxides not only in the infrared side but also in the ultraviolet side. Energy gaps are usually estimated by the $(h\nu\alpha)^2$–E plot, where h, ν and α are Planck constant, frequency and absorption coefficient respectively, as shown in Fig. 58.9. As the carrier concentration increases, absorption edges move to the higher energy side, enlarging apparent energy gaps and making optical windows wider in the ultraviolet region. This variation is attributed to the occupation of the conduction band by carrier electrons as shown in the *inset* in Fig. 58.9. In n-type TCOs, because carrier electrons

occupy the bottom of the conduction band, the optical bandgap energy E_g needed for the optical transition from the valence band to the unoccupied conduction band becomes larger than the original bandgap E_{g0}. This energy shift is called band filling or Bernstein moss (BM) shift.

58.2 Materials Design for TCOs

The essential factor of materials design for TCOs is determining how to dope carriers into oxides, because the metal oxides (except transition metals with an open shell electronic configuration) are basically transparent due to the large bandgap. As shown in (58.1), to increase the electrical conductivity is to increase carrier concentration and mobility. Because the carrier concentration can be controlled by users depending on purposes, the carrier concentration is generally independent from materials themselves. Therefore, the mobility is the material-dependent parameter to be designed. The mobility is a velocity of carriers under unit electric field strength and inversely proportional to the effective mass m^* of carriers as in (58.4).

$$\mu = \frac{v}{E} = \frac{e\tau}{m^*} \tag{58.4}$$

The effective mass m^* is theoretically deduced so that m^* is inversely proportional to the curvature of an energy band in the energy diagram as a function of wavenumber k as in (58.5)

$$\frac{1}{m^*} = \left(\frac{2\pi}{h}\right)^2 \frac{\partial^2 E}{\partial k^2} \tag{58.5}$$

In a simple one-dimensional crystal with lattice constant a, a simple energy band is formed and composed of a one-dimensionally aligned atomic orbital ϕ_m as shown in Fig. 58.10 [58.23]. The energy E of the band is expressed in (58.6) and (58.7) by using the orbital interaction or resonant integral H_{mn} between neighboring orbitals.

$$H_{mn} = \int \phi_m^* \hat{H} \phi_n \mathrm{d}x \,, \tag{58.6}$$

$$\begin{aligned} E &= H_{nn} + 2H_{mn}\cos(ka) \\ &\approx H_{nn} + 2H_{mn} - H_{mn}(ka)^2 \quad (x \approx 0) \end{aligned} \tag{58.7}$$

Equations (58.4)–(58.7) lead to a simple conclusion that the mobility is proportional to the orbital interaction H_{mn}

$$\mu \propto \frac{\partial^2 \mathrm{E}}{\partial k^2} = -2H_{mn}a^2 \,. \tag{58.8}$$

The value of H_{mn} is simply estimated so that H_{mn} becomes large when the overlap of atomic orbitals between ϕ_m and ϕ_n is large, because H_{mn} is calculated from a product of the atomic orbitals as seen in (58.6). Because making large overlap of the orbitals is just equal to increasing a probability of carrier transport or forming a conduction path in the crystal, carriers move between the orbitals through their overlapped areas. Therefore, a smooth conduction path for carriers must be constructed in wide-gap oxides by making sufficient overlap of component orbitals to provide them with large carrier mobility.

58.2.1 Electronic Structures of Oxides

Understanding of the electronic structures of simple oxides is inevitable for the materials design for TCOs. Figure 58.11 shows the typical electronic structure of metal oxide (MO) illustrated in the form of molecular orbitals and energy bands. The conduction band is composed of empty metal ns^0 orbitals and the valence band is composed of occupied oxygen 2p orbitals. The conduction band has antibonding features, and the bottom of the valence band has bonding features as a counterpart. The top of the valence band has nonbonding features because nonbonding oxygen 2p orbitals remain without changing the energies.

58.2.2 Materials Design for n-Type TCOs

For n-type TCOs, a conduction band consisting of empty orbitals becomes a conduction path for electrons. To obtain the sufficient overlap of orbitals for the conduction path, cations' orbitals should be extended as widely as possible and intercation distances should be as short as possible. Therefore, the essentials for developing n-type TCOs are to choose proper cations for widely extended orbitals, and to choose a proper crystal structure for shorter intercation distances [58.24–26].

In the choice of cations, p-block atoms should be chosen for widely extended orbitals. As known in a simple hydrogen atomic model, radii of orbitals are proportional to principal quantum number n, namely, the period in the periodic table in Fig. 58.12. Although heavy atoms with large n are preferable, atoms with $n = 6$ such as Tl and Pb are inadequate because their orbitals are too widely extended to keep the wide bandgap for transparency. Transition metal ions with d^n open shells are also improper due to the coloration. In addition to the radii of orbitals, the shape of orbitals is also important to maximize the orbital overlap. Isotropic s orbitals, which are free from bonding direction, are more preferable than p- or d orbitals. Therefore, cations with $d^{10}ns^0$ $(n = 4, 5)$ electronic configuration are favorable to form the conduction path for electrons in the conduction band. Actually, the selected cations includes cations such as Zn^{2+}, In^{3+} and Sn^{4+} found in major TCOs.

In the choice of crystal structures, the configuration of polyhedra consisting of a cation at the center and oxygen ions at the apexes should be examined. In the case of the cations with $d^{10}ns^0$ $(n = 4, 5)$ such as In^{3+} and Sn^{4+}, they usually form oxygen octahedra due to the size of the ions. Various configurations such as isolated octahedra, corner-sharing octahedra, edge-sharing and face-sharing octahedra are seen in crystal structures. Among them, intercation distances are the shortest in face-sharing structures as shown in Fig. 58.13. It is known, however, that such struc-

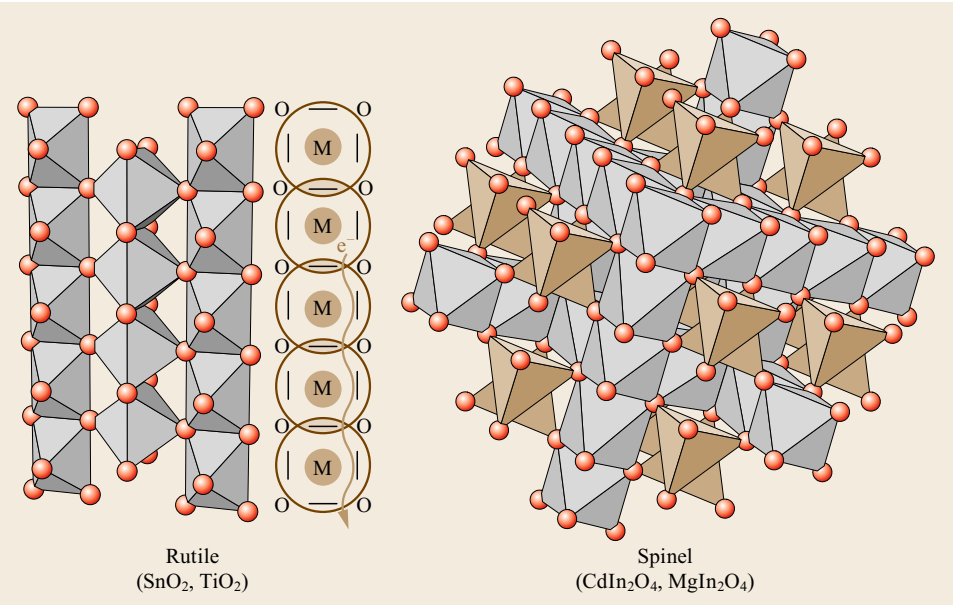

Fig. 58.14
Crystal structures of typical n-type TCOs

tures are usually unstable in oxides due to the intercation coulomb repulsion [58.27] and hardly seen in many crystal structures. Therefore, the edge-sharing structure substantially gives the shortest intercation distances. Accordingly, with widely extended orbitals, edge-sharing structures can form conduction paths in n-type TCOs.

Typical n-Type TCOs and Their Electronic Structure

From the concept of the materials design for n-type TCOs, the oxides, which include the cations with $d^{10}ns^0$ $(n = 4, 5)$ configuration and the partial crystal structures with edge-sharing octahedra, can be leading candidates. Actually, such materials often show transparent n-type conductive properties and some typical n-type TCOs are shown in Fig. 58.14. SnO_2 with a rutile structure composed of edge-sharing octahedra along the *c*-axis has been known as an n-type TCO for a long time. $CdIn_2O_4$ and $MgIn_2O_4$ with spinel structure have three-dimensionally connected edge-sharing octahedra [58.28, 29]. Although the effective ionic radii of In^{3+} and Sn^{4+} are 0.8 and 0.7 Å respectively, such ionic sizes neglect $5s^0$ orbitals. Interatomic distances are 3.2 Å in In metal and 3.0 Å in Sn metal, while intercationic distances are 3.3 Å in In_2O_3 and 3.2 Å in SnO_2. Because the intercationic distances in the oxides are very close to the interatomic distances in the metals, it would be easily supposed that $5s^0$ orbitals between In^{3+} or Sn^{4+} ions in the oxides can largely overlap as in the metals.

The large overlap of the orbitals in In_2O_3 and SnO_2 appears as a large energy dispersion of the conduction band in their energy diagrams as shown in Fig. 58.15 [58.30, 31], where the valence band maximum is set to zero in energy. The large energy dispersion results in the large curvature and large mobility at the bottom of the conduction band. These characteristic conduction band bottoms can be experimentally observed in the photoemission spectra of Fig. 58.16. Because the Fermi energy E_F is taken as zero in energy in Fig. 58.16, E_F is located at the bottom of the conduction band indicating these materials are n-type TCOs. The large dispersion of the conduction band causes a gentle increase of the density of states, which appears as a gradual increase in the photoemission intensity above E_F. The gradual increase at the bottom of the conduction band is in contrast to the steep increase at the top of the valence band, especially in In_2O_3.

Other n-Type TCOs

The characteristics of the crystal and electronic structures preferable to n-type TCOs are commonly seen in other n-type TCOs such as ZnO, Ga_2O_3, Cd_2SnO_4 and $SrGeO_3$ [58.32–36]. The edge-sharing octahedra in crystal structures are not always necessary if the overlap of the orbitals for the conduction band is large enough to form a conduction path. Therefore, even amorphous oxides such as a-In_2O_3-ZnO and a-In_2O_3-Ga_2O_3-ZnO can be n-type TCOs because the conduction paths are formed by the orbitals' overlap in these materials irrespective of the crystal structures [58.37–39]. Since

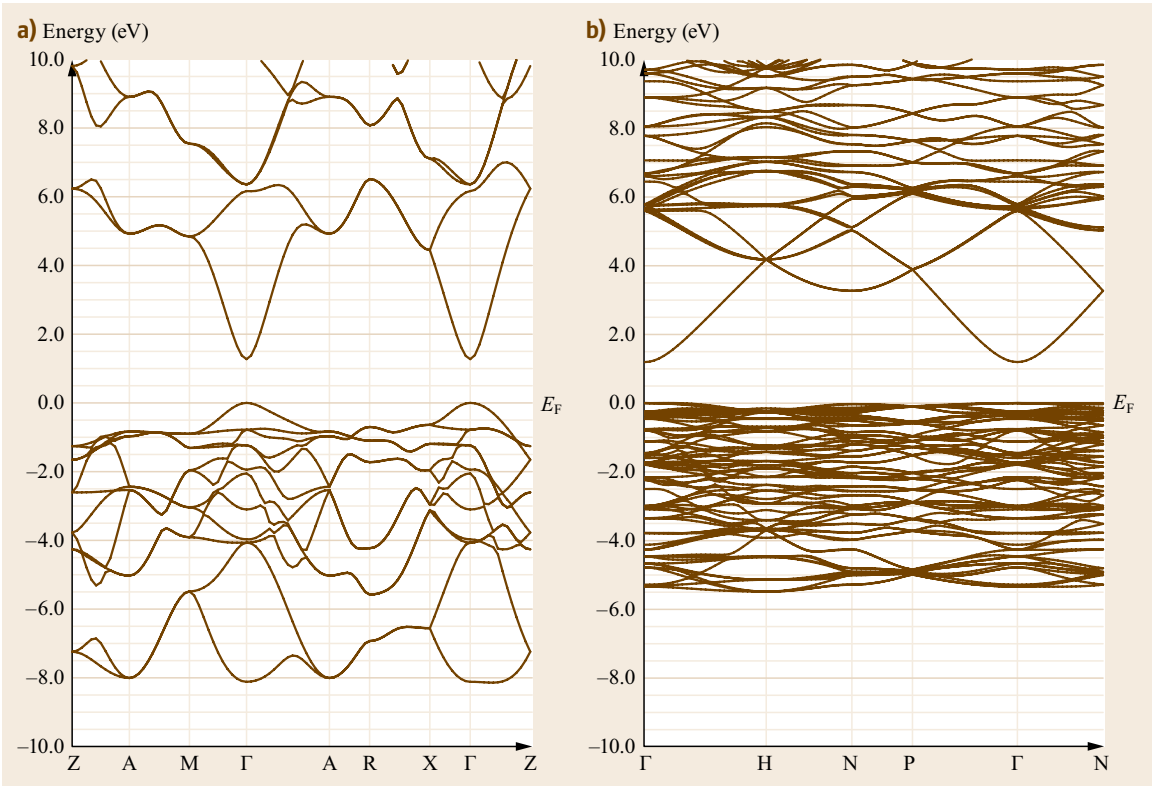

Fig. 58.15a,b Energy band diagrams of SnO_2 **(a)** and In_2O_3 **(b)**

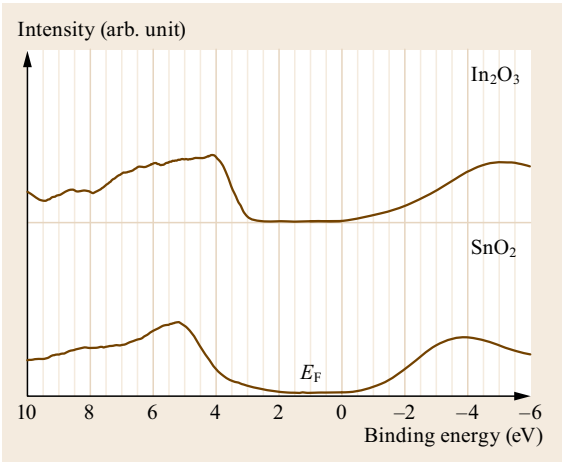

Fig. 58.16 Normal and inverse photoemission spectra of SnO_2 and In_2O_3

the amorphous TCO thin films can be formed at low temperatures and durable during bending, they can be deposited on not only in inorganic glasses but also in organic plastic plates or films. Their advantages are utilized in growing applications such as flexible electronics and printable electronics.

Some TCOs such as TiO_2 and $KTaO_3$ have the conduction bands that are not composed of s^0 orbitals but d^0 orbitals [58.40–42]. These materials are considered to have conduction paths consisting of the d^0 orbitals. Because the d^0 orbitals are not isotropic in shape, the electrical conductivity would be largely influenced by the symmetry of the crystals.

58.2.3 Materials Design for p-Type TCOs

In p-type TCOs, in contrast to n-type TCOs, it is the filled valence bands rather than the the empty conduction bands that form the conduction paths for carriers, namely positive holes. However, the formation of the hole conduction paths are not as easy as that of the electron conduction paths. This is why p-type TCOs are rare [58.43].

The valence bands of oxides are generally composed of filled oxygen 2p orbitals. Accordingly, the oxygen 2p orbitals must be sufficiently overlapped with each other to form the conduction paths for holes. However, the oxygen 2p orbitals at the valence band maximum consist of nonbonding states, which indicate almost no interaction, namely no orbitals overlap between oxygen ions. This makes it very difficult to

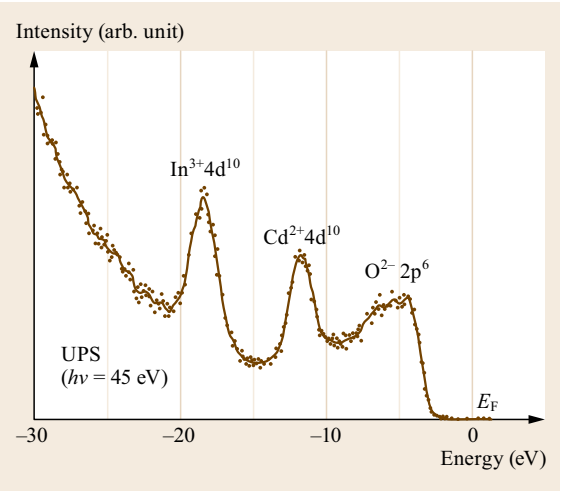

Fig. 58.17 Ultraviolet photoemission spectrum of $CdIn_2O_4$

form the hole conduction paths at the valence band, resulting in considerably small hole mobility even if the holes are doped into the valence band. Hole doping is also substantially difficult in oxides because oxygen has large electronegativity indicating that O^{2-} ions with closed shells are too stable to accept holes. Actually, the energy of oxygen 2p orbitals is very deep from the vacuum level, giving oxygen the large electron affinity. Therefore, it is considered that the formation of a hole conduction path by using only oxygen 2p orbitals is almost impossible.

To improve the nature of the low hole mobility and difficulty in hole-doping in oxides, chemical modulation of the valence band was proposed by hybridizing cations' orbitals with oxygen 2p orbitals [58.43, 44]. The hybridization of orbitals usually occurs between orbitals with similar energies. Therefore, the energy of the candidate cations' orbitals must be close to that of oxygen 2p orbitals. Figure 58.17 shows the photoemission spectrum of a $CdIn_2O_4$ n-type TCO. As similar to In_2O_3 and SnO_2 in Fig. 58.16, the oxygen $2p^6$ band consists of the valence band. In addition to the oxygen 2p valence band, Cd^{2+} $4d^{10}$ and In^{3+} $4d^{10}$ bands are located at higher binding energies with almost the same energy intervals. Because the Cd and In are located at adjacent positions on periodic table as in Fig. 58.12, the periodicity predicts that the energy of Ag^{+} $4d^{10}$ or Cu^{+} $3d^{10}$ orbitals are very close to the oxygen 2p energy and they are easily hybridized with the oxygen 2p orbitals. From the viewpoint of chemical stability, Cu $3d^{10}$ orbitals are considered to be the most favorable for the chemical modulation of the valence band.

Hybridization between Cu $3d^{10}$ and oxygen 2p nonbonding orbitals newly forms Cu–O bonding and antibonding states, and the Cu–O antibonding states become the top of the valence band as shown in Fig. 58.18 [58.45]. Therefore, the valence band is mainly composed of a Cu–O bonding band (A), an M–O bonding band (B), a Cu nonbonding band (C) and a Cu–O antibonding band (D). The chemical modulation by Cu $3d^{10}$ orbitals varies the nonbonding oxygen 2p orbitals to the Cu–O antibonding band at the top of the valence band and elevates the energy of the valence band maximum simultaneously. Accordingly, the shallow Cu–O antibonding band is expected to increase the hole mobility and make hole doping easier.

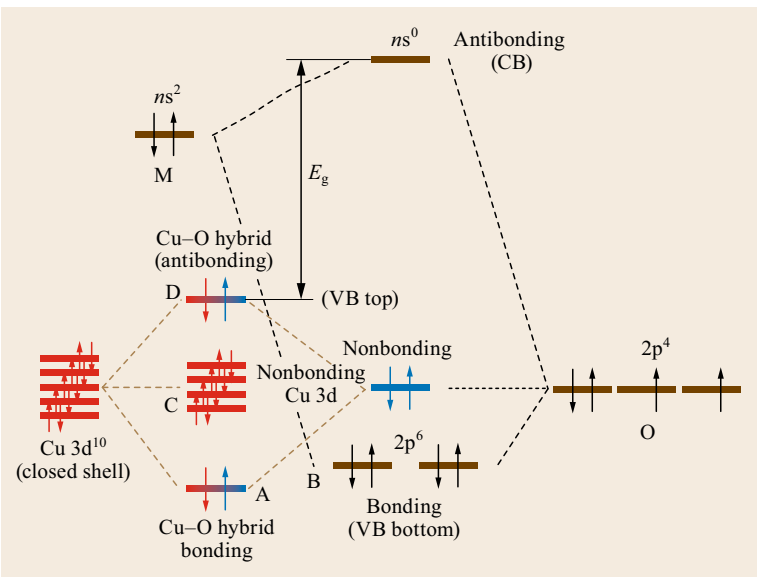

Fig. 58.18 Chemical modulation of the valence band by Cu $3d^{10}$ orbitals in oxides shown in a schematic molecular orbital diagram

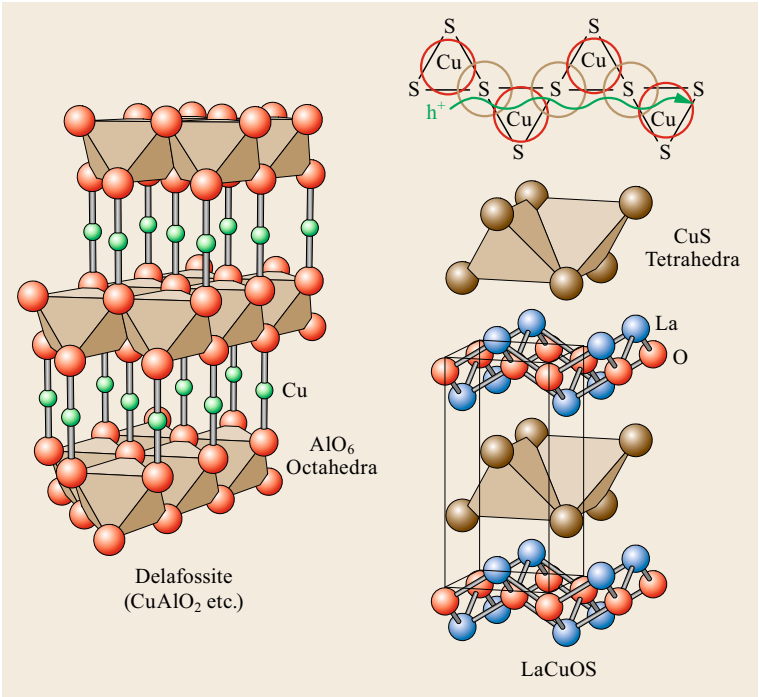

Fig. 58.19 Crystal structures of typical p-type TCOs

The chemical modulation works more effectively in oxysulfides, in which Cu 3d orbitals hybridize not oxygen 2p orbitals but sulfur 3p orbitals forming Cu–S bonding (A′) and antibonding (D′) band [58.46]. Because sulfur 3p orbitals are shallower in energy and more covalent than oxygen 2p orbitals, larger hybridization is expected at the top of the valence band. The larger modulation leads to higher hole mobility by forming a steady hole conduction path at the valence band maximum.

The chemical modulation usually narrows the bandgap by the formation of the shallow antibonding band at the top of the valence band. Because the degree of the modulation is usually dependent on the dimension of crystal structures, lower dimensional crystal structure gives a moderate hybridization, namely a moderately shallow antibonding band. Therefore, layered structures and chain structures are preferable to maintain wide bandgap and transparency.

Typical p-Type TCOs and Their Electronic Structure

From the materials design for p-type TCOs, the Cu^+ containing oxides with layered structures or chain structures can be leading candidates. $CuAlO_2$ with delafossite structure was proposed as a prototype of p-type TCOs [58.43, 47]. $CuAlO_2$ is a layered structure composed of Cu^+ and AlO_6 octahedra layers as shown in Fig. 58.19. Although p-type Cu_2O, in which an O^{2-} ion bonds to four Cu^+ ions, shows deep dark red color, $CuAlO_2$ is almost transparent in the visible region because an O^{2-} ion in $CuAlO_2$ bonds to only one Cu^+ and three Al^{3+} ions resulting in a moderate Cu–O hybridization. Another example of a transparent p-type material is LaCuOS, which is also a layered structure composed of CuS and LaO layers [58.48]. The hybridization between Cu 3d and S 3p orbitals occurs in the CuS layer separated by the LaO layer. Because the LaO layers are inserted between CuS layers reducing dimensionality, the layered structure brings about a moderate Cu–S hybridization to maintain transparency.

The chemical modulation at the top of the valence band in $CuAlO_2$ and LaCuOS is seen in the energy diagram of Fig. 58.20 [58.47, 49, 50]. In contrast to the energy diagram of the valence band for n-type TCOs, especially In_2O_3, dispersed bands are observed in the energy range from 0 to −2 eV above several flat bands densely gathered at around −3 eV. The dispersed bands and flat bands are derived from the Cu–O/S antibonding bands and Cu nonbonding bands respectively. The dispersed bands are considered to form a hole conduction path and increase hole mobility at the top of the valence band. These features in the valence band can be experimentally observed in the photoemission spectra of Cu_2O, $CuGaO_2$ delafossite and LaCuOS as shown in Fig. 58.21. The Fermi energy E_F is located

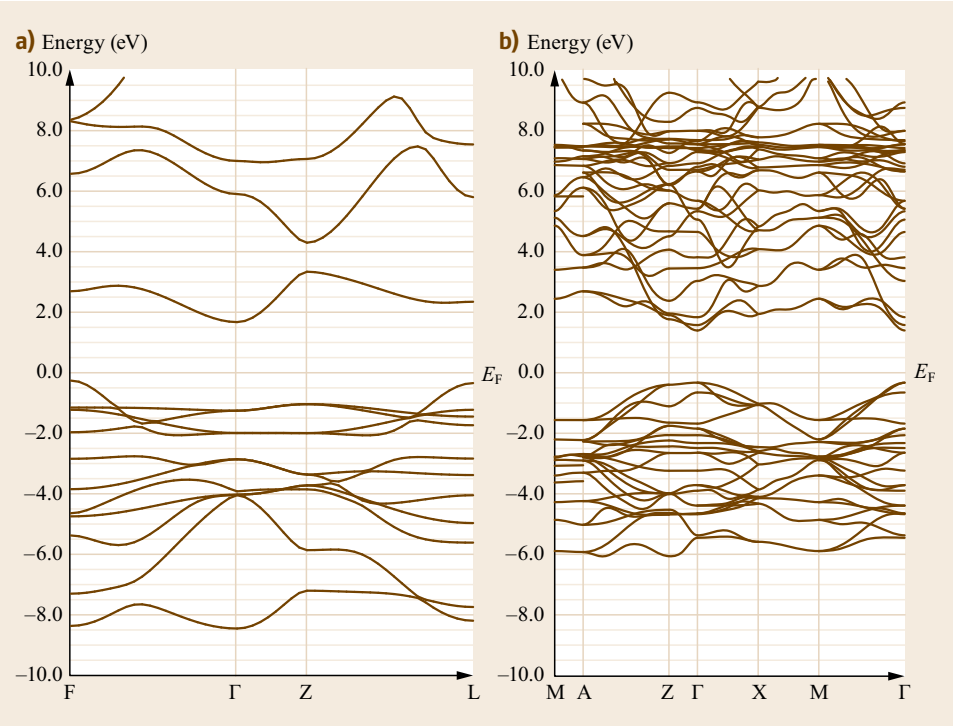

Fig. 58.20a,b Energy band diagrams of $CuAlO_2$ delafossite **(a)** and LaCuOS **(b)**

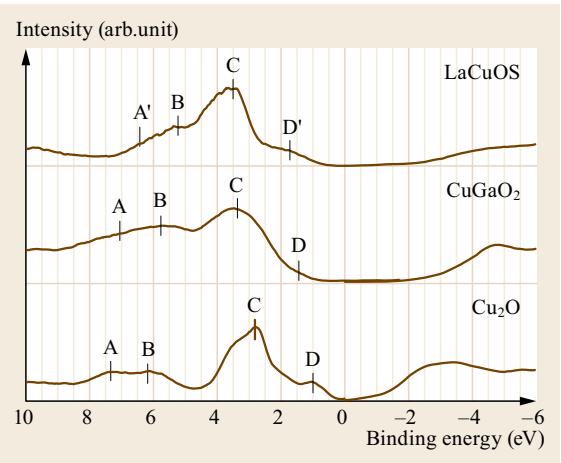

Fig. 58.21 Normal and inverse photoemission spectra of Cu_2O, $CuGaO_2$ and LaCuOS

near the top of the valence band indicating these materials show p-type conductions. The narrow bandgap of Cu_2O is also observed in contrast to wide bandgaps of $CuGaO_2$ and LaCuOS. In the valence band, the main four bands A–D, explained in molecular orbital diagram of Fig. 58.18, can be found in all materials. The Cu–O hybridized band D is located just below E_F and the presence of the band D demonstrates that the chemical modulation by Cu $3d^{10}$ orbitals is effective in the materials design of p-type TCOs. The typical electrical properties of some p-type materials are listed in Table 58.2.

Table 58.2 Electrical properties of Cu^+-based p-type TCOs

Materials	σ [a] ($S\,cm^{-1}$)	μ [b] ($cm^2\,V^{-1}\,s^{-1}$)	E_g (eV)	Reference
$CuAlO_2$	0.34	0.13	3.5[d], 1.8[c]	[58.47]

[a] Conductivity, [b] Mobility, [c] Direct transition, [d] Indirect transition

Other p-Type TCOs

The concept of the chemical modulation by Cu $3d^{10}$ orbitals is also applicable to other Cu-containing materials such as $SrCu_2O_2$, LaCuOSe and BaCuFSe as listed in Table 58.2 [58.47, 51–56]. The crystal structure of $SrCu_2O_2$ has low dimensional zigzag chains of Cu–O bonds, which enables a moderate Cu–O hybridization and transparency. LaCuOSe and BaCuFSe have the similar crystal structures to LaCuOS, in which

CuSe and BaF layers replace CuS and LaO layers respectively.

From other concepts of materials design for p-type TCOs, SnO [58.57, 58] and $ZnRh_2O_4$ [58.59] have been developed. Sn^{2+} in SnO has a lone pair of $5s^2$ electrons, which mainly occupy the bottom of the valence band. However, partial densities of Sn 5s orbitals also compose the top of the valence band along with Sn 5p orbitals and O 2p orbitals. This feature is similar to the modulation by Cu 3d orbitals and can be interpreted that the top of the valence band is composed of their hybridized states. The bandgap of SnO is as small as 0.2–0.7 eV for indirect transition, but as large as 2.7–3.1 eV for direct transition. Although the conductivity and transparency is not as high as Cu^+-based materials, SnO shows transparent p-type conductivity of approximately $10^{-1}\,S\,cm^{-1}$.

$ZnRh_2O_4$ with spinel structure includes Rh^{3+} ions with open shells of $4d^6$, which is not preferable for transparency. Rh^{3+} ions occupy the octahedral sites in the spinel structure and are influenced by the crystal field. Because the crystal field in $ZnRh_2O_4$ is sufficiently strong, the Rh^{3+} 4d orbitals are no longer usual open shells but two largely separated bands of occupied $4d^6$ and empty $4d^0$ orbitals, namely t_{2g}^6 band and e_g^0 band, with the bandgap as large as 2.1 eV. The p-type conductivity by holes, which probably originate from cationic vacancies, is reported to be approximately $1\,S\,cm^{-1}$.

There are several controversial reports on novel p-type TCOs such as p-type SnO_2. The experimental determination of p- or n-type conduction is sometimes difficult when carrier concentration is extremely high/low or both electrons and holes are present in conductors. Theoretical verification such as evaluation of acceptor formation energy becomes important, as well as experimental demonstration, to identify novel TCOs [58.60].

58.3 New Approach to Explore Candidate Materials: Materials Genome Approach

The materials design of TCOs explained above is empirically deduced from simple theories and some experimental data on electronic structures. However, recent remarkable progress in computational ability has enabled the calculation of essential parameters for TCOs such as bandgaps and carrier effective masses in almost all oxides (except strongly electron correlated systems) accumulated in databases. Because the candidates for TCOs are extracted from materials databases, this process is a kind of materials genome approach, which is similar to the biomedical approach in the human genome project.

For instance, by targeting new p-type TCOs through high-throughput computations and screening, groups at Université Catholique de Louvain (IMCN) and the Massachusetts Institute of Technology predicted several candidates of novel p-type TCOs such as $K_2Sn_2O_3$ as shown in Fig. 58.22 [58.61]. The electronic structures of more than 3000 binary and ternary oxides in the inorganic crystal structure database (ICSD) were computed and oxides with exceptionally low effective mass less than 1.5 were selected. The bandgaps of the selected oxides were estimated more accurately by a calculation based on many-body perturbation theory. In addition to the calculation of bandgaps and hole effective masses, the p-type dopability was also evaluated by calculating the defect formation energies. From the viewpoint of the electronic structure and p-type dopability, several candidates were selected and two design principles for p-type TCOs were drawn; one is to hybridize cations' $(n-1)d^{10}ns^2$ $(n = 5, 6)$ orbitals such as Sn^{2+} $5s^2$ with oxygen $2p^6$ orbitals; and the other is to include anions' p orbitals such as S^{2-} and P^{3-} $3p^6$ orbitals, which are more delocalized than oxygen $2p^6$ orbitals. This approach looks promising and having applicability as methodology. However, one has to keep in mind that practical TCO materials have to meet various fundamental properties such as chemical stability and etching ability.

59. Inorganic Perovskite Oxides

Tatsumi Ishihara

Crystal structure and important functions of inorganic perovskite oxides are introduced. Perovskite oxides comprise large families among the structures of oxide compounds, and several perovskite-related structures are currently recognized. Typical structures (ABO_3) consist of large-sized 12-coordinated cations at the A-site and small-sized 6-coordinated cations at the B-site. Several complex halides and sulfides and many complex oxides have a perovskite structure. From a variety of compositions and structures, a variety of functions are observed in perovskite oxides. In particular high electronic conductivity, which is at a similar level as metal, and surface activity to oxygen dissociation, are highly attractive in this oxide. Perovskite oxide is now widely used for solid oxide fuel cells.

Oxide groups consisting of two or more different cations are called complex or mixed oxides, and many types of crystal structures are known. In some special cases, oxides consisting of single cations in different oxidation states are also classified as mixed oxides. For example, in Eu_3O_4, the mixed oxide consists of Eu(III) and Eu(II) in 6- or 8-coordination respectively. However, the most typical structure of a mixed oxide consists simply of two or more different cations with different oxidation states, ionic radii, and coordination numbers. This diversity, which comes from the complexity of these structures, results in a larger number of different properties as compared to those of simple oxides. One of the most well known and important complex oxide structures is the spinel structure (AB_2O_4), which shows important magnetic properties. The structure of such oxides displays a most interesting complexity. Since the size of the A and B ions in this structure is close, oxides of this type are typical examples of the versatility of mixed oxides.

Another important structure of mixed oxide is perovskite and a variety of related structures are classified as this oxide. The typical chemical formula of the perovskite structure is ABO_3, where A and B denotes two different cations. The ilmenite structure has the same composition as the perovskite one, i. e., ABO_3; however, A and B in this structure are cations of approximately the same size, which occupy an octahedral site. Therefore, in spite of the fact that they share the same general chemical formula, structures classified as ilumenite- or ilmenite-related structures (e.g., $LiSbO_3$) are different from perovskite.

Perovskite oxides comprise large families among the structures of oxide compounds, and several perovskite-related structures are currently recognized. Typical structures consist of large-sized 12-coordinated cations at the A-site and small-sized 6-coordinated cations at the B-site. Several complex halides and sulfides and many complex oxides have a perovskite structure. In particular, $(Mg,Fe)SiO_3$ or $CaSiO_3$ is thought to be the predominant compound in the geosphere [59.1, 2]. Perovskite compounds with different combinations of charged cations in the A and B-sites, for example $1+5$, $2+4$ and $3+3$, have been discovered. Even more complex combinations are observed, such as $Pb(B'_{1/2}B''_{1/2})O_3$, where $B' = Sc$, Fe and $B'' = Nb$, Ta, or $La(B'_{1/2}B''_{1/2})O_3$, where $B' = Ni$, Mg, etc. and $B'' =$ Ru(IV) or Ir(IV). In addition, many ABO_3 compounds

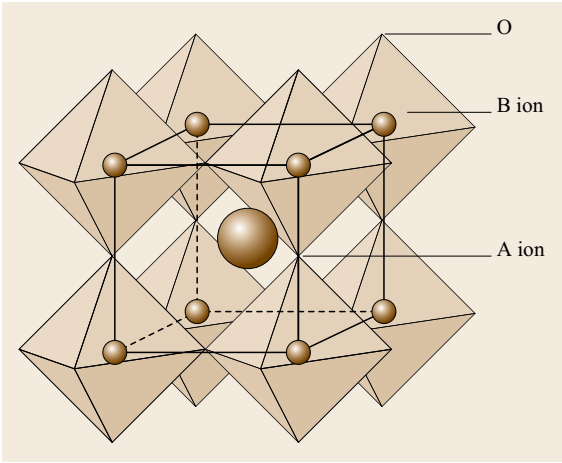

Fig. 59.1 Ideal cubic perovskite structure

crystallize in polymorphic structures, which show only a small distortion from the most symmetrical form of the perovskite structure.

The ideal structure of perovskite, which is illustrated in Fig. 59.1, is a cubic lattice. Although few compounds have this ideal cubic structure, many oxides have slightly distorted variants with lower symmetry (e.g., hexagonal or orthorhombic). Furthermore, even though some compounds have ideal cubic structure, many oxides display slightly distorted variants with lower symmetry. Several examples of perovskite oxides are listed in Table 59.1, where it is clear that a large number of perovskite oxides have a rombohedral lattice. Additionally, in many compounds a large extent of oxygen or cation deficiency has been observed. Due to the large lattice energy, many compounds are classified as perovskite oxides in spite of the large cation and/or oxygen deficiencies. There are various types of distortions in the perovskite structure that are strongly related to their properties, in particular their ferromagnetic or ferroelectricity.

In order to understand the deviations from the ideal cubic structure, these ABO_3 oxides are first regarded as purely ionic crystals. In the case of the ideal structure, the following relationship between the radii of the A, B, and O^{2-} ions holds true

$$r_A + r_O = \sqrt{2(r_B + r_O)}\,.$$

Therefore, the deviation from the ideal structure in perovskite oxides can be expressed through the following so-called *tolerance factor t*

$$t = \frac{(r_A + r_O)}{\sqrt{2(r_B + r_O)}}$$

Table 59.1 Typical peroskite compound

Compound	Lattice parameter (Å)		
	a	b	c
Cubic structure			
$KTaO_3$	3.989		
$NaTaO_3$	3.929		
$NaNbO_3$	3.949		
$BaMnO_3$	4.040		
$BaZrO_3$	4.193		
$SrTiO_3$	3.904		
$KMnF_3$	4.189		
$KFeF_3$	4.121		
Tetragonal structure			
$BiAlO_3$	7.61		7.94
$PbSnO_3$	7.86		8.13
$BaTiO_3$	3.994		4.038
$PdTiO_3$	3.899		4.153
$TlMnCl_3$	5.02		5.04
$LaAlO_3$ type			
$LaAlO_3$	5.357	$\alpha = 60°06'$	
$LaNiO_3$	5.461	$\alpha = 60°05'$	
$BiFeO_3$	5.632	$\alpha = 60°06'$	
$KNbO_3$	4.016	$\alpha = 60°06'$	
$GdFeO_3$ type			
$GdFeO_3$	5.346	5.616	7.668
$YFeO_3$	5.283	5.592	7.603
$NdGaO_3$	5.426	5.502	7.706
$CaTiO_3$	5.381	5.443	7.645
$NaMgF_3$	5.363	5.503	7.676

In perovskite-type compounds, the value of t lies between approximately 0.80 and 1.10. It is noted that the oxides with the lower t values crystallize in the ilmenite structure, which is a polymorph of the perovskite structure. It seems superfluous to say that for the ideal cubic structure, the value of t is close to 1 or at least higher than 0.89. Figure 59.2 shows the crystal groups for $A^{2+}B^{4+}O_3$ and $A^{3+}B^{3+}O_3$ combinations, which are related to deviation from the ideal structure [59.3]. As the value of t decreases, the structure of the unit lattice is shifted from cubic to triclinic due to the increased distortions. Figure 59.3 shows chemical elements that can be accommodated within the perovskite structure. It is evident that almost all elements except for noble gases can occupy either A or B lattice positions in the perovskite structure, including dopants. The stability and the crystal group is mainly determined by the ratio of the ionic radii of the A and B cations. Indeed, the structure is dependent not only on the size but also on the nature of the A and B atoms. For example, $AMnO_3$ compounds crystallize in the perovskite structure when A cation is La or Ce–Dy, whereas a new hexagonal structure with 5- and 7-coordination of Mn and A respectively, is formed when A = Ho–Lu or Y if A = La

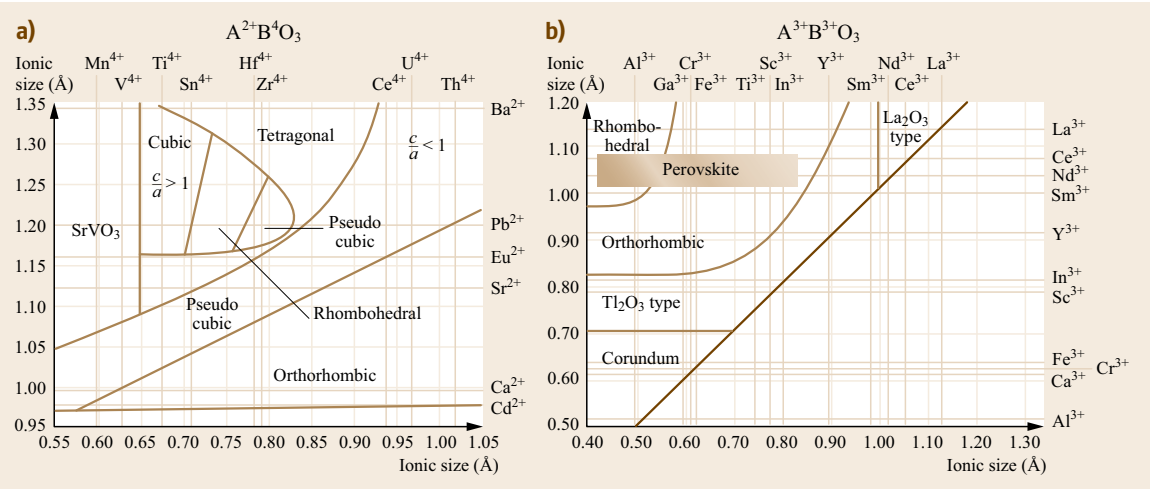

Fig. 59.2a,b The effect of ionic size of A- and B-site cations on the observed distortions of the perovskite structure; **(a)** $A^{2+}B^{4+}O_3$ case **(b)** $A^{3+}B^{3+}O_3$ case

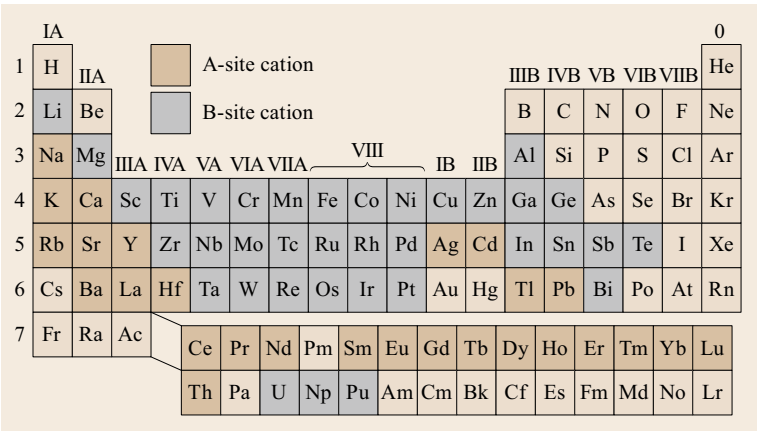

Fig. 59.3 Chemical elements that can occupy cation sites in the perovskite structure

or Ce–Dy [59.4]. Here, the attention should be paid to the nature of the B atom, where the nature of the bond is highly covalent, and therefore the coordination number is lower than 6. The typical example of this type structure is $BaGeO_3$. In spite of the t value close to $t = 1$, i. e., ideal ionic size combination, $BaGeO_3$ crystallizes not in the perovskite structure but in the silicate-related one. This is attributable to the fact that the preferred coordination number of Ge is 4. On the other hand, due to the progress in high pressure technology, the synthesis of new Ge-based perovskite oxides has been reported [59.5]. Since the coordination number of Ge increases with the pressure, the perovskite structures with higher coordination numbers are preferred, and a typical example of this is $CaGeO_3$. Another group of interesting perovskite compounds is the oxynitrides, i. e., $LaWO_{3-x}N_x$, $LaTaO_2N$, etc. Therefore, the value of t, which is determined by the ionic size, is an important index for the stability of perovskite structures; however, the contribution of the chemical nature, such as coordinating number of the constituent elements, needs to be taken into account.

The formation of superstructures in the perovskites is discussed next. If a B-site cation is progressively replaced by a dopant, a large difference in ionic radii tends to lead to the formation of the superstructures rather than random arrangements of the two kinds of ions. The typical case of this is Ba_2CaWO_6, which is regarded as $Ba_2(CaW)O_6$. Similarly, in the compounds with the general formula $Ba_3MTa_2O_9$, there is random distribution of M and Ta ions in the octahedral positions when M is Fe, Co, Ni, Zn, or Ca, whereas the formation of the superstructure with a hexagonal lattice is observed in $Ba_3SrTa_2O_9$. Another interesting type of superstructure observed in the perovskite is the ordering of cation vacancies located on A-sites: for example

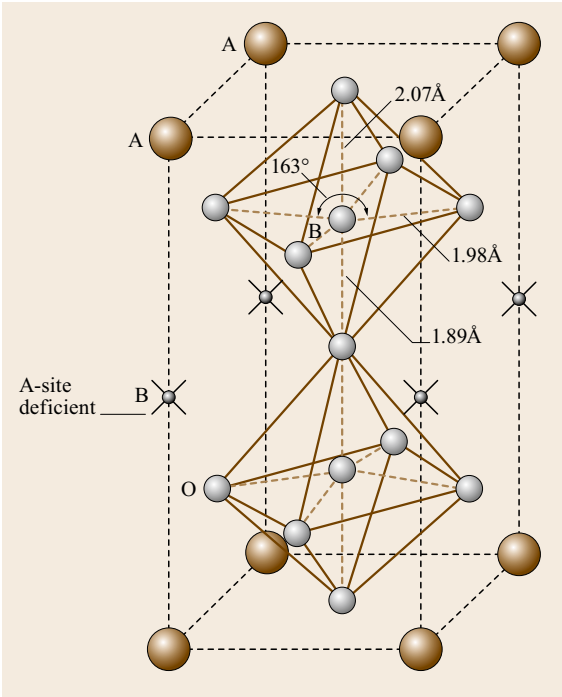

Fig. 59.4 Structure of $LaNb_3O_9$, an A-site-deficient perovskite oxide

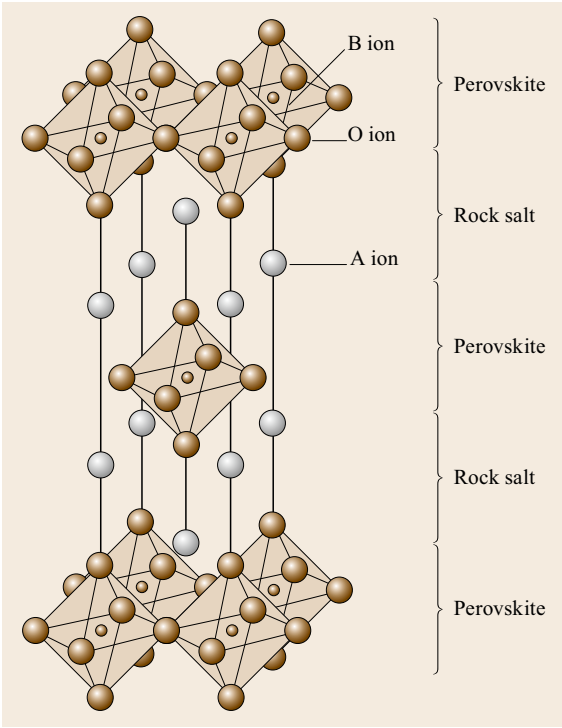

Fig. 59.5 K_2NiF_4 structure, a perovskite-related structure

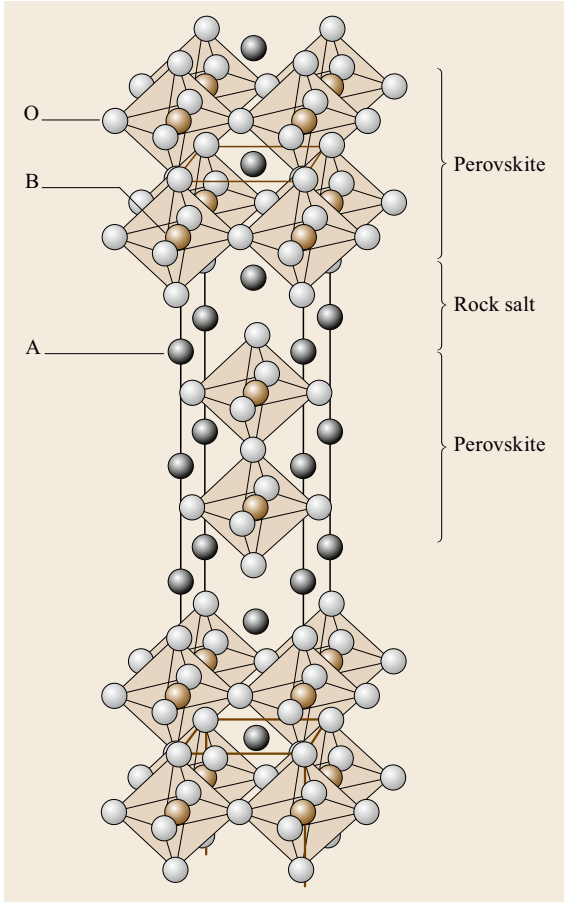

Fig. 59.6 Ruddelsden–Popper structure, another type of perovskite-related structure

MNb_3O_9 (M = La, Ce, Pr, Nb) and MTa_3O_9 (M = La, Ce, Pr, Nd, Sm, Gd, Dy, Ho, Y, Er). In these oxides, there is an octahedral framework of the ReO_3 type with incomplete occupancy of the 12-fold coordinated A-sites. Figure 59.4 shows the structure of $LaNb_3O_9$. The B-sites of the perovskite structure are occupied by Nb ion and two-thirds of the A-sites remain vacant.

Other typical polymorphs of the perovskite structure are Brownmillalite ($A_2B_2O_5$) and K_2NiF_4 structures. Brownmillalite ($A_2B_2O_5$) is an oxygen-deficient type of perovskite where oxygen vacancy is ordered. The unit cell contains BO_6 and BO_4 units in an ordered arrangement. Due to the oxygen deficiency, the coordination number of A-site cations decreases to 8. The lattice parameter of the Brownmillalite structure relates to cubic lattice parameter (a_p) of the ideal perovskite as $a = b = \sqrt{2}a_p$, $c = 4a_p$. Cu-based oxides or Ni-based oxides tend to adopt these oxygen-deficient structures because of the large amount of oxygen defects.

A combination of ordered B-sites and oxygen defects is seen in K_2NiF_4 structures, which are well-known as they show superconducting properties. The K_2NiF_4 structures consist of two units; a $KNiF_3$ perovskite unit and a KF rock salt unit (Fig. 59.5), which are connected in series along the *c* axis. Since the rock salt structure is embedded into the *c* axis direction, the K_2NiF_4 compound shows strong two-dimensional properties. Based on the intergrowth of the different number of $KNiF_3$ and KF units, there are many structures called Ruddelsden–Popper compounds with the general formula $(ABO_3)_nAO$ (Fig. 59.6), i. e., $Sr_3Ti_2O_7$ ($n = 2$), $Sr_4Ti_3O_{10}$ ($n = 3$). It is interesting to compare the isostructural Sr_2TiO_4 or Ca_2MnO_4 with $SrTiO_3$ or $CaMnO_3$, which crystallize in the perovskite structures. Two different A cations forming the perovskite and the rock salt units are also possible, and $LaO \cdot nSrFeO_3$ is the typical example of this arrangement. Another interesting variant of these K_2NiF_4 structures is when two different anions occupy the two building blocks exclusively, i. e., $SrFeO_3 \cdot SrF$ or $KNbO_3 \cdot KF$. In any case, it is evident that perovskite oxides comprise a large family of oxides. As a result, a variety of crystal structures and properties is expected in these compounds. For further detailed discussion on the perovskite-related oxides, the reader is referred to references [59.5–8].

59.1 Typical Properties of Perovskite Oxides

Due to the variety of structures and chemical compositions, perovskite oxides exhibit a large variety of properties. The well-known properties of the perovskite oxides are ferroelectricity in $BaTiO_3$-based oxides and superconductivity in $Ba_2YCu_3O_7$ etc. In addition to these well-known properties, several perovskite oxides exhibit good electrical conductivity, which is close to those of metals, ionic conductivity as well as mixed ionic and electronic conductivity. Based on these variations in the electrical conducting property, perovskite oxides are chosen as the components for solid oxide fuel cells (SOFCs). It is also well known that several perovskite oxides exhibit high catalytic activity with respect to various reactions, in particular oxidation reactions [59.9]. Table 59.2 provides examples of the typical properties of perovskite oxides. In this section, several typical properties of the perovskite oxides, namely ferroelectricity, magnetism, superconductivity, and catalytic activity, are briefly overviewed.

59.1.1 Dielectric Properties

Ferroelectricity, piezoelectricity, electrostriction, and pyroelectricity are special properties inherent to dielectric materials, and are important properties of electroceramics. The most well-known property of perovskite oxides is ferroelectric behavior, where $BaTiO_3$, $PdZrO_3$, and their doped compounds are representative examples. The study of the ferroelectricity in $BaTiO_3$ has long history, and many detailed reviews have been published. Furthermore, since the ferroelectric behavior of $BaTiO_3$ has a strong relationship with the crystal structure, detailed studies of the crystal structure have been reported for $BaTiO_3$. $BaTiO_3$ undergoes mainly three phase transformations from, i. e., monoclinic to tetragonal and cubic as the temperature increases. Above 303 K, $BaTiO_3$ crystallizes in the cubic perovskite structure, which does not show ferroelectric behavior. The high dielectric constant observed in $BaTiO_3$ can be explained by the basis of the anisotropy of the crystal structure.

59.1.2 Electrical Conductivity and Superconductivity

One of the most well-known properties of perovskite oxides is superconductivity. In 1984, superconductivity was first reported by *Bednorz* and *Müller* in La–Ba–Cu–O perovskite oxide [59.10]. After their report, much attention has been paid to new types of high-temperature oxide superconductors, mainly Cu-based oxides. As a result, several superconducting oxides with different A-site cations have been discovered. However, the presence of Cu on the B-site is found to be essential

Table 59.2 Typical properties of perovskite oxides

Typical property	Typical compound
Ferromagnetism	$BaTiO_3$, $PdTiO_3$
Piezoelectricity	$Pb(Zr, Ti)O_3$, $(Bi, Na)TiO_3$
Electrical conductivity	ReO_3, $SrFeO_3$, $LaCoO_3$, $LaNiO_3$, $LaCrO_3$
Superconductivity	$La_{0.9}Sr_{0.1}CuO_3$, $YBa_2Cu_3O_7$, $HgBa_2Ca_2Cu_2O_8$
Ion conductivity	$La(Ca)AlO_3$, $CaTiO_3$, $La(Sr)Ga(Mg)O_3$, $BaZrO_3$, $SrZrO_3$, $BaCeO_3$
Magnetism	$LaMnO_3$, $LaFeO_3$, La_2NiMnO_6
Catalytic properties	$LaCoO_3$, $LaMnO_3$, $BaCuO_3$
Electrode materials	$La_{0.6}Sr_{0.4}CoO_3$, $La_{0.8}Ca_{0.2}MnO_3$

for superconductivity to occur. High-temperature oxide superconductors of the $YBa_2Cu_3O_7$ system [59.11] and the $Bi_2Sr_2Ca_2Cu_3O_{10}$ system [59.12] were reported in 1987 and 1988 respectively, and currently the critical temperature of the superconducting transition (T_c) has been further increased to 130−155 K in the $HgBa_2Ca_2Cu_3O_{8+\delta}$ system [59.13]. Since all high-temperature superconducting oxides are cuprites (Cu-based oxides), superconductivity is clearly related to the Cu–O layers. The critical temperature for superconductivity, T_c, is related to the number of Cu–O layers in the crystal structure:

1. Cu–O layer $T_c \approx 30\,K$
2. Cu–O layers $T_c \approx 90\,K$
3. Cu–O layers $T_c \approx 110\,K$
4. Cu–O layers $T_c \approx 120\,K$.

It is expected that further increase in the number of Cu–O layers may result in the higher T_c values. However, due to the low chemical stability, synthesis of five or more Cu–O layered compounds has not been successful so far. $YBa_2Cu_3O_7$ is one of the most important superconductor systems with high T_c, and detailed studies of its crystal structure have been performed. Also, the content of oxygen nonstoichiometry is an important factor for high T_c. When the value of d is smaller than 0.5, $YBa_2Cu_3O_7$ crystallizes in an orthorhombic structure, which is superconductive, while for $d > 0.5$, $YBa_2Cu_3O_7$ has a tetragonal structure, which does not exhibit superconductivity.

In addition to superconductivity, there are many perovskite oxides showing high electronic conductivity, which is close to those of metals like Cu. The typical examples of such perovskite oxides are $LaCoO_3$, $LaFeO_3$, and $LaMnO_3$, which are now commonly used as cathodes in SOFCs. These perovskite oxides show superior hole conductivity, which is as high as $\sigma = 100\,S/cm$ originated from excess oxygen [59.14, 15]. Doping of aliovalent cations on the A-site is also highly effective in enhancing the electrical conductivity due to the increased number of mobile charge carriers generated by the charge compensation.

59.1.3 Catalytic Activity

Because of the variety of component elements and the high chemical stability, perovskite oxides have also been extensively studied as catalysts for various reactions. Two types of research trends clearly emerged from the above reasons. The objective of the first one is the development of the oxidation catalysts or oxygen-activated catalysts as an alternative to catalysts containing precious metals. The second trend regards perovskite as a model for active sites. The stability of the perovskite structure allows preparation of compounds with unusual valence states of elements or a high extent of oxygen deficiency. It is also noted that the high catalytic activity of perovskite oxides is based partially on the high surface activity to oxygen reduction or oxygen activation due to the large number of oxygen vacancies presented.

Among the various catalytic reactions studied, the ones applicable to environmental catalysis (e.g., automobile exhaust gas cleaning catalysts) attract particular attention. Initially, it was reported that perovskite oxide consisting of Cu, Co, Mn or Fe exhibited superior activity to NO direct decomposition at higher temperature [59.16–18]. The direct NO decomposition reaction ($2NO = N_2 + O_2$) is one of the *dream reactions* in the catalysis field. In this reaction, the ease in the removal of surface oxygen as a product of the reaction plays an important role, and due to the facility of oxygen deficiency present, perovskite oxides are active with respect to this reaction at high temperatures. It is pointed out that the doping is highly effective in enhancing NO decomposition activity. Under an oxygen enriched atmosphere (up to 5%), a relatively high NO decomposition activity was reported for $Ba(La)Mn(Mg)O_3$ perovskite [59.19].

Recently, another interesting application of perovskite oxides as an automobile catalyst has been reported, namely the so-called *intelligent catalyst* [59.20]. Up to now, three-way Pd–Rh–Pt catalysts have been widely used for the purpose of removal of NO, CO, and uncombusted hydrocarbons. In order to decrease the amount of precious metals, the catalyst consisting of fine particles with high surface-to-volume ratio is required. However, these fine particles are not stable under the operating conditions and easily sinter, resulting in the deactivation of the catalyst. In order to maintain a high dispersion state, the redox property of perovskite oxides has been proposed, i. e., under oxidation conditions, palladium is oxidized and exists as $LaFe_{0.57}Co_{0.38}Pd_{0.05}O_3$, and under reducing conditions, palladium is deposited as fine metallic particles with a radius of 1−3 nm. This cycling of the catalyst through oxidizing and reducing conditions results in the partial substitution of Pd into, and deposits from, the perovskite framework, thus maintaining a high dispersion state of Pd. This was found to be highly effective in improving the long-term stability of Pd during removal of NO_x, CO, and hydrocarbons from the exhaust gas. The high dispersion state of Pd can be recovered by exposing the catalyst to oxidation and reduction environments. As a result this catalyst is called an *intelligent* catalyst. This unique property also originates from the high stability of the perovskite crystal structure and

charge compensation is automatically done by redox couples of another cation in the lattice.

Another interesting application of perovskite oxide is as a photocatalyst for water splitting. Among the catalysts for water splitting into H_2 and O_2, it is reported that Ta- or Nb-based perovskite oxide shows high activity by using ultraviolet light. This will be introduced in detail in the next section.

59.2 Photocatalytic Activity

Photo-excited electrons and holes can be used for splitting water into H_2 and O_2 and this reaction is attracting much interest for converting solar energy to hydrogen. Various inorganic catalysts have been studied as photocatalysts for water splitting, in particular, Pt/TiO_2 is a well-known inorganic semiconductor for photocatalysis. Among the various catalysts reported, in this section, photocatalysts based on perovskite structure are briefly introduced. The Ta-based oxide is generally active in the photocatalytic water splitting reaction [59.22]. In particular, the Ta-based perovskite oxide, $ATaO_3$ (A = alkaline cation) shows high activity in water splitting [59.23]. The activity is strongly affected by the A cation and this is because crystal structure is related to the electronic configuration of the oxide. The bond angles of Ta–O–Ta are 143° ($LiTaO_3$), 163° ($NaTaO_3$), and 180° ($KTaO_3$). As the bond angle is close to 180°, migration of excited energy in the crystal occurs more easily and the band gap becomes smaller. Therefore, the order of the delocalization of excited energy is $LiTaO_3 < NaTaO_3 < KTaO_3$, while that of the band gap is reversed in the order as shown in Fig. 59.7. Table 59.3 shows photocatalytic activities for water splitting into H_2 and O_2 in pure water on alkali tantalite photocatalysts with and without NiO cocatalysts. $NaTaO_3$ photocatalysts showed the highest photocatalytic activity when NiO cocatalysts were loaded. In this case, excess sodium in the starting material was indispensable for showing the high activity [59.23]. The conduction band level of the $NaTaO_3$ photocatalyst was higher than that of NiO (-0.96 eV) as shown in Fig. 59.7 [59.23]. Moreover, the excited energy was delocalized in the $NaTaO_3$ crystal. Therefore, the photogenerated electrons in the conduction band of the $NaTaO_3$ photocatalyst were able to transfer to the conduction band of the NiO cocatalyst of an active site for H_2 evolution, resulting in the enhancement of the charge separation. Therefore, NiO loading was effective for the $NaTaO_3$ photocatalyst even without special pretreatment.

It is reported that the activity of photocatalytic water splitting is also much increased by additives. For

[c] Estimated from the onset of absorption

example, Table 59.4 shows band gaps, surface areas and photocatalytic activities for water splitting into H_2 and O_2 in pure water on various lanthanide-doped $NaTaO_3$ (denoted as $NaTaO_3$:Ln hereafter) with NiO cocatalysts [59.21]. $NaTaO_3$:Ln powders had larger surface areas than that of nondoped $NaTaO_3$. Band gaps of $NaTaO_3$:Ln are slightly higher than that of nondoped $NaTaO_3$. The activity of the NiO/$NaTaO_3$ photocatalyst is remarkably improved by doping of Ln, except for Eu and Yb. In particular, obviously, NiO/$NaTaO_3$:La is the most active: H_2 and O_2 evolved steadily and efficiently as shown in Fig. 59.8. The optimized NiO(0.2 wt%)/$NaTaO_3$:La(1.5%) photocatalyst evolves H_2 and O_2 with the rates of 14.6 and 7.2 m mol h^{-1} respectively. The apparent quantum yield is approximately 50% at 270 nm. Thus, it is demonstrated that the photocatalytic water splitting is able to proceed efficiently using a photocatalyst powder system.

On the other hand, effects of substitution of Ta-sites of $KTaO_3$ are also reported [59.24]. Not only dopants at A-sites, but also those at B-sites are strongly influenced by photocatalytic activity. Since Pyrex glass was used for the reactor, the catalytic activity is different from those in Table 59.4 because of negligible ultraviolet light, and it is reported that $KTaO_3$ is more active than that of $NaTaO_3$, which corresponds with the most narrow band gap among $ATaO_3$. The effects of substitution of various elements on mainly Ta-sites in $KTaO_3$ on photocatalytic activity to water splitting are shown in Table 59.5. Obviously, H_2 and O_2 formation rates are

significantly increased by doping Ta-sites, in particular, the highest H_2 formation rate can be achieved by substituting Ta partially with Zr or HF. Since positive effects are tended to be obtained by doping tetravalent cations, it seems that a decrease in carrier density is effective for increasing photocatalytic activity for water splitting.

In addition to Ta-based perovskite, another important oxide based on the perovskite structure is $SrTiO_3$, which has narrower band gap than that of Ta-based perovskite oxide [59.25]. Since the valence band is not low enough for the formation of O_2, complete decomposition of water can be achieved by combining with oxygen-formation catalysts such as $BiVO_4$ with $Pt/SrTiO_3$ doped with Rh [59.22]. Among the various catalysts reported, it is obvious that perovskite oxide is an important family for photocatalysts from a unique semiconducting property viewpoint, and it is expected that research is expanded to the oxygen-deficient-type perovskite oxides such as K_2NiF_4-type structures.

59.3 Application for Solid Oxide Fuel Cells (SOFCs)

An important application area of inorganic perovskite oxide is solid oxide fuel cells and air electrodes of metal-air batteries because of high catalytic activity to oxygen reduction and superior mixed conductivity achieved simultaneously. In this section, the application of perovskite oxide for SOFCs is briefly mentioned. Further details are available in the another book [59.26].

Table 59.6 summarizes the important applications of perovskite oxides for solid oxide fuel cell technology. As shown in Table 59.6, $LaCoO_3$ or $LaMnO_3$ are promising candidates for SOFC cathodes and $LaGaO_3$-based oxides for the electrolyte. In addition, recently there have been several reports on the application of Cr-based perovskites as anodes. Therefore, the concept of SOFCs based entirely on perovskite components, *all-perovskite SOFCs*, is also proposed and some preliminary results have been reported [59.27]. In contrast to the SOFCs using oxide-ion-conducting electrolytes, the development of SOFCs using high-temperature proton-conducting electrolytes is slightly delayed, particularly when compared with development of polymer electrolyte-type fuel cells. However, the Toyota group has quite successfully demonstrated a high-power SOFC using a $BaCeO_3$-based electrolyte film on Pd foil [59.28]. Their data suggest that the proton-conducting perovskite oxides might also be an important component in real SOFCs in the near future.

59.3.1 Cathode

The principal requirement for a cathode of a SOFC is to electrochemically reduce oxygen molecules into oxide ions, and there are several requirements for oxide applied for cathodes of SOFCs i. e., catalytic activity, thermodynamic stability and compatibility in mechanical and chemical properties. Perovskite oxide is the most suitable material satisfying these requirements for cathodes. Figure 59.9 shows the reaction route considered for cathodes of SOFCs. Oxygen reduction proceeds on the electrode surface or at the electrode/electrolyte/gas-phase interface; the so-called triple phase boundary (TPB). The electrode material catalyzes the oxygen molecules to be dissociated into atoms, charged and incorporated into the electrolyte (Fig. 59.9). For the cathode material, the electrocatalytic activity is an important parameter to be considered. The surface reaction rate constant in oxygen isotope exchange is a good measure for the catalytic activity. *Kilner* et al. [59.29] compared various oxides in isotope diffusion coefficient and found a positive correlation between those parameters. A highly mixed electronic and ionic conductor may be a promising candidate in terms of the electrode performance. At the early stage of SOFC development, $La_{0.8}Ca_{0.2}MnO_3$ or $La_{0.6}Sr_{0.4}MnO_3$ were widely used, however, because of low oxide ion conductivity in Mn-based perovskite oxide, the reaction is limited to a three-phase boundary resulting in large cathodic overpotential. Recently, several oxides have been reported to show extremely high surface exchange rate for oxygen activation. *Baumann* et al. [59.30] compared several Co- and Fe-based perovskites in a controlled shape and found $Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_3$ shows 100 times smaller electrochemical resistance than that of $La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_3$ (LSCF) which is

often used for the intermediate-temperature SOFC cathode. One reason for such high cathodic activity is assigned to the high mixed conductivity and large reaction area available, i. e., the two phase boundary (route 2 in Fig. 59.9) is also contributed to the oxygen dissociation reaction. Another active composition to the cathode is $Sm_{0.5}Sr_{0.5}CoO_3$, which also has high oxide ion conductivity [59.31]. However, the most popular composition used for SOFC is $La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_3$ (LSCF) due to surface activity and stability. Recently, research has shifted to the more oxygen-deficient perovskites such as double (A_2BaO_6), Rudrusden–Poppered ($A_xB_yO_z$), or K_2NiF_4 structure. *Sase* et al. [59.32] reported that existence of a $(La, Sr)_2CoO_4$ phase on the $(La, Sr)CoO_3$ electrode enhances the oxygen exchange reaction rate. The double perovskite phase of $PrBaCo_2O_6$ is also reported as an active phase for oxygen dissociation [59.33] and so not only perovskite but also perovskite-related phases, in particular the oxygen-deficient perovskite phase, is now attracting as much attention as the active cathode catalyst for intermediate temperature operations.

On the other hand, one of another important issues for SOFC development is long-term stability and decrease in cathode performance is pointed out. There are several reasons decreasing cathodic performance is reported, i. e., chemical poisoning with Cr, S and B and sintering, and phase separation. Among them, surface segregation with Sr on the perovskite cathode has been suggested recently [59.34]. Figure 59.10 shows the change in surface composition of LSCF by low-energy ion scattering techniques, which are sensitive to the elements in the outermost surface layer. Obviously, the surface of LSCF is immediately enriched with Sr and it is considered that an Sr-enriched surface is highly reactive with Cr or S, resulting in the decrease in surface activity. Apparently, the surface composition of perovskite is slightly different from that of bulk, however, reactivity for oxygen dissociation is more strongly affected by B-site cations. Therefore, there is still some unclear points on parameters determining the activity for oxygen dissociation and this will be discussed more intensively in the future.

59.3.2 Anode

For the anode of SOFC, metal-oxide ion-conducting oxide composites named *cermet* have been widely used, in particular, Ni-Y_2O_3-stabilized ZrO_2 ($Y_{0.16}Zr_{0.84}O_2$, YSZ) cermet has been widely used. However, Ni is well known to be deactivated easily by aggregation and coarsening. In addition, re-oxidation of Ni is also occurs easily, resulting in the permanent failure of the cell. Therefore, recently, the application of oxide for the anode has also been proposed and among the proposed oxide anodes, perovskite oxides such as $SrTiO_3$ doped with La, Nd, etc. [59.35] or $La_{0.75}Sr_{0.25}Mn_{0.5}Cr_{0.5}O_3$ (LSCrM) [59.36] show interesting performance and are promising as oxide anodes.

In particular, improved performance has been obtained with complex perovskites based upon Cr and Mn at the B-sites forming compositions $(La,Sr)Cr_{1-x}M_xO_{3-\delta}$. Tao and Irvine have focused upon doped lanthanum chromite doped with Sr and Mn up to 20% dopant on the B-site, usually 5 or

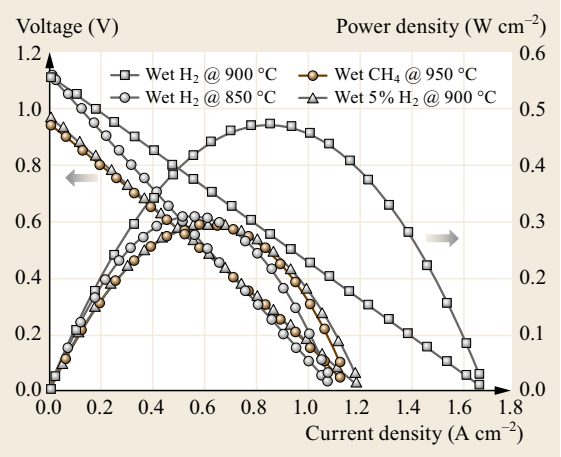

Fig. 59.11 Power generation property of the cell using $La_{0.75}Sr_{0.25}Cr_{0.5}Mn_{0.5}O_3$ for the anode

10%. $(La_{0.75}Sr_{0.25})Cr_{0.5}Mn_{0.5}O_3$ (LSCrM) exhibits comparable electrochemical performance to Ni/YSZ cermets [59.27, 36]. Figure 59.11 shows the I–V, I–P curves of the cell using LSCrM for the anode at 1173 and 1123 K. Apparently, the open circuit potential (OCV) is achieved to a theoretical level and reasonable power density of 0.4 W/cm^2 was achieved at 1173 K. The electrode polarization resistance approaches 0.2 Ω cm^2 at 1173 K in 97%H_2/3%H_2O. Good performance is achieved for methane oxidation without using excess steam. The anode is stable in both fuel and air conditions and shows stable electrode performance in methane. Thus both redox stability and operation in low steam hydrocarbons have been demonstrated. Catalytic studies of LSCM demonstrate that it is primarily a direct-oxidation catalyst for methane oxidation as opposed to a reforming catalyst, with the redox chemistry involving the Mn–O–Mn bonds. Although oxygen ion mobility is low in the oxidized state, the diffusion coefficient for oxide ions in reduced LSCrM is comparable to YSZ.

Another important double perovskite is $Sr_2MgMoO_{6-\delta}$, which has recently been shown to offer good performance, with power densities of 0.84 W/cm^2 in H_2 and 0.44 W/cm^2 in CH_4 at 1073 K, and good sulfur tolerance [59.37]. The molybdenum-containing double perovskite was initially prepared at 1473 K in flowing 5% H_2 and then deposited on top of a lanthanum ceria buffer layer before testing. Although there is some decomposition recognized, it is also reported that $La_{0.5}Sr_{0.5}MnO_3$ is active to not only the cathode but also the anode. The maximum power density of 1 W/cm^2 was reported at 1273 K when $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_3$ (LSGM, 0.5 mm thickness) is used for the electrolyte [59.38].

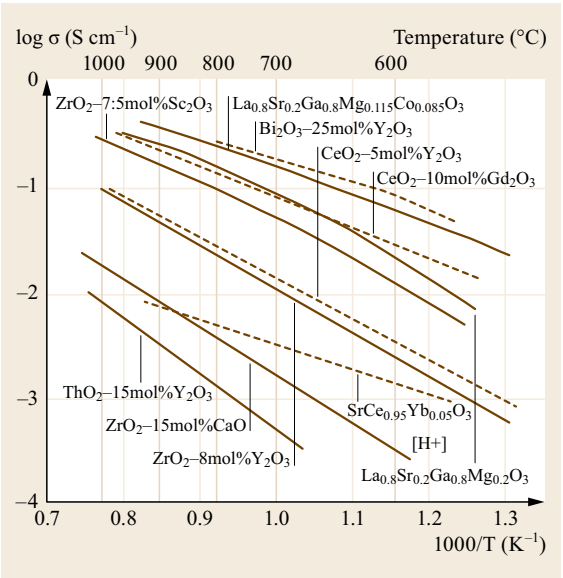

Fig. 59.12 Comparison of the oxide ion conductivity of LSGM with typical fluorite oxide

59.3.3 Electrolyte

An oxide ion conductor is widely used for electrolytes of SOFCs. In the case of SOFCs, solid proton conducting ceramics such as $BaZrO_3$ or $SrCeO_3$ doped with various rare earth cations to B-sites have been also studied [59.39], in particular for low-temperature SOFCs; however, considering the chemical stability and power density achieved, SOFCs using oxide ion conducting electrolytes are more promising. At present, almost all SOFCs under development for commercialization use YSZ for the electrolyte, with only a few exceptions. However, for increasing power density, there is still strong demand for replacing YSZ with an alternative electrolyte showing higher oxide ion conductivity. CeO_2 with fluorite structure and $LaGaO_3$ with perovskite structure are showing promise as electrolytes for this purpose. In particular, $LaGaO_3$ doped with Sr and Mg is the first pure oxide ion conductor with a perovskite structure [59.40]. Figure 59.12 shows a comparison of the oxide ion conductivity of LSGM with typical fluorite oxide. Apparently, oxide ion conductivity in LSGM is much higher than that of YSZ and almost comparable with Gd-doped CeO_2. In the case of CeO_2, partial electron conductivity appears in reducing atmospheres, however, LSGM exhibits the pure oxide ion conductivity across a wide p_{O_2} range, i. e., from pure oxygen to pure hydrogen.

The application of LSGM for electrolytes of SOFCs is also studied and the power generation property of the cell using LSGM is shown in Fig. 59.13. Since

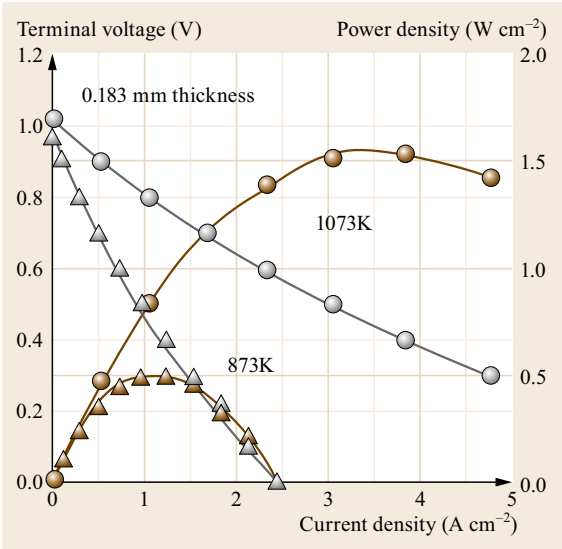

Fig. 59.13 Power generation property of the cell using LSGM with 0.182 mm thickness

transport number of the oxide ion in LSGM is close to unity from pure O_2 to pure H_2, the open circuit potential is 1.15 V, which is almost the same as that of theoretical open circuit potential. In addition, in spite of the thick electrolyte (0.5 mm), high maximum power density is achieved compared with that of the cell using YSZ. Therefore, it is expected that the operating temperature of SOFCs could be decreased by using LSGM for the electrolytes. Making thin films of LSGM is another important subject, however, it is reported that LSGM has some reactivity with Ni in the anode substrate and so the power density is not as high as expected from the film thickness and ionic conductivity. Therefore, for LSGM film cells, preventing reaction with Ni in the anode substrate is an important issue. *Huang* et al. reported that La-doped CeO_2 is effective for preventing Ni diffusion [59.41], however, electrical conductivity of La-doped CeO_2 is insufficient. Recently, *Hong* et al. reported that Ti- and La-codoped CeO_2 is promising as a buffer layer for preventing Ni diffusion with reasonable electrical conductivity and sintering properties [59.42]. In any case, LSGM perovskite oxide has a high potential as a fast oxide ion conductor for intermediate-temperature SOFCs and as an alternative to YSZ. Another interesting oxide ion conductor is $Ba_2In_2O_5$, which is a Brownmillerite structure and although oxide ion conductivity is slightly lower than that of YSZ, this new family of oxide ion conductors is also considered as a promising electrolyte for SOFCs [59.43].

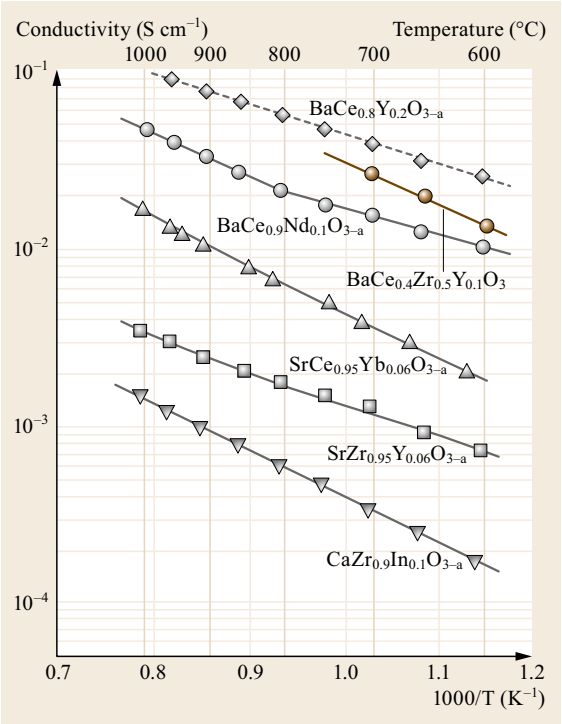

Fig. 59.14 Comparison of proton conductivity in perovskite oxide. (After [59.44].) Plots for $BaCe_{0.4}Zr_{0.5}Y_{0.1}O_3$ were added from [59.45]

Another important family for electrolytes of SOFC is oxide proton conductor and perovskite oxide of $ACeO_3$ or $BZrO_3$(A = Ba and Sr), which shows fast proton conductivity. Protons in perovskite oxide were formed by the following equation and the interstitial protons are mobile at the interstitial position of the perovskite lattice. Figure 59.14 shows the comparison of proton conductivity in perovskite oxide [59.44]. $BaCeO_3$ doped with Y shows reasonably high proton conductivity at low temperature. It is reported that extremely large power density is achieved by using $BaCeO_3$ doped with a Y thin film for the electrolyte of SOFC; however, these proton-conducting perovskites show high reactivity with CO_2 resulting in decomposition by formation of carbonate. Therefore, an increase in chemical stability is required for these oxide perovskite. Recently, there has been high interest on $ACe_{1-x}Zr_xO_3$-based oxides doped with Y from chemical stability; in particular it is reported that $BaCe_{0.4}Zr_{0.5}Y_{0.1}O_3$ shows reasonably high proton conductivity and reasonable chemical stability to CO_2 and hydrolysis with water [59.45].

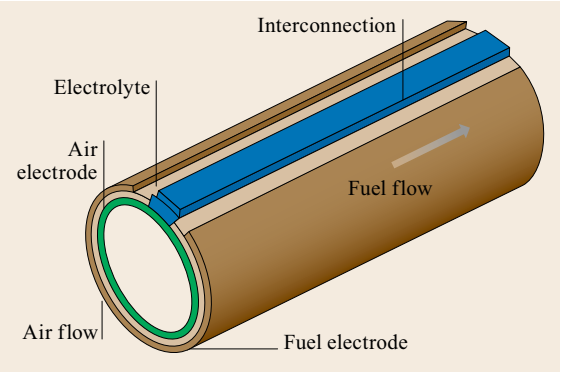

Fig. 59.15 Schematic view of the SOFC stack

59.3.4 Interconnector

The interconnector is an important component for stacking SOFCs and requires high stability in reducing and oxidizing atmospheres. The interconnector is used for connecting the SOFC single cell as shown in Fig. 59.15 and so high electrical conductivity and no oxide ion conductivity are also required for the high performance of the SOFC stack. Perovskite oxides of $LaCrO_3$ have been also widely used for interconnectors. Although $LaCrO_3$ is stable under reducing and oxidizing atmospheres, the electrical conductivity is still insufficient and also sintering is rather difficult. Therefore, doping Ca^{2+} for La-site in $LaCrO_3$ is generally performed for increasing conductivity as well as sintering properties.

Figure 59.16 shows electronic conductivity of doped $LaCrO_3$ as a function of temperature [59.46, 47]. The electronic conductivity increases with increasing temperature, suggesting the semiconductor temperature dependence. An increasing of the Ca concentration in $La_{1-x}Ca_xCrO_{3-\delta}$ enhanced the electronic conductivity due to the increase of Cr^{4+} concentration. There are some deviations of the electrical conductivity among the examined alkaline earth elements: Ca-doped $LaCrO_3$ shows larger electrical conductivity than Sr-doped $LaCrO_3$. This difference was reported to be due to the difference of lattice distortion and phase stability. The activation energy for conductivity was 0.12–0.14 eV and the mobility was $0.066–0.075\,cm^2/(Vs)$ at 1173–1323 K.

The electronic conductivity decreases with a reduction of oxygen partial pressure because of the decrease of Cr^{4+} concentration in a reducing atmosphere. The

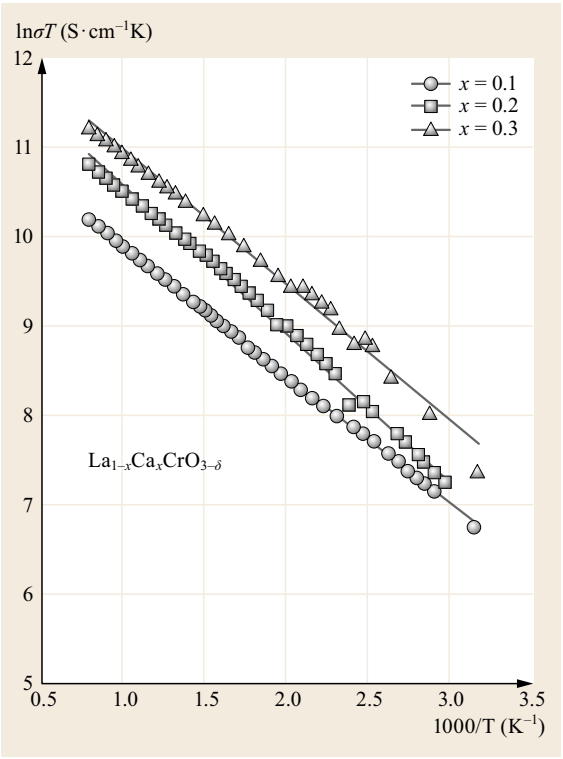

Fig. 59.16 Electrical conductivity of $La_{1-x}Ca_xCrO_{3-\delta}$ ($x = 0.1–0.3$) in air as a function of inverse temperature. (After [59.47])

electrical conductivity decreases with a reduction of oxygen partial pressures. The electrical conductivity is proportional to $p_{O_2}^{1/4}$, which is consistent with the defect chemistry of $La_{1-x}Ca_xCrO_{3-\delta}$ [59.47]. A doping of the B-site has been also considered by several authors [59.48]. A typical dopant cation is Mg^{2+}, replaced into Cr^{3+} sites. This substitution also increases the concentration of Cr^{4+}, and eventually increases the electrical conduction. Because of low sintering property, $SrTiO_3$ doped with La for Sr sites or Nd for Ti sites is also studied as an interconnector. Perovskite oxide is also important for interconnectors of SOFCs.

In summary, perovskite oxide is widely used for current SOFCs and becomes important compounds for SOFC components. Therefore, the all-perovskite concept is also proposed for SOFC and the device consisting of materials with the same structure is highly interesting.

59.4 Oxygen Separating Membrane

Perovskite oxide shows high electronic and oxide ionic conductivity and these conductors are called mixed conductors. Since charge compensation by ion transport can be automatically achieved with electronic conductivity in mixed conductors, so ions can be transported in mixed conductors without outside circuits. Therefore, an important application of such mixed conductors is as a separation membrane for oxygen from air. The oxygen permeation rate is shown as the following equation if the bulk diffusion is a rate-limiting step

$$J_{O_2} = \frac{RT\sigma_{el}\sigma_{ion}}{16F^2(\sigma_{el}+\sigma_{ion})t}\ln\frac{p_h}{p_l} \qquad (59.1)$$

Here, J_{O_2}; oxygen flux, σ_{el}; electron conductivity, σ_{ion}; oxide ion conductivity, F; Faraday constant, R; gas constant, t; membrane thickness, T; temperature and p_h, p_l means high and low oxygen partial pressure respectively.

From (59.1), the oxygen permeation rate is limited by bulk diffusivity of oxygen. Figure 59.17 shows the diffusivity of oxide ions in several perovskite oxides considered for oxygen permeation membranes [59.49]. Apparently, Fe- or Co-based perovskite oxides show fast oxide ion conductivity and so large oxygen permeation rate is expected on these perovskite oxides. In fact, a large oxygen permeation rate of 1.05 ml/(cm^2 min) at 1173 K is reported for $Ba_{0.5}Sr_{0.5}Fe_{0.8}Co_{0.2}O_3$ (BSCF) (2 mm thickness) [59.50]. According to (59.1), the oxygen permeation rate is determined by the diffusivity of oxide ions and the thickness of the membrane when the oxygen partial pressure differential across the membrane is the same. Therefore, the oxygen permeation rate should be increased with decreasing membrane thickness; however, it is reported that the oxygen permeation rate is dependent on membrane thickness when thickness is large, but with decreasing thickness, the oxygen permeation rate becomes independent of oxygen permeation rate because of the limitation by surface reactions of oxygen dissociation. To achieve the large oxygen permeation rate, not only high diffusivity of oxide ion in bulk but also high surface activity to oxygen dissociation is required.

Recently, perovskite-related oxides are also attracting much interest as mixed conductors, and applied use for oxygen permeation membranes. Among the perovskite-related oxides, there is strong interest for the K_2NiF_4-type oxide because of the large amount of oxygen deficiency. As explained in Figure 59.5, K_2NiF_4 oxides consist of a series of connected perovskite and rock salt blocks, and a large free volume exists in the rock salt block. Therefore, interstitial oxygen can be easily introduced into the rock salt block. For the K_2NiF_4 oxides, the oxide ion permeation property in La_2NiO_4-based oxide is now studied in detail and it is reported that doping Cu and Ga is effective for increasing oxygen permeation rate and $Pr_2Ni_{0.71}Cu_{0.24}Ga_{0.05}O_3$ (denoted as PNCG) is the optimized composition for oxygen permeation and permeation rate of approximately 3 cc/(min cm^2) was reported on PNCG with 0.5 mm thickness from air to He [59.51]. The oxygen transport route is also studied by neutron diffraction analysis and as shown in Fig. 59.18, oxide ion transports through interstitial positions in the rock salt block is clearly demonstrated. Therefore, in this PNCG, oxide ions are mainly transported through rock salt but not in the perovskite block. On the other hand, PNCG shows high hole conduction and holes are mainly transported in the perovskite block; and so in PNCG, it is interesting that two different routes for oxide ion and hole conduction are expected [59.52].

The most interesting use of mixed conductors is to combine the catalytic reaction and the so-called membrane reactor system; and several catalytic reactions such as NO_x decomposition and partial oxidation of alkanes are reported by using mixed conductors for removing the reactant from or into reaction systems. To permeate oxygen through mixed conductor membranes, a gradient in oxygen partial pressure is required as a driving force for oxygen transport; however, in membrane reactor system, differences in oxygen partial pres-

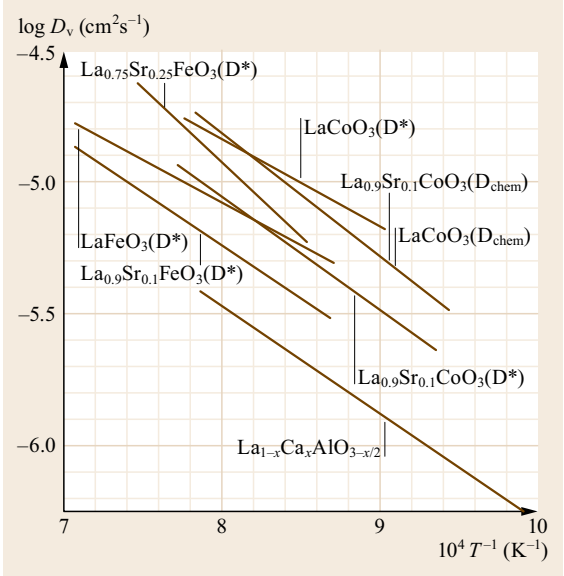

Fig. 59.17 Diffusivity of oxide ion in several perovskite oxides considered for an oxygen permeation membrane. (After [59.49])

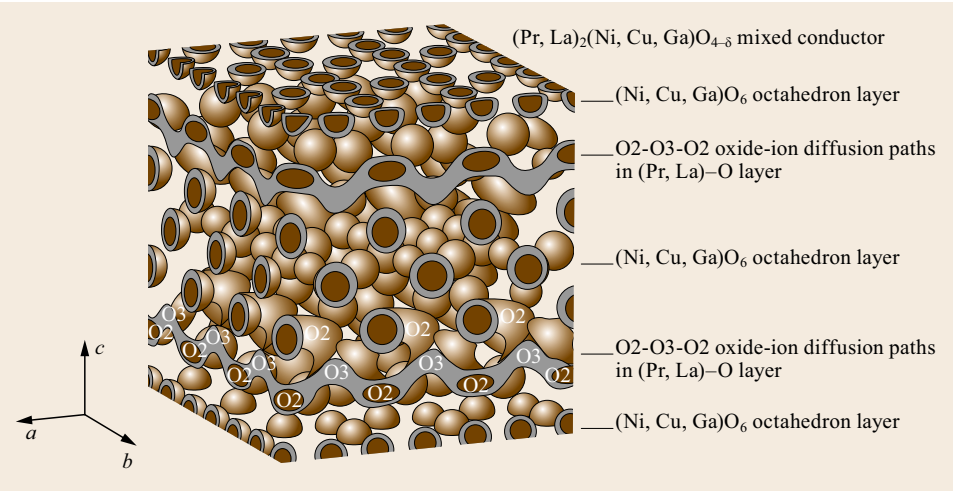

Fig. 59.18 Oxygen transport route in $Pr_2Ni_{0.81}Cu_{0.24}Ga_{0.05}O_4$ estimated by neutron diffraction analysis. (After [59.52])

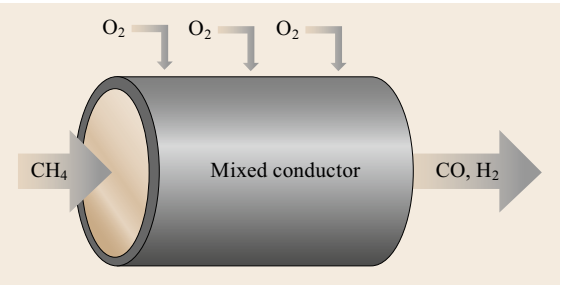

Fig. 59.19 Schematic image of the catalytic membrane reactor using mixed conductors

sure are automatically achieved. Therefore, the combination of mixed conductors with catalytic reactions is the most ideal usage. From this aspect, partial oxidation of CH_4 has been studied with perovskite mixed conductors for oxygen separation from air [59.53]. The schematic image of this catalytic reactor system was shown in Fig. 59.19. Since oxygen partial pressure in CH_4 is as low as approximately 10^{-20} atm, a large oxygen permeation rate is achieved under CH_4 partial oxidation conditions and it is reported that an oxygen permeation rate of $5\,\mathrm{cc/(min\,cm^2)}$ was achieved by using $SrFe_{0.8}Co_{0.2}O_3$ perovskite [59.54]. However, the oxygen permeation rate is decreased by phase changes in a reducing atmosphere of CH_4. Therefore, although Fe- or Co-based perovskites have been mainly studied, the most important issues for application of perovskite oxides to catalytic membrane reactors are stability in a wide oxygen partial pressure range and it is reported that Ni- or Fe-doped $LaGaO_3$ shows hole and oxide ion conductivity stably over wide p_{O_2} ranges and the oxygen permeation rate of $12\,\mathrm{cc/(min\,cm^2)}$ was exhibited on $La_{0.7}Sr_{0.3}Ga_{0.6}Fe_{0.4}O_3$ of 0.2 mm thick at 1273 K in CH_4 partial oxidation [59.55]. As a result, obviously, perovskites are important materials for oxygen separation membranes and the application of catalytic membrane reactors is an important area; albeit the chemical stability is required to be much improved.

59.5 Summary

In this chapter, crystal structures of perovskites and related oxides were explained. Perovskite oxide has a variety of composition and component elements. In addition, there are many isomorphs in crystal structure. Therefore, based on variety of crystal structures, there are many functions and rich application areas. In particular, in this chapter, the application of perovskite oxides for photocatalytic properties and solid oxide fuel cells were briefly overviewed. Since high electric conductivity and surface activity to oxygen dissociation are achieved simultaneously, perovskite oxides, mainly Co-, Fe- and Mn-based oxides are widely used for SOFCs and oxygen permeation membranes. On the other hand, for the application to photocatalysts, Ta- or Ti-based perovskites are highly active. Therefore, perovskite oxide is a highly important compound for these areas.

About the Authors

Martin Abkowitz (deceased)

Chapter D.37

Sadao Adachi

Chapter D.30

Gunma University
Faculty of Science and Technology
Gunma, Japan
adachi@gunma-u.ac.jp

Sadao Adachi received his PhD from Osaka University and is a Professor Emeritus of the Faculty of Science and Technology at Gunma University. He has published and presented over 300 technical papers and 25 textbooks on semiconductor physics and technology. His current research interests include physical properties of semiconductors and new functional materials.

Guy J. Adriaenssens

Chapter A.7

University of Leuven
Lab. for Semiconductor Physics
Leuven, Belgium
guy.adri@fys.kuleuven.be

Guy Adriaenssens received his PhD from the University of Washington (1971) for an NMR study of ferroelectric phase transitions. After postdoctoral studies at the University of Saarland, Germany, he joined the University of Leuven, Belgium, in 1973. There his main research interests centered on the electronic transport properties and the electronic density of states of amorphous semiconductors, chalcogenide glasses and conjugated polymers, and on defect structures in CVD diamonds.

Wilfried von Ammon

Chapter A.5

Von Ammon Consulting
Roth, Germany
wilfried.ammon@aon.at

Wilfried von Ammon studied Physics at the Technical University of Munich and at the University of Regensburg; he received his PhD in Physics in 1981. He then joined Wacker Siltronic, working in research and development. His main focus was on silicon crystal growth, silicon-layer growth by chemical vapor deposition, neutron transmutation doping, thermal treatment of silicon, and behavior of defects in silicon. He is now retired.

Hajime Asahi

Chapter C.23

Osaka University
Inst. of Scientific and Industrial Research
Osaka, Japan
asahi@sanken.osaka-u.ac.jp

Hajime Asahi received his PhD degree from the University of Tokyo, Japan in 1976. He then joined NTT Laboratories, where he engaged in research on MBE of III-V semiconductors and their optical device applications. In 1987 he joined ISIR, Osaka University, then focussing on research on MBE of III-nitride, diluted magnetic and temperature-insensitive semiconductors, quantum nanostructures, and their device applications.

Peter Ashburn

Chapter C.22

University of Southampton
School of Electronics and Computer Science
Southampton, UK
pa@ecs.soton.ac.uk

Peter Ashburn received a PhD degree in Electrical and Electronic Engineering in 1974 from the University of Leeds and then joined the Philips Research Laboratories. In 1978 he joined the University of Southampton and is currently a Professor of Microelectronics. His research interests include SiGe heterojunction bipolar transistors (HBTs), ultimate CMOS and carbon nanotubes. He has published over 200 papers in the scientific literature and has authored two books on bipolar transistors.

Mark Auslender

Chapter C.21

Ben-Gurion University of the Negev Beer Sheva
Dept. of Electrical and Computer Engineering
Beer Sheba, Israel
marka@bgu.ac.il

Mark Auslender received a PhD in Solid-State Theory in 1977. He was a Certified Senior Researcher at the Institute of Metal Physics (Ural Branch, USSR Academy of Sciences). In 1991 he joined the Department of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Israel, where he is a Grade A Researcher and Adjunct Full Professor in the department. His present interests focus on micro- and nanophotonics, optical sensors, graphene, and manganites.

Darren M. Bagnall

University of New South Wales
School of Photovoltaic and Renewable Energy Engineering
Sydney, Australia
d.bagnall@unsw.edu.au

Chapter C.22

Darren Bagnall is a senior lecturer at the School of Electronics and Computer Science at Southampton University. His research has included pioneering work on molecular-beam epitaxy (MBE) and chemical vapor deposition (CVD) for the development of new nano and quantum devices based on ZnO, silicon and silicon germanium. He has published over 50 refereed papers.

Ian M. Baker

Leonardo MW Ltd
Southampton, UK
ian.m.baker@leonardocompany.com

Chapter D.34

Ian Baker received his PhD in Silicon Sensors from Southampton University in 1973. His career in solid state imaging has spanned visible imaging CCDs to advanced infrared detectors. He has presented over 90 papers and has 32 patents. He was awarded an MBE for services to industry in 2008. His current interests are avalanche photodiode arrays for long range surveillance and astronomy.

Sergei Baranovskii

Philipps University
Dept. of Physics
Marburg, Germany
baranovs@staff.uni-marburg.de

Chapter A.9

Sergei Baranovskii received his PhD (1981) at Ioffe Institute, St. Petersburg, Russia, where he worked as a Senior Researcher till 1990. Since 1990 he has been working at Philipps University Marburg, Germany. His research interests are devoted to optical properties and charge transport in disordered semiconductors. He has edited two books, co-authored seven book chapters, and published 230 peer-reviewed articles.

Mark Baxendale

Queen Mary University of London
School of Physics and Astronomy
London, UK
m.baxendale@qmul.ac.uk

Chapter E.47

Mark Baxendale has been a Reader in Nanotechnology at Queen Mary University of London since 2002. His general research interest is in self-organization and emergent phenomena in the physical and life sciences with a focus on the science and applications nanoscale carbon macromolecules (fullerenes, carbon nanotubes, and graphene) in the physical and life sciences.

Mohammed L. Benkhedir

Tebessa University
Lab. of Applied and Theoretical Physics
Tebessa, Algeria
benkhedir@gmail.com

Chapter A.7

Mohammed L. Benkhedir received an MS in Physics from the University of Annaba, Algeria, and holds a lectureship at the Centre Universitaire de Tebessa, Algeria. He gained a PhD in Physics from the University of Leuven, where he studied the electronic properties and density of states in amorphous selenium by means of photoconductivity techniques. He is currently Professor at the University of Tebessa, Algeria.

Monica Brinza

ASML Netherlands B.V.
Veldhoven, The Netherlands
monica.brinza@asml.com

Chapter A.7

Monica Brinza received a PhD from the University of Leuven in 2004 with a thesis on electronic transport properties of hydrogenated amorphous silicon. She continued her research work at Utrecht University, with a post-doc focused on low temperature amorphous and microcrystalline solar cells. In 2010 she joined ASML as a design engineer in the Development and Engineering Department of EUV lithographic systems.

Paul D. Brown

University of Nottingham
Dept. of Mechanical, Materials and Manufacturing Engineering
Nottingham, UK
paul.brown@nottingham.ac.uk

Chapter B.17

Paul D. Brown received a PhD in Applied Physics from the University of Durham in 1989. He is presently Professor of Materials Characterisation at the University of Nottingham. His current research interests are concerned with the interrelationship between the processing, structure, and property of structural, functional, and biomedical materials, assessed using a broad range of characterization techniques, with emphasis on novel variants of electron microscopy.

Peter Capper Chapters B.12, B.14, B.15 For biographical profile, please see the section "About the Editors".

R. Lawrence Comstock (deceased) Chapter E.49

Ray DeCorby

University of Alberta
Electrical and Computer Engineering
Edmonton, Canada
rdecorby@ualberta.ca

Chapter D.41

Ray DeCorby is a Professor of Electrical and Computer Engineering at the University of Alberta, Edmonton, Canada. His research is in the area of integrated optics, with a current focus on air-core waveguides and microcavity devices for sensing, lab-on-a-chip, and quantum information applications.

M. Jamal Deen

McMaster University
Dept. of Electrical and Computer Engineering
Hamilton, Canada
jamal@mcmaster.ca

Chapter B.20

M. Jamal Deen is a Distinguished University Professor and Senior Canada Research Chair in Information Technology at McMaster University, Canada. He has published over 500 peer-reviewed articles, two textbooks, six patents, and has 14 best paper/poster/presentation awards. His current research interests are nanoelectronics, optoelectronics, nanotechnology, and their emerging applications to health and environmental sciences. Dr Deen is currently serving as President of the Academy of Science, The Royal Society of Canada.

Leonard Dissado

University of Leicester
Dept. of Engineering
Leicester, UK
lad4@leicester.ac.uk

Chapter A.10

Professor Emeritus Leonard Dissado works on the theory of dielectric response and electrical breakdown phenomena in a wide range of materials from glasses and high voltage insulators to bio-tissues. He was awarded a DSc from the University of London (1990), a Docteur (hc) by Paul Sabatier University, Toulouse, France (2007), and an Honorary Professorship from Xi'an Jiaotong University, China (2009).

David Dunmur

University of Southampton
Chemistry
Southampton, UK
d.dunmur@tiscali.co.uk

Chapter D.36

David Dunmur received his DPhil degree from the University of Oxford in 1965. His research has been concerned with the dielectric, optical, electro-optical and elastic properties of liquid crystals. He was Founding Editor of Liquid Crystals Today and the 1999 recipient of the G.W. Gray Medal of the British Liquid Crystal Society. Professor Dunmur has now retired from the University of Southampton.

Lester F. Eastman (deceased) Chapter D.32

Andy Edgar

Victoria University
School of Chemical and Physical Sciences
Wellington, New Zealand
andy.edgar@vuw.ac.nz

Chapter D.38

Andy Edgar is an Associate Professor and Senior Research Fellow at the School of Chemical and Physical Sciences of Victoria University, Wellington, New Zealand. His research interests are in materials science, particularly glasses, ceramics, and glass ceramics for opto-electronic applications such as radiation imaging and detection. He is also interested in the development of optical camera-based systems for X-ray imaging.

Vassili Fedotov

University of Southampton
Optoelectronics Research Centre
Southampton, UK
vaf@orc.soton.ac.uk

Chapter E.56

Vassili Fedotov received a PhD degree in Laser Physics in 2003 from the University of Southampton and is presently a Principal Research Fellow at the university's Optoelectronics Research Centre. His research interests lie in the fields of metamaterials, plasmonics, and toroidal electrodynamics, and he has authored and co-authored over 70 peer-reviewed journal publications on these topics.

Romualdo A. Ferreyra

Kyoto Institute of Technology
Innovation Center
Kyoto, Japan
raferrey@kit.ac.jp

Chapter D.31

Romualdo Alejandro Ferreyra received his PhD from Virginia Commonwealth University, Richmond, USA, in 2014. Since 2015, he has held a post-doctoral researcher position at Kyoto Institute of Technology, Japan. His main areas of research interest are III-nitride materials' growth, deposition of insulators and their related solid state physics, design, fabrication, and characterization of electronic devices, and their mathematical and computational calculations.

Paul Fons

National Institute of Advanced Industrial Science and Technology
Tsukuba, Japan
paul-fons@aist.go.jp

Chapter E.46

Paul Fons joined the National Institute of Advanced Industrial Science and Technology in 1993. At AIST he has worked on both molecular beam epitaxy growth and characterization of materials using synchrotron radiation techniques such as diffraction, EXAFS, and HAXPES. He also employs density-functional theory calculations. He is currently a Chief Senior Researcher in the Systematic Materials Design Group.

Brian E. Foutz

Charlottesville, USA
foutz@cadence.com

Chapter D.32

Brian E Foutz completed his PhD at Cornell University studying electron transport and semiconductor device physics. He is a member of the IEEE and recently served on the Standards Committee for IEEE 1687. Currently, he works for Cadence Design Systems developing new techniques and logic for automated testing of semiconductor systems on chips.

Mark Fox

University of Sheffield
Dept. of Physics and Astronomy
Sheffield, UK
mark.fox@sheffield.ac.uk

Chapter D.40

Mark Fox is Professor of Optical Physics at the University of Sheffield. He obtained his DPhil degree from the University of Oxford in 1987 and worked at AT&T Bell Laboratories and at Oxford before joining the University of Sheffield in 1998. His research interests include low-dimensional semiconductor structures, quantum optics, and ultrafast laser spectroscopy. He has authored more than 150 papers and two texts in the Oxford Masters Series in Physics.

Darrel Frear

NXP Semiconductor
Core Technology in Package Innovation
Chandler, USA
darrel.frear@nxp.com

Chapter E.53

Darrel Frear earned MS and PhD degrees in Materials Science from the University of California, Berkeley. He is currently the Director of Core Technology in Package Innovation at NXP. Previously, Darrel was with Sandia National Labs, Motorola and Freescale Semiconductor. Darrel works in advanced packaging research and development including materials, modeling, manufacturing, and reliability.

Jacek Gieraltowski

European Institute for Marine Studies
Oceanic Domains Laboratory
Plouzané, France
jacek.gieraltowski@univ-brest.fr

Chapter A.4

Jacek Gieraltowski holds a DSc from Warsaw University (Poland). He has been involved in research on magnetic materials (ferrites, thin films and nanowires) for more than 35 years. Presently, he is Professor Emeritus of Physics at Institut Universitaire Européen de la Mer (IUEM), working on fast switching magnetization problems for high density magnetic recording, giant magnetoimpedance sensors, and the application of magnetism to biological and medical applications.

Robert D. Gould (deceased)

Chapter C.28

Yaser M. Haddara

McMaster University
Dept. of Electrical and Computer Engineering
Hamilton, Canada
yaser@mcmaster.ca

Chapter C.22

Yaser Haddara is Associate Professor of Electrical Engineering at McMaster University. He received his PhD in Electrical Engineering from Stanford University in 1997. His research interest is in semiconductor fabrication process modeling. He has published on modeling diffusion in GaAs, Si, and SiGe, as well as modeling of defect formation, nanowire growth, and SiGe oxidation. His current research is on cobalt germanidation, polymer sensors, and SiC process technology.

Walid A. Hadi

University of Windsor
Dept. of Electrical and Computer Engineering
Windsor, Canada
abdulhw@uwindsor.ca

Chapter D.32

Walid Hadi received his PhD in Electrical Engineering from the University of Windsor. He is currently an Assistant Professor at Saint Clair College and an Adjunct Professor at Lawrence Technological University. Dr Hadi is a post-doctoral fellow at the University of British Columbia. His research is on III-V and II-VI semiconductors and their application in high electron mobility transistors.

Shlomo Hava

Ben-Gurion University of the Negev Beer Sheva
Dept. of Electrical and Computer Engineering
Beer Sheba, Israel
hava@bgu.ac.il

Chapter C.21

Shlomo Hava received a PhD in Electrical Engineering from the University of Delaware in 1982. Since then he has worked in the Department of Electrical and Computer Engineering at Ben-Gurion University of the Negev, Israel. Currently he is a Faculty Professor and Head of the Microelectronics Laboratory in this department. His present research interests include micro- and nanometer-scaled diffraction gratings in optical elements and light emitters, and the effects of gamma radiation and vacuum on optoelectronic devices.

Masahiro Hiramoto

Institute for Molecular Science
Dept. of Materials Molecular Science
Okazaki, Japan
hiramoto@ims.ac.jp

Chapter E.54

Masahiro Hiramoto received a PhD in Chemistry from Osaka University in 1986. He started research on organic semiconductors and organic solar cells in 1988 at the Graduate School of Engineering, Osaka University. He joined the Institute for Molecular Science in 2008 as Professor. He has published over 130 papers and is the inventor of the blended junction and tandem junction for organic solar cells.

Hideo Hosono

Tokyo Institute of Technology
Materials Research Center of Element Strategy
Yokohama, Japan
hosono@msl.titech.ac.jp

Chapter E.58

Hideo Hosono obtained his PhD in Applied Chemistry from Tokyo Metropolitan University in1982 and became a Professor at Tokyo Institute of Technology in 1999. He is a pioneer of transparent oxide semiconductors represented by IGZO ($InGaZnO_x$)-thin film transistors used to drive LCDs and OLEDs and discovered the iron pnictide superconductor. His current concern is design and exploration of novel semiconductors, superconductors, and catalysts.

Colin Humphreys

University of Cambridge
Dept. Materials Science and Metallurgy
Cambridge, UK
colin.humphreys@msm.cam.ac.uk

Chapter 1

Colin Humphreys is Professor of Materials Science and Director of Research at the University of Cambridge. He is the founder and the Director of the Cambridge Centre for Gallium Nitride, which researches GaN-based LEDs and electronic devices. He is a Fellow of the Royal Society and the Royal Academy of Engineering.

Mehrdad Irannejad

University of Waterloo
Dept. of Mechanical and Mechatronics Engineering
Waterloo, Canada
mehrdad.irannejad@uwaterloo.ca

Chapter D.41

Mehrdad Irannejad received his MSc degrees from the University of Shiraz, Iran (2000) and the University of Leeds, UK (2008). He received his PhD degree in Photonic Materials Science Engineering from the University of Leeds in 2012. Currently, he is a Research Associate in Mechanical and Mechatronics Engineering at the University of Waterloo. His research interests include photonic glasses and polymers, and their integration with 2D materials in nanosensor platforms.

Stuart Irvine

Swansea University
College of Engineering
Swansea, UK
s.j.c.irvine@swansea.ac.uk

Chapters B.14, E.43

Stuart Irvine is Professor of Solar Energy Materials in the College of Engineering, Swansea University, and Director of the Centre for Solar Energy Research. He was awarded his BSc in Physics (1974, Loughborough University), his PhD in Materials Science (1978), and his DSc in Physics (1994, University of Birmingham). His research on metalorganic chemical vapor deposition (MOCVD) of II-VI semiconductors has been applied to infrared detectors and PV solar energy.

Tatsumi Ishihara

Kyushu University
Dept. of Applied Chemistry
Fukuoka, Japan
ishihara@cstf.kyushu-u.ac.jp

Chapter E.59

Tatsumi Ishihara is Professor at the International Institute for Carbon-Neutral Energy Research (I2CNER) at Kyushu University (Japan). He received his PhD from Kyushu University in 1991 and has been working there since 2003. His research interests lie in the fields of catalysts, solid state electrochemistry, solid state ionics, the development of energy-related materials like fuel cells, rechargeable batteries and photocatalysts, environment catalysts like deNOx, and low temperature PM oxidation catalysts for cars.

Radu Ispasoiu

ON-Semiconductor
Image Sensor Group
San José, USA
radu.ispasoiu@onsemi.com

Chapter D.40

Radu Ispasoiu has held engineering management and technical leadership positions in the hi-tech optoelectronics industry in Silicon Valley, California, since 2001. He is currently Senior Manager of Pixel Design and Image Sensor Characterization at ON Semiconductor, Image Sensor Group (formerly Aptina Imaging). He has a PhD in Physics (1996), with a dissertation on the optical spectroscopy of III-V semiconductor quantum well structures.

Minoru Isshiki

Tohoku University
Inst. of Multidisciplinary Research for Advanced Materials
Sendai, Japan
isshiki@agate.plala.or.jp

Chapters B.16, D.33

Minoru Isshiki is an Emeritus Professor, Tohoku University. He retired in 2012 as a Professor at the Institute for Advanced Materials Processing, Tohoku University. He received his PhD in Materials Science from Tohoku University in 1976. His research interests focus mainly on the purification of metals, single crystal growth of bulk, and thin film II-VI compound semiconductors and impurity effects on their properties.

Tim Joyce

University of Liverpool
School of Engineering
Liverpool, UK
t.joyce@liverpool.ac.uk

Chapter B.14

Tim Joyce has 35 years' experience in semiconductor growth and materials characterization, mainly at Liverpool University. He migrated from MOVPE to MOMBE of III-V materials and then to III-nitride MBE and to ALD of oxide films. More recently he has concentrated on AFM and electron microscopy. He is an active committee member of BACG.

M. Zahangir Kabir

Concordia University
Dept. of Electrical and Computer Engineering
Montreal, Canada
zahangir.kabir@concordia.ca

Chapter E.45

Zahangir Kabir is an Associate Professor in the Department of Electrical and Computer Engineering at Concordia University, Canada. His research interests include theory, modeling, and characterization of electronic materials and devices with applications to photoconductors for optical and x-ray detectors, HFETs, and thin-film solar cells. He has authored or co-authored more than 40 refereed journal papers in the above area.

Safa Kasap Chapters A.2, A.3, B.19, C.28, E.45 For biographical profile, please see the section "About the Editors".

Gudrun Kissinger

Innovations for High Performance
Microelectronics (IHP)
Frankfurt/Oder, Germany
gkissinger@ihp-microelectronics.com

Chapter A.5

Gudrun Kissinger obtained a PhD in Crystallography from the University of Leipzig and worked as a Research Scientist and Project Leader in IHP in Frankfurt (Oder), Germany, from 1984–2001. From 2001–2004 she co-founded and joined the start-up company Communicant Semiconductor Technologies. In 2004, she returned to IHP where she is now working as Project Leader in industrial cooperation with Siltronic AG.

Alexander V. Kolobov

National Institute of Advanced Industrial
Science and Technology
Tsukuba, Japan
a.kolobov@aist.go.jp

Chapter E.46

Alexander V. Kolobov has been involved in chalcogenide research since the late 1970s when he joined A.F. Ioffe Physico-Technical Institute in Leningrad (Russia). Since 1994 he has been working at the National Institute of Advanced Industrial Science and Technology in Tsukuba (Japan), where he is currently a Prime Senior Researcher.

Cyril Koughia

University of Saskatchewan
Dept. of Electrical and Computer
Engineering
Saskatoon, Canada
cyril.koughia@usask.ca

Chapters A.2, A.3

Cyril Koughia received his PhD from the A.F. Ioffe Physico-Technical Institute, St. Petersburg, Russia and is a Research Associate at the University of Saskatchewan, Canada. His current research interests include electronic and optical properties of amorphous semiconductors and rare-earth doped glasses used in photonics and electronics. He has written many invited papers and has published extensively in international journals in this field.

Roger Lewis

University of Wollongong
School of Physics
Wollongong, Australia
roger@uow.edu.au

Chapter E.55

Roger Lewis is a Professor of Physics and Associate Dean of Research in the Faculty of Engineering and Information Sciences at the University of Wollongong, Australia. Lewis holds a BSc (Honours) from the University of Sydney and a PhD from Griffith University, Australia. He is a fellow of the Australian Institute of Physics and of the Royal Microscopical Society.

Geoffrey Luckhurst

University of Southampton
Chemistry
Southampton, UK
gl@soton.ac.uk

Chapter D.36

Geoffrey Luckhurst was awarded his PhD in 1965 from the University of Cambridge, having obtained his BSc at the University of Hull. His research into liquid crystals started in Cambridge and continues at Southampton where he is Emeritus Professor of Chemical Physics. His work is concerned with many aspects of this interdisciplinary field including the design of novel materials, their molecular orientational order, macroscopic order and dynamics.

Jiří Málek

University of Pardubice
Dept. of Physical Chemistry
Pardubice, Czech Republic
jiri.malek@upce.cz

Chapter B.19

Jiří Málek received his PhD degree from the Institute of Chemical Technology, Pardubice (1986) and his DSc degree from the Faculty of Chemical Engineering in Prague (2000). He has been a Full Professor of Physical Chemistry at the University of Pardubice since 2002. His interests include kinetics of nucleation-growth processes, structural relaxation, and visco-elastic behavior of non-crystalline materials and highly supercooled, glass-forming liquids.

Akihisa Matsuda

Osaka University
Dept. of Systems Innovation
Osaka, Japan
matsuda@ee.es.osaka-u.ac.jp

Chapter C.25

Akihisa Matsuda has an MS degree from Waseda University, a PhD from Tokyo Institute of Technology, and was Chief Senior Researcher at ETL, MITI Japan. He was also the Director of the Research Initiative for Thin-Film Silicon Solar Cells at AIST, METI Japan. He was also a Professor at the Tokyo University of Science, Chiba, Japan.

Naomi Matsuura

University of Toronto
Dept. of Materials Science & Engineering
Toronto, Canada
naomi.matsuura@utoronto.ca

Chapter D.39

Naomi Matsuura is an Associate Professor in the Faculty of Applied Science and Engineering at the University of Toronto. She received her PhD from the University of Toronto in 2003 for the development of three-dimensional nanoscale architectures. Her research focuses on the design of new materials for enhanced interaction with medical imaging radiation for image-guided and targeted treatment of disease.

Jan Mistrik

University of Pardubice
Center of Materials and Nanotechnology
Pardubice, Czech Republic
jan.mistrik@upce.cz

Chapter A.3

Jan Mistrik is currently Senior Scientist at the Center of Materials and Nanotechnology at the University of Pardubice, Czech Republic. He obtained his MSc (1998) and PhD (2003) from Charles University in Prague (quantum optics and optoelectronics). In 2002, he received a doctoral degree in materials science from the University of Versailles, France. His research interest is optical characterization of nanostructures, in particular spectroscopic ellipsometry and magneto-optics with about 50 refereed journal papers in the field.

Winfried Mönch

University Duisburg-Essen
Faculty of Physics
Duisburg, Germany
winfried.moench@uni-due.de

Chapter A.8

Winfried Mönch received a Dr. rer. nat. degree from the Universität Göttingen in 1961. He spent three years at the AEG-Forschungsinstitut before joining the RWTH Aachen. There he qualified as university lecturer in 1968 and became Associate Professor two years later. In 1974 he was appointed Professor at the Universität Duisburg and retired in 1999. He was Walter Schottky Visiting Professor at Stanford University in 1981 and received the E.W. Müller Award 1984 of the University of Wisconsin–Milwaukee. He has authored two monographs on semiconductor surfaces and interfaces.

Donald T. Morelli

Michigan State University
Chemical Engineering and Materials Science
East Lansing, USA
dmorelli@egr.msu.edu

Chapter E.57

Donald Morelli is Professor of Materials Science and Adjunct Professor of Physics at Michigan State University. His research interests span a variety of topics, including: semimetals, conducting polymers, high temperature superconductors, wide and narrow band gap semiconductors, high thermal conductivity crystals, thermoelectric materials, and magnetism. Professor Morelli holds BS and PhD degrees in Physics from the University of Michigan.

Kazuo Morigaki

University of Tokyo
Tokyo, Japan
k.morigaki@yacht.ocn.ne.jp

Chapter C.24

Kazuo Morigaki received his PhD in Physics from Osaka University in 1959. Since then, he has worked for Osaka University, Sony Corporation Research Laboratory, Centre d'Etudes Nucléares de Saclay, University of Tokyo (Institute for Solid State Physics), Yamaguchi University, and Hiroshima Institute of Technology. He is now Professor Emeritus at the University of Tokyo. His current area of interest are light-induced phenomena and the electronic states of defects in amorphous and microcrystalline silicon.

Hadis Morkoç

Virginia Commonwealth University
Electrical and Computer Engineering
Richmond, USA
hmorkoc@vcu.edu

Chapter D.31

Hadis Morkoç received his PhD degree from Cornell University, Ithaca, NY, and a Honoris Causa from the University of Montpellier II. He is the Founders Professor of Engineering at Virginia Commonwealth University, Richmond, VA. He is among the most cited scientists in the fields of physics, engineering, and materials science. His research interests are semiconductors, oxides, electronic and optoelectronic devices, and sensors.

Jayanta Mukherjee

Compound Photonics UK Ltd
Durham, UK
jayanta.mukherjee@compoundphotonics.com

Chapter D.35

Jayanta Mukherjee is a Laser Design Engineer at Compound Photonics, United Kingdom, where he works on design, development and manufacturing of visible and infra-red high power semiconductor lasers and solid state lasers. He holds a BSc (Hons) in Physics, a Master's in Physics and Laser Engineering, and a PhD in Semiconductor Laser Physics.

Takashi Nagase

Osaka Prefecture University
Dept. of Physics and Electronics
Sakai, Japan
nagase@pe.osakafu-u.ac.jp

Chapter E.51

Takashi Nagase received his PhD degree in Electronic Engineering from Osaka Prefecture University in 2000. After a postdoctoral fellowship at the National Institute of Information and Communications Technology, he joined Osaka Prefecture University in 2006 where he is currently an Associate Professor in the Department of Physics and Electronics. His current research interests are organic electronics, molecular devices, and nanofabrication.

Hiroyoshi Naito

Osaka Prefecture University
Dept. of Physics and Electronics
Sakai, Japan
naito@pe.osakafu-u.ac.jp

Chapter E.51

Hiroyoshi Naito received his PhD degree in Electronic Engineering from Osaka Prefecture University in 1984 where he is now a Professor in the Department of Physics and Electronics. He has been engaged in the photoelectric characterization of disordered semiconductors such as amorphous chalcogenide glasses and of liquid crystalline materials. His current interests are the optical and electronic properties of organic semiconductors and their application to optoelectronic devices.

Arokia Nathan

University of Cambridge
Dept. of Electrical Engineering
Cambridge, UK
an299@eng.cam.ac.uk

Chapter E.44

Arokia Nathan holds the Chair of Photonic Systems and Displays in the Department of Engineering, Cambridge University. He has extensive experience in device physics and modeling, and materials processing. His present research interests lie in the integration of devices, circuits, and systems using a broad range of inorganic and organic thin film material systems on rigid and mechanically flexible substrates.

Stephen K. O'Leary

University of British Columbia
School of Engineering
Kelowna, Canada
stephen.oleary@ubc.ca

Chapter D.32

Stephen O'Leary received degrees from the University of Toronto. Currently, he is with The University of British Columbia. His current research interests are the material properties of electronic materials. Professor O'Leary is a registered Professional Engineer. He is currently a member of the American Physical Society, the Materials Research Society, and a Senior Member of the IEEE.

Chisato Ogihara

Yamaguchi University
Graduate School of Science and Engineering
Yamaguchi, Japan
ogihara@yamaguchi-u.ac.jp

Chapter C.24

Chisato Ogihara received his PhD degree in Physics from University of Tokyo in 1988. He joined the University of Strathclyde in 1989, Gifu University in 1991 and Yamaguchi University in 1993. His current research focuses on photoluminescence and light-induced creation of defects in hydrogenated amorphous silicon.

Fabien Pascal

University of Montpellier
Institute of Electronic and Systems
Montpellier, France
fabien.pascal@ies.univ-montp2.fr

Chapter B.20

Fabien Pascal is involved in a research group working in electronic devices (MOS, MODFET, MESFET, TBH Si–Ge, TBH III–V) by means of their proper background I–V/C–V characteristics and noise spectral analysis. He is also working on the technological qualification of contacts, semiconductor materials and carbon nanotubes based devices by the use of noise spectroscopy.

Michael C. Petty

Durham University
School of Engineering and Computing Sciences
Durham, UK
m.c.petty@durham.ac.uk

Chapter E.51

Michael Petty's higher education was at Sussex University, UK (BSc and DSc) and Imperial College, London (PhD). He is a Fellow of the Institute of Physics and of the Institution of Engineering and Technology. Mike's research activities focus on the properties of organized thin films of organic materials. He has a particular interest in the application of these layers to electronic and opto-electronic devices.

Henry H. Radamson

Chinese Academy of Science
Inst. of Microelectronics
Beijing, China
KTH Royal Institute of Technology
School of Information and Communication Technology
Stockholm, Sweden
rad@ime.ac.cn

Chapter E.48

Henry H. Radamson received the PhD degree in semiconductor materials from Linköping University in Sweden in 1996. He joined the Royal Institute of Technology in Stockholm in 1997 as a Senior Scientist. Since 2016, he is professor in Chinese Academy of Science in Beijing, China. His research field is nanoelectronics, nanophotonics, and nanosensing. He has published more than 200 scientific articles, including seven book chapters and one book about the integration of photonics and electronics.

Asim K. Ray

Brunel University London
Inst. of Materials and Manufacturing
Middlesex, UK
asim.ray@brunel.ac.uk

Chapters C.28, E.52

Asim K. Ray, BSc, MSc, PhD, DSc, holds the Chair of Electronic Materials and Devices at Brunel University London. Dr Ray is a Chartered Engineer and a Chartered Physicist. His nanoelectronics research activity is focused on electron transport in low dimensional nanostructures, organic/inorganic hybrid structures, and discotic liquid organic crystals and 2D graphene. He has published over 250 papers, including invited reviews and book chapters in his field of research.

Stephen Reynolds

University of Dundee
School of Science and Engineering
Dundee, UK
s.z.reynolds@dundee.ac.uk

Chapter A.7

Steve Reynolds received a PhD in Applied Physics (1983), and was BP Postdoctoral Fellow at the University of Edinburgh before moving to Dundee in 1987. He has had several periods in industry, and in 2005/2006 was Guest Scientist in the Institute of Photovoltaics, FZ Jülich, Germany. Steve is currently Programme Leader in Physics and Director of Solar Cities Scotland. His research interests include thin-film semiconductors, computer modeling, and renewable energy systems.

Oleg Rubel

McMaster University
Dept. of Materials Science and Engineering
Hamilton, Canada
rubelo@mcmaster.ca

Chapter A.9

Oleg Rubel received his PhD in Materials Science from the Zaporozhye National Technical University, Ukraine, in 2001. He has worked at the Central Technological Laboratory and the Semiconductor Theory Group, Philipps-University Marburg, Germany and at the Thunder Bay Regional Research Institute, Canada. His current research includes the development of first-principle approaches for predictive modeling of functional electronic materials.

Harry E. Ruda

University of Toronto
Dept. of Materials Science and Engineering, and Edward Rogers Dept. of Electrical and Computer Engineering
Toronto, Canada
harry.ruda@utoronto.ca

Chapters A.2, A.3, D.39

Harry Ruda received his PhD from MIT in 1982. He holds the Stanley Meek Chair in Nanotechnology at the University of Toronto and is Director of the Centre for Nanotechnology. His research interests focus on the fabrication and modeling of quantum functional nanostructures with applications in nanoelectronics and nanophotonics. He is a Fellow of the Royal Society of Canada and the Institute of Physics, and editor of several international scientific journals.

Andreas Sattler

Siltronic AG
München, Germany
andreas.sattler@siltronic.com

Chapter A.5

Andreas Sattler obtained his Doctor rerum naturalium in Physics from the University of Göttingen with a thesis on gettering of cobalt in silicon. His special fields of interest were solid state and semiconductor physics. He then joined the simulation group of Siltronic in 2002, where he is working on simulation of crystal growth with special emphasis on defect formation.

Peyman Servati

University of British Columbia
Electrical and Computer Engineering
Vancouver, Canada
peymans@ece.ubc.ca

Chapter E.44

Professor Peyman Servati is Director of Flexible Electronics and Energy Lab (FEEL) at the Department of Electrical and Computer Engineering, University of British Columbia. He has extensive experience in novel materials and devices for rigid and flexible displays and electronics and electronic textiles. His research interests lie in integrated sensors, electronics, and energy devices in mechanically flexible and textile substrates.

Derek Shaw

Hull University
Dept. of Physics
Hull, UK
derekshaw47@gmail.com

Chapter A.6

Derek Shaw has a BSc in Physics from Manchester University, UK, and a PhD from Imperial College. He worked for nine years in R&D in the electrical industry, primarily on thermionic emitters for magnetron valves and photoconductive CdS. He spent the remainder of his career at the University of Hull, where he initiated research into self and impurity diffusion in CdS, CdTe, HgCdTe, and GaSb.

Fumio Shimura

Shizuoka Institute of Science and Technology
Dept. of Materials and Life Science
Fukuroi, Japan
shimura@ms.sist.ac.jp

Chapter B.13

Fumio Shimura has been engaged in both fundamental and practical science and engineering related to semiconductor crystal technology and semiconductor device processing, and is the author of a book. Fumio Shimura received his PhD degree in Applied Physics from Nagoya University, Japanin 1982. He is currently a Professor at the Sizuoka Institute of Science and Technology and Adjunct Professor, North Carolina State University.

Yusuke Shinmura

Institute for Molecular Science
Dept. of Materials Molecular Science
Okazaki, Japan
shinmura@ims.ac.jp

Chapter E.54

Yusuke Shinmura received a PhD in Science from the Graduate University for Advanced Studies (SOKENDAI) in Hayama, Japan, in 2015. He joined the Institute for Molecular Science in Okazaki, Japan, in 2010. His current research interests are doping effects to organic semiconductors and organic photovoltaic cells.

Michael S. Shur

Rensselaer Polytechnic Institute
Dept. of Physics, Applied Physics, and Astronomy
New York, USA
shurm@rpi.edu

Chapter D.32

Dr Michael Shur is Patricia W. and C. Sheldon Roberts Professor at RPI. His interests are in semiconductor physics. He is Foreign Member of the Lithuanian Academy of Sciences and Fellow of IEEE, APS, IET, ECS, MRS, OSA, SPIE, EMA, and AAAS, received IEEE and other awards, and holds Honorary Doctorates from St. Petersburg Technical University and the University of Vilnius.

Poppy Siddiqua

University of British Columbia
School of Engineering
Kelowna, Canada
siddiquapoppy@gmail.com

Chapter D.32

Poppy Siddiqua is currently a PhD student at the University of British Columbia. Her research interests are focused on the electron transport within wide-energy gap compound semiconductor materials and their device implications. She worked as a Lecturer at Daffodil International University, Bangladesh prior to joining the University of British Columbia as a PhD student.

Jai Singh

Charles Darwin University
School of Engineerng and Information Technology
Darwin, Australia
jai.singh@cdu.edu.au

Chapter A.3

Jai Singh is Professor of Physics at the Charles Darwin University, Darwin, Australia and Fellow of the Australian Institute of Physics. His research interests are in condensed-matter theory, covering areas of excitonic processes in crystalline and amorphous semiconductors, nanostructures, and design of solar cells, OLEDs, and scintillators. He has written two books, edited three books and five conference proceedings, and published 200 research papers.

Tim Smeeton

SHARP Laboratories of Europe
Oxford, UK
tim.smeeton@sharp.co.uk

Chapter 1

Tim Smeeton is a Chief Technologist at SHARP Laboratories of Europe, leading development of novel light-emitting devices and photonic systems, including lasers, LEDs, deep ultraviolet (UVC) technologies, and photonics-based sensors. He received his PhD from the University of Cambridge in 2005 for research into the nanostructures of InGaN quantum wells using transmission electron microscopy and X-ray scattering techniques.

Hitoshi Suzuki

Hiroshima University
Graduate School of Advanced Sciences of Matter
Higashihiroshima, Japan
hitoshi-suzuki@hiroshima-u.ac.jp

Chapter E.51

Hitoshi Suzuki received his PhD degree in Applied Physics from Tokyo Institute of Technology and then joined the Communications Research Laboratory (National Institute of Information and Communications Technology). In 2007 he joined Hiroshima University. His current research focuses on the analysis of self-assembled structures of organic molecules using scanning probe microscopy and fabrication of functional nanostructures for biomolecules.

Roman Svoboda

University of Pardubice
Dept. of Physical Chemistry
Pardubice, Czech Republic
roman.svoboda@upce.cz

Chapter B.19

Roman Svoboda was born in 1980 in Hradec Krylova, Czech Republic. He received his PhD degree in Physical Chemistry from the University of Pardubice (2008), where he currently works as a senior scientist. His interests include advanced kinetic analysis of complex physical-chemical processes, structural relaxation phenomena in non-crystalline materials, and novel methods of thermal analysis.

Stephen J. Sweeney

University of Surrey
Dept. of Physics and Advanced Technology Institute
Guildford, UK
s.sweeney@surrey.ac.uk

Chapter D.35

Stephen John Sweeney is Professor of Physics and Head of the Department of Physics at the University of Surrey, UK. He holds a BSc (Hons) in Applied Physics and a PhD in Semiconductor Laser Physics. His research interests are in low-dimensional and novel semiconductors for use in photonic devices with applications including communications, energy generation and efficiency, sensing, and healthcare.

David Sykes

Loughborough Surface Analysis Ltd
Loughborough, UK
d.e.sykes@lsaltd.co.uk

Chapter B.18

David Sykes is a Director of Loughborough Surface Analysis Ltd. He was Chairman of the UK Surface Analysis Forum (UKSAF) 2000–2015, Chairman of the British Vacuum Council (BVC) 2006–2008, Recording Secretary of the International Union for Vacuum Science Technique and Application (IUVSTA) 2004–2016, and Chairman of the ISO/TC201 Subcommittee on Data Management and Treatment in Surface Chemical Analysis 1993–2017.

Keiji Tanaka

Hokkaido University
Dept. Applied Physics
Sapporo, Japan
keiji@eng.hokudai.ac.jp

Chapter D.42

After graduating from Hokkaido University in 1970, Keiji Tanaka worked at Canon Co. Ltd. for two years. He then returned to Hokkaido University and was promoted to Professor in 1991. In 2011 he became an Emeritus Professor. He has worked on physical properties and photoinduced phenomena of amorphous materials, specifically chalcogenide glasses, and received the first Ovshinsky Award in 2001.

Charbel Tannous

University of Western Brittany
Lab. of Magnetism of Brittany
Brest, France
charbel.tannous@univ-brest.fr

Chapters A.4, E.49

Charbel Tannous holds a DSc from Joseph Fourier University (Grenoble, France) and a PhD from the University of Sherbrooke (Quebec). He has worked on *1/f* noise in fractal circuits and microelectronic device simulation, and also on wireless communications and non-linear signal processing. He is now a Full Professor of Physics working on fast switching magnetization problems for high density magnetic recording and magnetic sensors.

Ali Teke

Balikesir University
Dept. of Physics
Balikesir, Turkey
ateke@balikesir.edu.tr

Chapter D.31

Ali Teke is currently an Associate Professor in the Physics Department at the Balikesir University, Turkey. He received his BSc (1992) and PhD (1997) degrees from Physics Departments of the Middle East Technical University, Turkey and Essex University, UK, respectively. His current research activities include the investigation of the electronic and optical properties of wide-band-gap semiconductors such as GaNand ZnO and exploring new devices for electronic and optoelectronic applications. He has published more than 30 journal and conference papers, and chapters in books.

Junji Tominaga

National Institute of Advanced Industrial Science and Technology
Tsukuba, Japan
j-tominaga@aist.go.jp

Chapter E.46

Junji Tominaga is a Prime Senior Researcher at the National Institute of Advanced Industrial Science and Technology (AIST), Japan. He received his PhD from Cranfield Institute of Technology, UK (1991). He was the Director of the Center for Applied Near-Field Optics Research until 2009. His current research is on non-volatile solid-state phase change memory using superlattice structures.

Harry Tuller

Massachusetts Institute of Technology
Dept. of Materials Science and Engineering
Cambridge, USA
tuller@mit.edu

Chapter A.11

Harry Tuller received his EngScD from Columbia University (1973) and honorary doctorates from Universities of Marseille and Oulu. He is Editor-in-Chief, Journal of Electroceramics and President, International Society of Solid State Ionics, Fellow American Ceramic and Electrochemical Societies, von Humboldt awardee, and co-founder of Boston MicroSystems. His research focuses on defects and properties of metal oxides with applications to sensors, energy conversion, memory, and MEMS devices.

Kazushige Ueda

Kyushu Institute of Technology
Dept. of Materials Science
Kitakyushu, Japan
kueda@che.kyutech.ac.jp

Chapter E.58

Kazushige Ueda received a Master's degree in Inorganic Materials in 1993 and a Doctoral degree in Materials Science in 1998 from Tokyo Institute of Technology (Tokyo Tech.). He studied transparent conducting materials at the Materials and Structures Laboratory at Tokyo Tech. After moving to Kyushu Institute of Technology in 2003, he started research on luminescent inorganic materials.

Robert M. Wallace

University of Texas at Dallas
Dept. of Materials Science and Engineering
Richardson, USA
rmwallace@utdallas.edu

Chapter C.27

Robert M. Wallace earned his PhD in Physics from the University of Pittsburgh in 1988. In 1990, Wallace joined Texas Instruments, working on advanced device concepts and associated integration issues. In 2003, he joined the University of Texas at Dallas, where he is Professor of Materials Science and Engineering. His research interests include surfaces and interfaces of electronic materials. He has over 300 publications and 65 US and international patents.

Jifeng Wang

Rasa Industries Ltd.
Advanced Microelectronic Materials
Development Center
Tokyo, Japan
wypwm6866@yahoo.co.jp

Chapters B.16, D.33

Jifeng Wang is a Senior Manager at Rasa Industries, Ltd., Japan. He retired from Tohoku University in 2008 as an Associate Professor. He received his PhD in Solid State Physics from the Chinese Academy of Sciences in 1991. His research interests focus on the microelectronic materials and he is the author of over 90 publications.

David S. Weiss

Molecular Glasses, Inc.
Rochester, USA
dweiss2@rochester.rr.com

Chapter D.37

David S. Weiss is the Research Director of Molecular Glasses, Inc. and a Senior Scientist at the University of Rochester. He retired from Eastman Kodak in 2009 as a Scientist Fellow. He received his PhD in Chemistry from Columbia University in 1969. His research interests focus on the photochemistry, photophysics, and photoelectrical properties of organic materials. He holds 26 US patents and has authored over 100 publications and co-authored one book.

Rainer Wesche

Swiss Federal Institute of Technology
Lausanne
Swiss Plasma Center
Villigen, Switzerland
rainer.wesche@psi.ch

Chapter E.50

Rainer Wesche studied physics at the University of Constance, Germany. After completing his diploma in 1984, he was assistant from 1985 to 1989 (PhD in 1988). From 1989 to 1993 he was a research scientist at the Paul Scherrer Institute in Switzerland, where he led an experimental study of high-current applications of high-T_c superconductors funded by the Swiss National Science Foundation. Since 1994 he has been a research scientist at the Swiss Federal Institute of Technology Lausanne. His present research is in the field of applied superconductivity.

Roger Whatmore

Imperial College London
Dept. of Materials
London, UK
roger.whatmore@gmail.com

Chapter C.26

Roger Whatmore worked with ferroelectrics for more than 40 years. A winner of the Nelson Gold Medal and the Griffith Medal, he is SRA at Imperial College London and Emeritus Professor at University College Cork. He is a Fellow of the Royal Academy of Engineering and the Institutes of Physics and Materials, Minerals and Mining, and a Member of the Royal Irish Academy.

Neil White

University of Southampton
School of Electronics and Computer Science
Southampton, UK
nmw@ecs.soton.ac.uk

Chapter C.29

Neil White is Professor of Intelligent Sensor Systems in the Department of Electronics and Computer Science at the University of Southampton, UK. He is a Fellow of the Institution of Engineering and Technology (IET) and the Institute of Physics (IOP), as well as a Senior Member of the IEEE. Professor White has published over 200 papers in the field of sensor technology and novel sensing materials.

Congyong Zhu

Infineon Technologies
Chandler, USA
zhuc@mymail.vcu.edu

Chapter D.31

Congyong Zhu received his BSc from Wuhan University and his MPhil from The University of Hong Kong. He received his PhD in Electrical and Computer Engineering from Virginia Commonwealth University (VCU). His research experience in VCU expands from epitaxy growth, electrical characterization, simulation, phase noise, and reliability study of GaN based HEMTs to phase shifters based on $BaSrTiO_3$. In 2013, he joined International Rectifier Inc. (now Infineon Technologies Americas Corp.).

Detailed Contents

List of Abbreviations XXIX

1 **Perspectives on Electronic and Photonic Materials**
Tim Smeeton, Colin Humphreys 1
1.1 Tremendous Integration 2
1.2 The Silicon Age 3
1.2.1 The Transistor and Early Semiconductor Materials Development 3
1.2.2 The Integrated Circuit 5
1.3 The Compound Semiconductors 7
1.3.1 High-Speed Electronics 8
1.3.2 Light Emitting Devices 9
1.3.3 The III-Nitrides 11
References 14

Part A Fundamental Properties

2 **Electrical Conduction in Metals and Semiconductors**
Safa Kasap, Cyril Koughia, Harry E. Ruda 19
2.1 Fundamentals: Drift Velocity, Mobility and Conductivity 20
2.2 Matthiessen's Rule 22
2.3 Resistivity of Metals 23
2.3.1 General Characteristics 23
2.3.2 Fermi Electrons 25
2.4 Solid Solutions and Nordheim's Rule 26
2.5 Carrier Scattering in Semiconductors 28
2.6 The Boltzmann Transport Equation 29
2.7 Resistivity of Thin Polycrystalline Films 30
2.8 Inhomogeneous Media: Effective Media Approximation 32
2.9 The Hall Effect 35
2.10 High Electric Field Transport 37
2.11 Impact Ionization 38
2.12 Two-Dimensional Electron Gas 40
2.13 One-Dimensional Conductance 42
2.14 The Quantum Hall Effect 43
References 44

3 **Optical Properties of Electronic Materials: Fundamentals and Characterization**
Jan Mistrik, Safa Kasap, Harry E. Ruda, Cyril Koughia, Jai Singh 47
3.1 Optical Constants 47
3.1.1 Refractive Index and Extinction Coefficient 48
3.1.2 Kramers–Kronig Relations 49

3.2 Refractive Index 50
3.2.1 Cauchy Dispersion Equation 50
3.2.2 Sellmeier Dispersion Equation 50
3.2.3 Gladstone–Dale Formula 51
3.2.4 Wemple–DiDominico Dispersion Relation 52
3.2.5 Group Index (N_g) 53
3.3 Optical Absorption 53
3.3.1 Lattice or Reststrahlen Absorption and Infrared Reflection 53
3.3.2 Free-Carrier Absorption (FCA) 54
3.3.3 Band-to-Band or Fundamental Absorption 56
3.3.4 Exciton Absorption 62
3.3.5 Impurity Absorption 65
3.3.6 Effects of External Fields 68
3.4 Optical Characterization 69
3.4.1 Bulk Samples 71
3.4.2 Thin Film Optics 75
3.5 Optical Materials 79
3.5.1 Abbe Number or Constringence 79
3.5.2 Optical Materials 79
3.5.3 Optical Glasses 80
References 82

4 **Magnetic Properties: From Traditional to Spintronic**
Charbel Tannous, Jacek Gieraltowski 85
4.1 Traditional Magnetism 87
4.1.1 Fundamental Magnetic Quantities 88
4.1.2 The Hysteresis Loop 89
4.1.3 Intrinsic Magnetic Properties of a Material 93
4.1.4 Traditional Types of Magnetism and Classes of Magnetic Materials 96
4.2 Nonconventional Magnetism and Progress Toward Spintronics and Quantum Devices 99
4.2.1 Types of Exchange and Coupling in Magnetic Materials 99
4.2.2 Thin Magnetic Films 100
4.2.3 Electronic Properties: Localized, Free, Itinerant Magnetism and Spin-Polarized Band Structure 101
4.3 Spintronics and Quantum Information Devices 104
4.3.1 Magnetic Signal Processing Devices 106
4.3.2 Magnetic Quantum Dot Arrays 107
4.3.3 Magnetic Vortex Properties and Applications 107
References 109

5 **Defects in Monocrystalline Silicon**
Wilfried von Ammon, Andreas Sattler, Gudrun Kissinger 111
5.1 Technological Impact of Intrinsic Point Defects Aggregates 112
5.2 Thermophysical Properties of Intrinsic Point Defects 113

5.3 Aggregates of Intrinsic Point Defects 115
5.3.1 Experimental Observations 115
5.3.2 Theoretical Model: Incorporation of Intrinsic Point Defects 118
5.3.3 Theoretical Model: Aggregation of Intrinsic Point Defects 120
5.3.4 Effect of Impurities on Intrinsic Point Defect Aggregation 123
5.4 Formation of OSF Ring 127
References 129

6 **Diffusion in Semiconductors**
Derek Shaw 133
6.1 Basic Concepts 134
6.2 Diffusion Mechanisms 134
6.2.1 Vacancy and Interstitial Diffusion Mechanisms 135
6.2.2 The Interstitial–Substitutional Mechanism: Dissociative and Kick-Out Mechanisms 135
6.2.3 The Percolation Mechanism 135
6.3 Diffusion Regimes 136
6.3.1 Chemical Equilibrium: Self- and Isoconcentration Diffusion 136
6.3.2 Chemical Diffusion (or Diffusion Under Nonequilibrium Conditions) 136
6.3.3 Recombination-Enhanced Diffusion 138
6.3.4 Surface Processing Effects 138
6.3.5 Short-Circuit Paths 138
6.4 Internal Electric Fields 138
6.5 Measurement of Diffusion Coefficients 139
6.5.1 Anneal Conditions 139
6.5.2 Diffusion Sources 139
6.5.3 Profiling Techniques 139
6.5.4 Calculating the Diffusion Coefficient 140
6.6 Hydrogen in Semiconductors 140
6.7 Diffusion in Group IV Semiconductors 141
6.7.1 Germanium 141
6.7.2 Silicon 141
6.7.3 $Si_{1-x}Ge_x$ Alloys 141
6.7.4 Silicon Carbide 142
6.8 Diffusion in III–V Compounds 143
6.8.1 Self-Diffusion 143
6.8.2 Dopant Diffusion 143
6.8.3 Compositional Interdiffusion 144
6.9 Diffusion in II–VI Compounds 144
6.9.1 Self-Diffusion 145
6.9.2 Chemical Self-Diffusion 145
6.9.3 Dopant Diffusion 145
6.9.4 Compositional Interdiffusion 146
6.10 Nano Volume Diffusion 146
6.11 Diffusion in Molten Semiconductors 146
6.12 The Meyer–Neldel Rule 146

6.13 Conclusions 147
6.14 General Reading and References 147
References 147

7 **Photoconductivity in Materials Research**
Stephen Reynolds, Monica Brinza, Mohammed L. Benkhedir, Guy J. Adriaenssens 151
7.1 Steady-State Photoconductivity (SSPC) 153
7.1.1 Definitions and Overview 153
7.1.2 Example Applications in Materials Research 154
7.2 Constant Photocurrent Method (CPM) and Related Techniques 157
7.2.1 CPM 157
7.2.2 Dual Beam Photoconductivity (DBP) 158
7.2.3 Fourier-Transform Photocurrent Spectroscopy (FTPS) 159
7.3 Steady-State Photocarrier Grating Method (SSPG) 160
7.4 Modulated Photocurrent Spectroscopy (MPC) 161
7.4.1 MPC Background and Experiment 161
7.4.2 MPC Density of States Analysis 162
7.4.3 MPC Applications 163
7.5 Switch-on and Switch-off Transients 164
7.5.1 Switch-on Transient 164
7.5.2 Switch-off Transient 165
7.6 Transient Photocurrent Spectroscopy (TPC) 166
7.6.1 TPC Principles 166
7.6.2 TPC Experiment 166
7.6.3 TPC Density-of-States Analysis 167
7.6.4 TPC Applications 168
7.7 Time-of-Flight (TOF) and Related Techniques 168
7.7.1 TOF Mobility and DOS Measurements 168
7.7.2 Interrupted Field TOF (IFTOF) 170
7.8 Other Photoconductivity-Related Techniques 171
7.8.1 Surface Photovoltage (SPV) 171
7.8.2 Spin-Dependent Recombination 171
7.8.3 Time-Resolved Microwave Conductivity (TRMC) 171
References 172

8 **Electronic Properties of Semiconductor Interfaces**
Winfried Mönch 175
8.1 Experimental Database 177
8.1.1 Barrier Heights of Laterally Homogeneous Schottky Contacts 177
8.1.2 Band Offsets of Semiconductor Heterostructures 180
8.2 IFIGS-and-Electronegativity Theory 181
8.3 Comparison of Experiment and Theory 183
8.3.1 Barrier Heights of Schottky Contacts 183
8.3.2 Band Offsets of Semiconductor Heterostructures 184
8.4 Modifications of Schottky Contacts 187
8.4.1 Nonalloyed Ohmic Contacts or MUTIS Schottky Contacts 187
8.4.2 Atomic Interlayers 189

8.5 Graphene Schottky Contacts 190
8.6 Final Remarks 190
References 191

9 **Charge Transport in Disordered Materials**
Sergei Baranovskii, Oleg Rubel 193
9.1 General Remarks on Charge Transport in Disordered Materials 195
9.2 Charge Transport in Disordered Materials via Extended States 198
9.3 Hopping Charge Transport in Disordered Materials via Localized States 200
9.3.1 Nearest-Neighbor Hopping 201
9.3.2 Variable-Range Hopping 203
9.3.3 Description of Charge-Carrier Energy Relaxation and Hopping Conduction in Inorganic Noncrystalline Materials 205
9.3.4 Description of Charge-Carrier Energy Relaxation and Hopping Conduction in Organic Noncrystalline Materials 211
9.4 Concluding Remarks 215

Glossary of Defining Terms 1461
Subject Index 1495

Glossary of Defining Terms

π Band
Equivalent of the valence band in an organic semiconductive material

π^* Band
Equivalent of the conduction band in an organic semiconductive material

π Bond
Chemical bond formed between the nuclei of atoms. There are two bonding regions above and below a nodal plane containing the nuclei. In ethylene, a π-bond is formed by the overlap of p orbitals on the carbon atoms

σ Bond
Bond formed along the internuclear axis, between the nuclei of the atoms. In ethylene, a σ bond is formed by the overlap of two carbon sp^2 hybrid orbitals

A

Abbe Number (ν_d)
A measure of the dispersion (wavelength dependence) of the refractive index n of transparent materials at visible wavelengths; $\nu_d = (n_d - 1)/(n_F - n_C)$, where $d = 587$ nm, $F = 486$ nm, and $C = 656$ nm. Typically ν_d takes values of 80–20, which decreases with increasing n_d from 1.5 to 1.9

Absorption Coefficient (α)
The absorption coefficient represents the logarithmic decrement of the incident light intensity per unit length in the material

Accelerated Crucible Rotation Technique (ACRT)
A means to stir liquids in sealed ampoules, leading to improvements in crystal properties

Acceptor
Impurity in a semiconductor or any other electroluminescent device capable of inducing hole conduction and accepting a valence-band electron to produce an acceptor energy level

Acceptor Concentration
Number of acceptors per cm^3. It refers to the total concentration N_a and the concentration of ionized acceptors N_a^-

Acceptor Level
A level with energy E_a that acquires an electron captured from the valence band to an orbit near the acceptor's atom

Accumulation
The condition in which, for an MIS structure, the applied voltage to the gate electrode V_G results in an increase in the density of majority carriers near the surface of the underlying semiconductor. The applied voltage is less than the flat band voltage, $V_G < V_{FB}$

Active Material
The main functional component of thick-film paste, usually in the form of a finely divided powder

Active Matrix Addressing
The technique used to write and change images on complex liquid-crystal displays. Each display consists of thousands of picture elements (pixels) arranged as a matrix of columns and rows. Each pixel has a transistor switch (thin-film transistor – TFT), which has been deposited onto one plate of the liquid-crystal display. A voltage is applied sequentially to the rows of pixels, and selected pixels within each row are switched on by data voltages on the columns. As the next row in the sequence is activated, the elements of the previous row are switched off from the data line by the TFT, but hold their charge as an electrical capacitor until the row is addressed next time in the sequence, after a full frame time. Thus the image is built up line by line, and individual pixels must hold their charge for the period of the full frame-address time

Air Mass (AM) Number
This is often abbreviated to AM followed by a number and characterizes the intensity and spectrum of light (modified by absorption in the atmosphere). The AM number is 0 for no air mass (i. e., for a satellite solar array), 1 for the sun directly overhead, and 1.5 for the sun at 45° to the horizon

All-Optical Switch
Optical inputs are switched by other optical signals. In many cases, the switching is produced by refractive-index changes. Comparing electronic devices such as transistors, in which an electrical input is controlled by an electrical current, we expect that the all-optical switch can work faster, being free from electrical noise. However, at present, in contrast to the μm scale of a transistor, an all-optical switch may have cm scales

Amorphous Metal oxides
Glassy alloys of a transition metal with oxygen, typical examples being TiO_2, Ta_2O_5, Nb_2O_5, and Y_2O_3. In bulk form, these materials are typically polycrystalline or crystalline ceramics. However, amorphous thin films can be deposited with relative ease and they have been widely used as high-index layers in optical filter design and as dielectric layers in the microelectronics industry

Amorphous Network
Network consisting of atoms distributed randomly with a short-range order, i. e., holding a regular coordination of atoms

Amorphous Semiconductors
Semiconducting materials having a random network without long-range order

Amorphous Silicon
Thin films of silicon with a structure that is noncrystalline but which have the advantage of a higher absorption coefficient compared to crystalline silicon

Amphiphilic
An organic molecule possessing both polar (hydrophilic) and non-polar (hydrophobic) chemical groups. The classic examples are fatty acids, which consist of a non-polar ($-CH_2-$) chain terminating in a polar $-$COOH acid group

Amphoteric Dopants
Dopants that may serve both as acceptors and donors

Amphotericity
This occurs when an impurity can act either as an acceptor or a donor. In GaAs, a Si atom can take up a site on either sublattice and can act as a shallow donor or shallow acceptor

Analytical Electron Microscopy
The application of transmission and/or scanning electron microscopy for the purpose of structural and/or chemical microanalysis

Anharmonicity
The deviation of lattice vibrations in solids from those of a simple harmonic oscillator, which lead to nonzero lattice thermal resistivity

Anion
The electronegative atomic component in a compound, e.g., As in GaAs, Se in ZnSe

Annealing
Low-temperature heat treatment, normally in the presence of Hg, with the aim of adjusting the electrical properties of materials. The process of heating and slowly cooling semiconductor materials to reverse lattice damage. As a metallurgical term, annealing describes the use of heat to reduce the internal energy of a crystal. This energy may be mechanical (strain) or may represent variations in concentration, which can be reduced by diffusion, etc.

Antiferromagnetically Coupled Media (AFC)
See *Synthetic Ferrimagnetic Media* (SFM)

Antisite Defect
Occurs in semiconductor compounds and is an anion (cation) replacing a cation (anion) on a regular cation (anion) lattice site, e.g., As_{Ga} (Ga_{As}). The anion As_{Ga} (cation Ga_{As}) anti-site is expected to be a donor (acceptor) in the III–Vs and similarly in the II–VIs

Apparent Band gap Narrowing
Definition of apparent band gap seen in bipolar transistors due to the combined effects of band gap narrowing due to heavy doping and the use of Fermi–Dirac statistics

Areal Density
Number of bits per unit area stored on a recording medium. In disk drives, it is the product of the bits/unit length times the number of tracks per unit length (usually inches; the areal density is frequently quoted in Gbit/in^2)

Arrhenius Relation
A general expression connecting the value of a parameter in a thermally activated process to the absolute temperature T. Thus, a diffusivity $D = D_0 \exp(-Q/(k_B T))$, where D_0, Q and k_B are the pre-exponential factor, the activation energy for diffusion, and Boltzmann's constant, respectively

Artificial Magnetism
A phenomenon characterized by the appearance of a strong magnetic response (most notably at optical frequencies) in a material composite engineered from inherently non-magnetic materials

Astigmatism
A defect in the performance of a lens arising from lens asymmetry about the optic axis, leading to loss of sharpness of an image at focus

A-Swirl
A network of dislocations loops. The origin is a stacking fault of Si interstitials. The size of the dislocation loops can be many μm

Asymmetric Transmission
A new fundamental phenomenon of electromagnetism, which manifests itself as a difference in the overall intensity of circularly polarized waves transmitted in the opposite directions. It resembles the non-reciprocity of the Faraday effect in magnetized media but requires no magnetic field for its observation, and is fully compliant with the Lorentz reciprocity principle. The effect is observed in planar chiral metamaterials and involves partial conversion of the incident wave into one of the opposite handedness, and it is the efficiency of this conversion that is asymmetric with respect to the direction of propagation

Attenuated Total Reflection (ATR)
Technique to measure infrared absorption spectra of thin films on a prism with enhanced sensitivity utilizing multiple reflections of an infrared beam in the prism

Auger Electron Spectroscopy (AES)
A method in which an electron spectrometer is used to measure the energy distribution of Auger electrons emitted from a surface

Auto-Compensation
Often associated with amphotericity, auto-compensation occurs when the incorporation of electrically active impurities of one type leads to the automatic incorporation of electrically active defects of the opposite type. As an example, the doping of melt-grown GaAs with donors always leads to inadvertent incorporation of acceptors at about one tenth of the donor concentration

B

Back End of Line (BEOL)
A term generally describing the final points in the IC fabrication process line, such as the interconnection and packaging fabrication steps. These process steps generally require lower thermal budgets

Background-Limited Performance (BLIP)
Describes the best signal-to-noise performance that can be achieved with a detector. In this condition the only noise stems from the random arrival rate of photons and is, therefore, at a theoretical minimum

Backscattered Electrons
Incident electrons that have interacted with atomic nuclei and scattered backwards with comparable incident energy. They may be used for sample imaging with contrast dependent on the local averaged atomic number

Baldereschi Concept
Mean-value k-points in the Brillouin zone are defined such that the value that any given periodic function of the wavevector assumes at these special k-points is an excellent approximation to the average value of the same function throughout the Brillouin zone

Ballistic-Electron-Emission Spectroscopy (BEEM) Technique
A method to determine the barrier heights of Schottky contacts by tunnel injection of almost monoenergetic electrons from a biased metal tip into metal–semiconductor contacts that pass the metal films as ballistic electrons and are collected by the semiconductors, provided their energy is high enough to overcome the interfacial barriers

Band Alignment
Type I: electrons and holes are confined within the same layer. Type II: electrons and holes are confined in different (adjacent) layers

Band Filling
An effect that takes place when a semiconductor is illuminated with light at a frequency within the absorbing region. Upon absorption of the incident photons, the electrons undergo a transition from an occupied band (VB) to the empty band (CB), thereby partially populating the empty band

Band Gap (BG) or Energy Gap
The forbidden energy gap between the valence band, normally filled with electrons, and the conduction band, normally empty of electrons. The band gap energy measures the energy difference between the top of the valence band and the bottom of the conduction band. The optical BG is the photon energy above which the semiconductor absorbs energy of incident EM radiation. It may be direct or indirect, depending on the type of electron transition from VB to CB the radiation induces; in Si, the optical BG is indirect with $E_g = 1.17\,\text{eV}$ at 4.2 K

Band Gap Engineering
The science of tailoring the semiconductor band gap to control the electrical and optical properties of the material

Band Offset
The valence and conduction-band offsets describe the corresponding band-edge discontinuities at intimate and abrupt semiconductor–semiconductor interfaces

Barrier Height
The barrier height of a Schottky contact is the energy distance right at the metal–semiconductor interface from the Fermi level to the majority-carrier band-edge, i. e., the conduction-band maximum in n-type and the valence-band maximum in p-type contacts

Beam Effective Pressure Ratio
In molecular beam epitaxy, this is the ratio between the partial pressures of the various components of the molecular source beams

Birefringent Crystals
Crystals such as calcite that are optically anisotropic, which leads to an incident light beam becoming separated into ordinary (o-) and extraordinary (e-) waves with orthogonal polarizations; incident light becomes doubly refracted because these two waves experience different refractive indices n_o and n_e

Blended Junction
A mixed junction that contains donor/acceptor molecular contacts acting as photocarrier generation sites

Blocking Temperature
Temperature where the magnetic exchange coupling between an antiferromagnet and a ferromagnet vanishes

Bolometer
A sensitive detector of terahertz radiation, in many circumstances the most sensitive. The resistance of a detector material, typically Si or Ge, is measured to evaluate the energy deposited. Performance improves on cooling, so operation is often at cryogenic temperatures, e.g., at the boiling point of helium, 4.2 K. The bolometer exhibits a relatively fast response (μs) for a thermal detector

Boltzmann Equation (BE)
Generally an integro-differential equation that governs the carriers' distribution function. At equilibrium the BE is automatically satisfied by a Fermi distribution. The generalized BE is a version revised to include quantum effects in the carrier's scattering and interaction with electromagnetic fields. Methods for the solution of the BE include the relaxation time and variational, displaced Maxwellian and Monte Carlo methods

Boule
There are many terms used for large crystals. These include boule, ingot, and crystal. The top of the crystal is called the seed end, the first to solidify, etc. The bottom is called the tail or tang end

Bragg's Law
Can be summarized by the defining equation $\lambda = 2d_{hkl}\sin\theta$, which must be satisfied for constructive interference to occur, corresponding to maxima in the positions of diffracted intensity

Bravais Lattice
A repetitive arrangement of points in space such that the environment of each point is identically similar to that of every other point. 14 such arrangements are used to describe crystal systems

Bremsstrahlung
Electromagnetic radiation produced by the rapid

deceleration of an electron in the vicinity of an atomic nucleus

Bridgman Growth
Technique developed in order to grow compounds where one component is volatile at the growth temperature. The growth is carried out by physically withdrawing the melt from its furnace, while the melt crystallizes on a seed. The volatile component is replenished from a reservoir in a separate furnace. The arrangement of the equipment can be horizontal or vertical, the former offering the possibility of viewing the top of the solid/liquid interface and giving visual feedback of the growth process

Bridgman Technique
Crystals are produced by progressively freezing a melt from one end, usually via crucible movement. A wide range of materials is made using this simple technique and its many variants

Brillouin Zone (BZ)
A primitive cell in the reciprocal-space lattice, which proves to be body-centered cubic (bcc) for Si. BZ provides the domain of wavevectors $\boldsymbol{k}$, which relate to the electron momentum in crystal $\boldsymbol{p} = \hbar\boldsymbol{k}$.

Broadband Sensitizer
Typically a species that is co-doped along with rare-earth ions into a glass host to increase the pumping efficiency or radiative efficiency of the rare-earth ions. Various sensitizers have been demonstrated, including silicon nanoclusters, silver ions, and other rare-earth ions (such as in the sensitization of erbium by ytterbium)

Brooks–Herring (BH) Formula
Celebrated equation for the carrier's momentum relaxation time due to scattering by ionized impurities

Bulk Modulus
Ratio of the compressive or tensile force applied to a substance per unit surface area to the change in volume of the substance per unit volume

C

Calamitic
Denotes the rod-like shape of the molecules forming the majority of liquid-crystal phases that, therefore, are known as calamitic liquid crystals

Capacitance Equivalent Thickness (CET)
Theoretical thickness of SiO_2 that would be required to achieve the same capacitance density as an alternative dielectric material. This is extracted directly from, for example, the accumulation region of a *C–V* curve and has no further correction

Capacitance–Voltage (*C–V*)
C–V measurements of a MOS capacitor can be used to determine the oxide thickness and the amount of electrically active defects (fixed charge, trapped charge, mobile charge, and interface trapped charge) and mobile contaminants in the oxide. It can also be used to determine the oxide thickness and the profile of dopants at the semiconductor surface. The *C–V* technique is a method to determine barrier heights of Schottky contacts from the variation of their capacitance as a function of applied voltage. It is a common characterization technique used in wafer fabrication facilities

Carrier Concentration
Number of current carriers per cm^3. It can be electron concentration n and/or hole concentration p. The intrinsic carrier concentration (n_i) is $n = p$ in a perfect crystal semiconductor that has not been doped (i. e., an intrinsic semiconductor). The value of n_i for Si is approximated to $1.08 \times 10^{10}\ cm^{-3}$ at 300 K

Carrier Mobility
Measure of the effect of applying an electric field to charge carriers (electrons or holes). It is the additional velocity acquired by the carriers (drift velocity) divided by the electric field

Carrier Range
Determines how far an injected carrier moves per unit field before becoming immobilized in a deep trap. Sometimes, it is calculated as the product of the drift mobility and lifetime

Carrier Velocity, Microscopic
Gradient of the specific band spectrum $E_s(\boldsymbol{k})$ with respect to $\boldsymbol{p}$

Cascaded Second-Order Materials
Materials that exhibit second-order nonlinear properties that act as an effective third-order nonlinear material

Cathodoluminescence
Luminescence stimulated by energetic electrons

Cation
Electropositive atomic component in a compound, e.g., Ga in GaAs, Cd in CdS

Cd-Based Compound Semiconductor
Semiconductor that contains the element Cd

Centro-Symmetric
A crystal structure in which a center of inversion exists is called centro-symmetric. There are 32 crystal classes, among which 11 are centro-symmetric

Cermets
Standard form of thick films requiring exposure to a high-temperature firing cycle, typically in the range 700−1000 °C

Chalcogenide Glasses
Glasses that are amorphous alloys containing S, Se, and/or Te. Typical examples include Se, GeS_2, $GeSe_2$, As_2S_3, As_2Se_3, and As_2Te_3. By intermixing these and other binary chalcogenide glasses, a wide variety of multicomponent glasses can be formed. Further, a wide range of nonstoichiometric compositions is possible. Several compositions have become standard industrial materials, including $Ge_{33}As_{12}Se_{55}$, and $Ge_{28}Sb_{12}Se_{60}$. Chalcogenide glasses are characterized by narrow band gaps and good transparency in the mid to far-infrared wavelength range

Chemical Vapor Deposition (CVD)
Technique for the growth of thin solid films on a crystalline substrate as the result of thermochemical vapor-phase reactions. This reaction occurs above

a solid surface, e.g., a single crystal diamond, which causes deposition onto that surface. In the CVD technique, thin films are obtained under equilibrium conditions. The gas-phase reaction is activated by temperature in order to create condensable species that lead to film growth. Different CVD techniques have been developed (see *Mercury-Sensitized Photo-CVD*, *Hot-Wire CVD*, *MOCVD*, *MPCVD*, and *PECDV*). All techniques used for the production of diamonds require a means of activating gas-phase carbon-containing precursor molecules, usually CH_4, diluted by hydrogen

Chiral Nematic
The liquid-crystal phase in which the director is twisted into a helical arrangement; the phase is, therefore, not superimposable on its mirror image and so exhibits macroscopic chirality. The chirality of the phase originates from that of the constituent molecules. The chiral nematic is sometimes referred to as a cholesteric phase

Chromatic Aberration
A blurring of resolution due to the differing focal lengths of a lens when acting on electrons of differing energy

Cleave and Stain
A rapid, although destructive, technique for assessing semiconductor structures. Particular chemical mixtures affect the surfaces of different semiconductor types in different ways, giving rise to effects that can be seen in a simple optical microscope. The sample is first cleaved to produce a clean surface, preferably at an angle that tends to magnify the scale of the structure, and then stained

Coefficient of Thermal Expansion (CTE)
Fractional increase in the length of a macroscopic material per unit temperature increase. The units of CTE are $1/\mathrm{K}$

Coercive Field
The electric field required to reduce the polarization in a ferroelectric material to zero in a fully saturated ferroelectric hysteresis loop

Coercive Squareness Parameter (S^*)
The slope of the major hysteresis curve of a ferromagnetic recording layer normalized to the ratio of the remanent magnetization to the coercive field $S^* = 1 - \left[M_\mathrm{r}/CH_\mathrm{c}\big/(\mathrm{d}M/\mathrm{d}H)_{H=-H_\mathrm{c}}\right]$

Coherence Length (ξ)
The shortest distance within which a considerable change of the Cooper-pair density is possible

Cohesive Energy
The energy required to dissociate the atoms of a solid into isolated atomic constituents

Columnar Phase
A liquid-crystal phase in which the constituent molecules, usually disc-like, are stacked into columns; these are arranged parallel to each other in either a hexagonal or rectangular array

Complementary Metal Oxide Semiconductor (CMOS)
An *MOS* device technology consisting of nMOS and pMOS transistor pairs

Complex
A bound state between two or more adjacent, like or unlike species, e.g., an antisite and a lattice vacancy at a nearest-neighbor site on the same sublattice such as $\mathrm{As_{Ga}V_{Ga}}$

Compositional Uniformity
A critical parameter in all ternary alloy systems that determines a material's usefulness in device applications

Compound Semiconductor
Semiconductor crystals composed of two or more atomic elements from different groups of the periodic chart

Compressive Strain
Type of strain obtained when a strained $\mathrm{Si_{1-x}Ge_x}$ layer is grown on a silicon substrate

Compton Scattering
Transfer of energy from a photon to an electron, leading to the scattering of a longer-wavelength photon

Concentration Quenching
The reduction in luminescence efficiency and luminescence lifetime of a laser glass when the rare-earth dopant concentration is high. Quenching is due to interactions between closely spaced rare-earth ions at high concentrations. These interactions create new pathways, other than the desired radiative decay, for the ions to relax to the ground state after they have been raised to a desired lasing level by pump energy

Conduction Band (CB)
Band of energies allowed for electrons in a semiconductor, which is empty in undoped semiconductors. There are many CBs, separated by band gaps. However, the term CB usually refers to the conduction band that has the lowest energies, or closest to the valence band (VB). It is separated from the VB by a band gap

Conductive Layer
The layer on which the charge-generation layer and charge-transport layer are coated. It is connected to the ground in the electrophotographic process

Conductivity
Product of the number of electrons or holes per unit volume, the electronic charge, and the mobility of the carrier $\sigma = ne\mu_\mathrm{e,h}$

Conductivity Mass
Used for electron or hole conductivity (mobility) calculations

Configuration Coordinate Model
Model of interaction between the electronic system of a luminescent center and the vibrational system of the surrounding atoms and ions

Converse Piezoelectric Effect
The generation of mechanical strain in a material in response to an applied electric field, where the strain is linearly proportional to the applied field

Conversion Efficiency
Ratio of incident photon energy and output electricity energy

Cooper Pairs
Bound electron pairs formed of electrons with opposite spins and momenta (in their ground state with zero electric field)

Corona Discharge
When a high voltage of 5−10 kV is applied to sharp edges or fine wires of metals, the gas such as air surrounding the metal is ionized and discharged. If the voltage is DC, ions having the same polarity as the DC voltage move toward a grounded electrode

Correlation Factor (f)
The jumps of a diffusing particle are generally not random but correlated, i. e., successive jumps are not independent of each other; f (always ≤ 1) is the ratio of the jump rate of correlated jumps to the jump rate if the jumps were random

Cotterell Atmosphere
The stress field around a dislocation can be reduced if defects congregate around it. This results in defect atmospheres, called Cotterell atmospheres, which are commonly observed even when the dislocation itself would not provide an observable signature. EL2 defects aggregate in this way in SI substrate material

Coupled Granular Continuous (CGC) Recording Media
In perpendicular recording media: a recording surface consisting of two layers, the first being granular and the second consisting of multilayers, typically of cobalt and palladium

Critical Field (B_c)
The magnetic field sufficient to destroy the superconducting state in a type I superconductor

Critical Fluctuations
Variations of the superconducting order parameter $\psi = n_C^{1/2} \exp(i\varphi)$ (where n_C is the Cooper-pair density) around the thermal equilibrium values

Critical Thickness
Maximum thickness of a strained layer that can be grown on a substrate before relaxation of the layer occurs

Critical (Transition) Temperature (T_c)
The T_c is a characteristic property of the superconductor in question. At T_c the resistance drops abruptly to an unmeasurably small value

Cryopanel
Liquid-nitrogen-cooled surface within the growth chamber arranged to minimize contamination of the wafer surface by impurities

Crystal-Originated Particle (COP)
A small aggregate or cluster of vacancies. Usually, it is of octahedral shape with (111) facets, but in the case of nitrogen doping, it can also adopt the form of a platelet or a rod-like cluster. The usual size is 70−200 nm

Current in the Plane (CIP)
Magnetoresistive device with the sense current flowing in the plane of the films

Current Perpendicular to the Plane (CPP)
Magnetoresistive device with the sense current flowing perpendicular to the plane of the films

Czochralski and Liquid-Encapsulated Czochralski (LEC) Growth
Czochralski growth pulls a crystal from the melt. The seed is held in a holder vertically above the melt and rotated. After partial immersion into the melt, it is slowly withdrawn and the crystal forms on the seed. The growth takes place because of the increased heat loss from the crystal compared to the melt. Rotation of the seed and growing crystal leads naturally to a near-cylindrical crystal from which circular substrates can be sawn. The GaAs melt must be protected against As loss if this method is to be used. Boric oxide (see *Liquid Encapsulation*) liquifies on the surface of the melt and, to some extent, on the crystal, and acts as a barrier against As loss. The boric oxide also insulates the melt from the crucible; reducing the rates at which impurities from the crucible are introduced into the melt and aiding withdrawal of the exhausted melt from the crucible after growth

D

Dangling Bonds (Broken Bonds)
Point-like defects that are produced by breaking covalent bonds. The dangling bond may have an unpaired electron, two paired electrons, or no electrons. These dangling bonds were denoted as D^0, D^-, and D^+ by Mott; the superscript represents the charge state

Dark Decay
Rate of decrease of the surface potential of a charged organic photoconductor

Data Rate
Rate at which the digital data, recorded or read back in a digital storage device, is transferred. Characterized by Mbyte/s or MB/s, where a byte (B) is 8 bits

Debye Length
A measure of the distance beyond which the electric field due to a point charge (e.g., an ionized dopant atom) is screened by the free carriers (electrons or holes) and becomes increasingly negligible

Deep-Energy-Level Impurities
Doping impurities or other impurities whose energy level lies toward the center of the band gap

Deep-Level Transient Spectroscopy (DLTS)
DLTS is a useful technique for measuring concentrations of deep levels in conducting semiconductors. Deep levels within the depletion layer of a pn junction are filled by putting the junction into forward bias. On applying a reverse bias, these levels are allowed to empty thermally. This produces a change in junction capacitance consisting of a series

of exponentials. From the temperature spectra generated for different time windows of the transient, Arrhenius plots can be made to determine the energy level (eV) and capture the cross-section (cm^2) of the defects

Defect Chemistry
Representation of interactions between defect species and free carriers (dopant, impurity, native defect, electrons, and holes) in terms of chemical-style equations from which the concentrations of the various species concerned can be obtained

Deformation Potential
Effective electric potential describing interaction of carriers with the lattice deformation irrespective of what is the cause of the deformation. It describes the phenomenology of the interaction between carriers and phonons of deformation types

Deformation Potential Parameters
There are two and four such parameters for electrons and holes in Si, respectively. For holes, the parameter set includes one describing interaction with anti-phase deformation of atoms in the nonequivalent primitive cells' positions

Density-Functional Theory (DFT)
DFT is a quantum-mechanical approach to many-body electronic structure calculations of molecular and condensed-matter systems. The many-electron wavefunction is written in terms of the electron density. The major problem with DFT is that the exact functionals for exchange and correlation are not known. The widespread approximations are the local-density approximation (LDA) and GW approximation (GWA). The LDA assumes that the functionals for exchange and correlation depend only on the density at the coordinate where the functional is evaluated. LDA DFT calculations dramatically underestimate the gaps of sp^3-bonded semiconductors and insulators. In GW approximation, the exchange and correlation is expressed as the product of a single-particle propagator G and a screened interaction W. GWA DFT calculations yield the gaps of sp^3-bonded semiconductors and insulators generally to within a few tenths of an eV

Density of States (DOS)
The density of states is the number of energy states per unit energy interval at the energy E. It stands for the density distribution of allowed electronic energies in a material and is widely used with respect to this distribution across the band gap of disordered semiconductors

Density-of-States Mass
Used for electron or hole density-of-states calculations

Depletion
The condition in which, for an MIS structure, the applied voltage to the gate V_G electrode results in a reduction of the majority carriers near the surface of the underlying semiconductor. This region is referred to as the depletion layer. Charge remaining in this near-surface region is due to ionized dopants present in the channel region. This condition occurs for applied voltages between the flat band and threshold voltages, i. e., $V_{FB} < V_G < V_{thr}$

Depth of Field
The distance along an optic axis that an object can be moved without noticeably reducing the resolution

Depth of Focus
Maximum spacing between an imaging screen and a photographic plate (or CCD) that allows a recorded image to be retained in focus

Depth Profiling
Monitoring of signal intensity as a function of a variable that can be related to distance normal to the surface, cf., the compositional depth profile. Note: the signal intensity is usually measured as a function of sputtering time

Depth Resolution
Depth range over which a signal changes by a specified quantity when reconstructing the profile of an ideally sharp interface between two media or a delta layer in one medium

Detection Efficiency
Percentage of radiation incident on a detector system that is actually detected

Detective Quantum Efficiency (DQE)
The ratio of the square of the signal-to-noise ratio at the output of the detector to that at the input. The relative increase in image noise due to an imaging system as a function of the spatial frequency, f, is expressed quantitatively as DQE(f), which represents the signal-to-noise transfer efficiency for different frequencies of information in an image

Detectivity
A signal-to-noise parameter, normalized to area and bandwidth, often used for photoconductive detectors or single-element photovoltaic detectors

Devitrification
The transition of a glassy material to its lower-energy crystalline state. This process is usually driven by thermal energy, such as if the material is held at some characteristic temperature above its glass-transition temperature. The difference between the crystallization temperature and the glass-transition temperature for a particular glass is one measure of its stability

Diamond Structure
A structure in which each atom lies at the center of a tetrahedron surrounded by four nearest neighbors located at the points of the tetrahedron. In such a structure diffusion is isotropic

Dielectric Constant/Susceptibility (DC/DS)
Basic material optical tensor property that linearly connects the electric displacement to the electric-field vector inside the material. For Si it is scalar. At optical frequency DC/DS is a complex quantity

Dielectric Materials
A class of materials that are insulators or nonconductors where charge imparted to one part of the material is not communicated to any other part

Diffraction
The process of scattering and reconstruction of radiation in specific directions as a consequence of interaction with a periodic structure, e.g., light interacting with a grating or X-rays interacting with a crystal lattice

Diffusion Coefficient or Diffusivity
The macroscopic parameter that characterizes the jump rate or jump frequency of a species at the atomic level. It is normally obtained by matching experimental profiles to solutions of the appropriate diffusion equation, e.g., Fick's second law. The diffusion coefficient measurement techniques include Haynes–Shockley, time-of-flight, and noise-measurement-based methods

Diffusion Length
Measure of the spatial extent of a diffusion region. Typically, the concentration of a diffusant can be expected to fall by more than a factor of 10^3 over three diffusion lengths

Digital Printing
Technologies in which the image is comprised of a pattern of pixels. In electrophotographic digital printing the electrostatic latent image is written on a charged photoreceptor using a computer-controlled laser or LED bar

Dipping
A *Liquid-phase epitaxy* technique in which the substrate is lowered into the melt in a vertical orientation

Dirac Fermion
Like electrons in graphene. These electrons behave massless or as relativistic particles like photons and they obey the Dirac equation

Direct Piezoelectric Effect
The generation of an electric polarization change or a charge separation in a material in response to an applied stress, where the polarization change is linearly proportional to the applied stress

Director
Symmetry axis for properties such as the refractive index or dielectric tensor of a liquid-crystal phase; at a molecular level it is commonly associated with the preferred orientation of the unique axis of the constituent molecules, either rod like or disc like

Discotic
Indicates the disc-like shape of the anisotropic molecules that constitute a class of liquid-crystal phases known as discotic liquid crystals

Disorder Model
Derived from Monte Carlo simulation studies, this model describes electronic transport in random media in terms of disorder-induced fluctuations of both hopping site energy and relative orientation

Distribution Function
A function of $\boldsymbol{p}$ (impulse) and the carrier's coordinate, which obeys *Boltzmann's equation* and presents a semiclassical probability description of a carrier's statistics and dynamics. At equilibrium, it converts to the Fermi function over the carrier's energy, which in turn reduces to a Maxwell–Boltzmann distribution for lightly doped semiconductors

Donor
An impurity in a material that is capable of inducing electrical conduction in that material by transferring an electron to the conduction band. A donor's level is the energy E_d of an electron in an orbit near the donor atom. The donor concentration is the number of donors per cm^3, referring to either the total concentration N_d or the concentration of ionized donors N_d^+

Donor-Acceptor Sensitization
Carrier generation via charge transfer (CT) exciton

Dopant
An atom from a different group of the periodic table from the host atom that substitutes for it. It can be a donor, acceptor, or amphoteric and is deliberately incorporated to give n- or p-type conductivity

Doped Semiconductor
A semiconductor that contains donors and/or acceptors. *Lightly* and *moderately-doped* semiconductors contain impurities with energy levels that are well separated from the CB and VB. *Heavily-doped* semiconductors (n^+- or p^+-type) contain so many dopants that their energy levels merge with CB or/and VB, which leads to metallic conduction at low temperatures. For n-Si, the critical donor concentration of this, Mott's insulator–metal transition, proves to be about 3×10^{18} cm^{-3}. Fermi–Dirac statistics must be used for carriers in n^+- or p^+-type semiconductors, but in n^+- or p^+-Si, full degeneracy of carriers is met only well below room temperature

Double-Negative Medium
A material composite or medium that exhibits simultaneously negative dielectric permittivity and magnetic permeability

Drift Mobility
Velocity per unit of applied field imparted to a charge carrier by the electric field. In the presence of carrier traps it is reduced from the free-carrier velocity by the fraction of time a carrier spends in the trapping centers

Drude Formula
Phenomenological equation for the free-carrier contribution to the *dielectric constant/susceptibility*. It contains two parameters: the effective plasma frequency and the relaxation time

Drum Photoreceptors
Devices where the layers are coated sequentially on a metal drum substrate

Dual-Layer Organic Photoconductor
A photoconductor with an architecture where the charge-generation and charge-transport functions are carried out in separate layers

Dynamic Coercivity
The change of coercivity of small ferromagnetic particles with switching time under thermal excitation

E

E Layer
Thin ferromagnetic cobalt alloy film added to one or two sides of the Ru layer in a synthetic ferrimagnetic media to increase the exchange coupling

E′ Center
A kind of unpaired-electron dangling bond in oxide glasses. In SiO_2, an Si atom that is bonded to three O atoms may have one E′ center. The center, which may be produced by radiation, gives ESR signals and optical absorption at $\hbar\omega \approx 6\,\mathrm{eV}$

Easy Axis
Direction in a ferromagnetic sample along which the magnetization is oriented in the absence of an external magnetic field. In thin films, the easy axis is the direction in a substrate surface along which the director tends to align; it is determined by the nature of the surface treatment

Edge-Defined Film-Growth Technique
Shaped crystals, including tubes, sheets, etc., are grown through a die placed on the melt surface

Edge-on Orientation
Parallel orientation of the π–π stack to the substrate

Effective Mass
Generally a set of parameters describing the dynamics of the current carriers, which may deviate drastically from the free-electron mass. For Si, it includes the effective mass tensor of electrons in the CB (m_t, m_t, m_l) and the masses of heavy (m_1), light (m_2) of spin orbital split-off (m_3) holes in the valence band. Generally, $m_{1,2}$ depend on the direction of hole's momentum. Different averages over this direction define masses that enter the conductivity and the density of states

Einstein Relation
An equation connecting the mobility μ, (speed per unit electric field) of a charged particle to its diffusivity D. Specifically $\mu = qD/(k_\mathrm{B}T)$, where q is the electric charge on the particle. This expression is only valid for nondegenerate material

Elastic Compliance Constant (*C*)
Defined from Hooke's law by $X = Ce$, where X is the stress and e is the strain. It has units of pressure

Elastic Deformation
Deformation of a body in which the applied stress is small enough that the object retains its original dimensions once the stress is released

Elastic Stiffness Constant (*S*)
Defined from Hooke's law by $e = SX$, where e is the strain and X is the stress. It has units of inverse pressure

Elasticity
A property of liquid crystals that causes the directors to be uniformly aligned parallel to each other. Deviations from this uniform ground state require the addition of elastic energy to the liquid crystal

Electrically Conductive Adhesives (ECA)
Composite materials consisting of a dielectric curable polymer and metallic conductive particles. The polymer is an adhesive material that chemically reacts with metals and other polymers to form a bond. The metallic particles in the ECA form a network in the cured joint, which forms an electrical conduction path

Electroabsorption
Generic term for all effects of changing the absorption coefficient upon applying a strong electric field. For Si, the dominant is the change of the free carriers' absorption in IR

Electroabsorption Modulator (EAM)
Light transmittance modulator based on the *Quantum-Confined Stark Effect* (QCSE)

Electron
Elementary particle having a negative charge of 1.602×10^{-19} C and rest mass m_0 equal to 9.109×10^{-31} kg

Electron Affinity
The energy distance from the conduction-band minimum to the vacuum level at the semiconductor surface

Electron-Beam Lithography
Method for micro and nanoscale fabrication where a pattern on a polymeric layer (resist) is exposed to electron irradiation

Electron Level Number 2 (EL2)
The deep levels in most semiconductors were labeled according to their observation during DLTS measurements. EL levels are donors (they are neutral when they have their electron). HL levels are acceptors (they are neutral when they have their hole). EL2 is the most important deep donor level (actually, a double donor) and is either the As anti-site defect or contains the As anti-site as a component

Electron–Phonon Scattering
In Si, in addition to scattering by deformation phonons, scattering may also occur with short-wavelength (inter-valley) phonons

Electronic Wavefunctions
Solutions (or eigenfunctions) of the Schrödinger equation which present the electron's position in an atom. The electronic wavefunctions have to be infinite, continuous, and single-valued and their square modulus presents the probability distribution of an electron in the atom

Electro-Optic Effect
A change in refractive index upon application of a strong electric field. This is linked to electro-absorption through the Kramers–Kronig relation. It manifests itself as a change in *birefringence* in response to an applied electric field

Electrophotography
Printing technology in which charged marking particles are developed on an organic photoreceptor with an image pattern of surface charge, the electrostatic latent image, and the subsequent transfer of these particles to a receiver

Electroplating
Process used to deposit a material on a conducting

substrate in a chemical bath containing metal ions using electrical current

Eley–Rideal Reaction
A surface-reaction scheme in which an arriving chemical species reacts on the surface without any surface diffusion process. It is considered the counterpart of a Langmuir–Hinshelwood reaction

Ellipsometry
Method of defining the optical constants by measuring the ratio of reflectance for s- and p-polarized radiation, and the relative phase shift between the two, at large incidence angles

Elliptical Dichroism
See *Asymmetric Transmission*

Emission Device
An emission device creates photons from extra electron–hole pairs through a process called radiative recombination. The electron–hole pairs are often created by forward-biasing a pn junction

Encapsulation
A dielectric polymer material that flows over and covers the electronic components in a package to provide mechanical and electrical protection to the packaged devices

Energy-Band Spectrum
Dispersion relation $E_s(\boldsymbol{k})$ of allowed electron energy to $\boldsymbol{k}$ within the *Brillouin zone*. As a function of small deviation of $\boldsymbol{k}$ from the extrema points of $E_s(\boldsymbol{k})$ it proves to be anisotropic parabolic for the conduction band and non-parabolic for valence band, forming ellipsoid valleys and warped spheres, respectively, in the *Brillouin zone*

Energy Gap
See *Band gap*

Epitaxial Layer (or Epilayer)
Thin crystalline layer on a single-crystal substrate with orientation and lattice structure determined by the substrate crystallography

Epitaxy
(Greek; arrange upon). This is the growth of one crystal (the epitaxial layer) on the surface of another (the substrate) and where the orientation of the grown layer is the same as the substrate. If the layer is of the same material as the substrate, the growth is homoepitaxial. If the layer and substrate are different, the growth is heteroepitaxial. Usually, epitaxy can only be performed where there is a close match between the lattice constants, although it is possible for a layer of quite different lattice constants to be grown if there is a change in crystal orientation between the layer and the substrate. The term epitaxy was introduced to describe the importance of having parallelism between two lattice planes with similar networks of closely similar spacing

Equivalent Oxide Thickness (EOT, t_{eq})
The theoretical thickness of SiO_2 that would be required to achieve the same capacitance density as an alternative dielectric material. This is often determined by quantum-mechanical modeling of the *C–V* curve for thin dielectric layers (where tunneling effects result in substantial *leakage* current) and/or where poly-Si gate electrodes (resulting in depletion effects) are present

Etch Pit Density (EPD)
The usual way in which substrate suppliers quote dislocation densities. EPD is found by etching the surface in molten alkalis, like KOH, and viewing the resulting pitted surface under an optical microscope. Each pit represents a single dislocation ending at the surface

Ewald Sphere
Geometrical construction used to illustrate the relationship between a diffraction pattern and the reciprocal lattice of a diffracting crystal

Exchange Field (H_{ua})
Parameter characterizing the strength of the coupling of a ferromagnetic to an antiferromagnetic film. Measured in Oe or A/m

Exciton
An electron–hole pair, which behaves like a H atom, with a binding energy of 10−100 meV and lifetime of ≈ 1 ns. The wavefunction, in principle, extends over the whole crystal

Exhaustion Concentration
$N = |N_d - N_a|$ is the maximum attainable carrier concentration in a doped semiconductor

Extrinsic Optical Activity
A rare instance of the optical activity phenomenon. It occurs in the presence of chirality, which is drawn extrinsically, i.e., from the experimental arrangement that includes not only molecules (or metamolecules) but also the wave propagation direction. The molecules (metamolecules) must be oriented and can be structurally achiral

F

Face-On Orientation
Perpendicular orientation of the π–π stack to the substrate

Fermi–Dirac Distribution
A distribution function that describes the number of particles over energy states in a material. The function is written as: $\bar{n}_i = 1/\left(e^{(\varepsilon_i-\mu)/(k_B T)} + 1\right)$, where k_B is Boltzmann's constant, T is the temperature, ε_i is the energy at state i, and μ is the chemical potential

Fermi Level or Fermi Energy
For a metal, the Fermi level is defined as that energy below which its one-electron levels are occupied and above which they are empty in the ground state, i. e., at zero temperature. In the context of semiconductors, the term Fermi level is a synonym for their electrochemical potential

Ferroelastic
A material that exhibits a phase transition from a non-strained to a strained state, generating a spontaneous strain at the transition, and in which the spontaneous strain can be switched between two or more stable states by the application of a stress

Ferroelectric
A polar dielectric in which the polarization can be switched between two or more stable states by the application of an electric field

Ferroelectric Domains
Adjacent regions in a ferroelectric crystal that have their spontaneous polarization vectors inclined to one another

Ferroelectric Hysteresis
The loop that is produced when the polarization in a ferroelectric material is plotted as a function of applied electric field

Ferroelectric Relaxor
A ferroelectric that shows a broad peak in relative permittivity at the paraelectric-to-ferroelectric phase transition and in which the temperature of the peak is strongly dependent upon measuring frequency

Fick's First Law of Diffusion
For diffusion parallel to the x-axis the diffusant flux (atoms per unit area per second) is equal to $-D\partial c/\partial x$, where c is the diffusant concentration that defines the diffusivity D

Fick's Second Law of Diffusion
Based on the first law, this law gives the rate of build up of the diffusant concentration at a given depth as $\partial c/\partial t = \partial(D\partial c/\partial x)/\partial x$

Field-Effect Transistor (FET)
A transistor where the current between two electrodes (the drain and source) is modulated by the electric field from a third electrode (the gate)

Field Emission
Electron emission from a metal or semiconductor into vacuum under the influence of a strong electric field

Figure-of-Merit (FOM)
Measure of the performance of an integrated circuit technology. The time delay associated with signal propagation is a common metric

Fill Factor (FF)
Measure of the maximum power that can be obtained from a photovoltaic solar cell compared with the product $I_{sc} \cdot V_{oc}$

Firing
One of the key stages of the thick-film production process. It is usually undertaken in a continuous-belt furnace at temperatures of up to 1000 °C

Flat band Voltage (V_{FB})
The voltage applied across an MIS device at which there exists no charge in the semiconductor. As a result, the valence and conduction band structure of the semiconductor are flat. This condition occurs when this voltage equals the work function difference between the metal electrode and the semiconductor under ideal conditions. The presence of charges in the insulator or at the interface, due to defects, modifies the voltage required to achieve the flat band condition

Flexoelectricity
Generation of a macroscopic electrical polarization in a nematic liquid crystal when the director distribution is deformed from its uniform state of alignment. The inverse of this effect is the deformation of the director distribution when an electric field is applied to a nematic; the magnitude of the deformation is linear in the field

Flip Chip
Integrated-circuit-level interconnect that can be used to replace wirebond interconnects. The flip chip is a solder bump on an area array on the chip surface that routes the power, ground, and signals from the integrated circuit to the bumps. The metallization on the IC surface is called the under-bump metallurgy and forms a metallurgical bond with the solder. The flip-chip die is joined to the package by placing the die face down on the matching bond pads on a substrate and reflowing the solder to form an electrical, thermal, and mechanical interconnect

Floating Gate Current
Very small gate currents ($\approx$ fA or less) can be measured using the floating gate technique in which the drain current of a MOS transistor is measured after the gate bias has been removed. Then, by using the decay in the drain current as a function of time and the measured drain current versus gate voltage characteristics and the oxide capacitance, the gate current can be calculated

Floating Zone (FZ) Technique
This technique uses a solid feed rod that is melted at its lower end by a high-frequency coil. The melt flows through a central hole of the coil down to the growing crystal below the coil. The FZ technique does not need a crucible. Hence, the melt is not contaminated by other materials. The crystals that are grown according to the FZ technique are called FZ crystals

Fluence
The total, time-integrated, flux of particles (electrons, protons, ions, etc.) that reach a unit area of sample. It can be used to represent the total number of ions implanted into a surface and is sometimes called the dose

Fluorescence
Luminescence with a lifetime $\lesssim 10$ ns

Fluoride Glasses
Multicomponent glasses, typically based on fluorides of zirconium, barium, lead, gallium, lanthanum, aluminum, and sodium. They have a wide transparency range, from ultraviolet to mid-infrared wavelengths. They also have low characteristic phonon energies and can dissolve large concentrations of rare-earth ions. For these reasons, they are extremely popular as hosts for rare-earth-doped amplifiers and lasers operating in the UV/visable and mid-infrared regions

Flux Lines (Vortices)
Regions in which magnetic flux enters a type II superconductor in the mixed state. Screening currents flow around each of the flux lines. Due to the repulsive vortex–vortex interactions a hexagonal flux line lattice is formed

Flux Pinning
An effect caused by defects. The energy for the formation of the normal cores of the flux lines is reduced in regions with a reduced Cooper-pair density

Flying Height
Spacing between the bottom of the slider and the top of the recording medium in a disk drive

Focal Plane Array (FPA)
Focal plane array consisting of an HgCdTe sensor on a silicon ROIC

Forced Convection
Process of forced flow of fluid

Fourier-Transform Infrared (FTIR) Spectrometry
A means of performing infrared absorption measurements with great speed and precision, based on an optical interferometer

Four-Point Probe
A popular technique used to measure the resistivity (Ω cm) of a semiconductor sample. Four collinear probes are equally spaced, a current is applied through the outermost probes, and the voltage difference across the two inner probes is measured. From the voltage and current values, the resistivity can be calculated assuming that the contact and spreading resistances between the probes and the semiconductor and the resistance of the probes are negligible in comparison to the resistance of the semiconductor

Franck–Condon Principle
Absorption and emission of light takes place in such a short time that the atomic coordinates in ground and excited states are unchanged; i. e., transitions are vertical on a configuration coordinate model

Free Convection
The process of movement of fluid through a temperature gradient

Free Film
Ferromagnetic film in a magnetoresistive or spin-valve read head in which the magnetization can respond easily to an external magnetic field

Frenkel Exciton
Strongly bound electron–hole pairs

Friedel's Law
A law that states that the intensity of an *hkl* reflection in a diffraction pattern is equal to the intensity in the opposite $\overline{hkl}$ reflection

Front End of Line (FEOL)
A term generally describing the initial points in the integrated-circuit fabrication process line, such as the transistor fabrication steps. These processes generally require higher thermal budgets

G

Gate Oxide Integrity (GOI)
GOI measures the breakdown stability of the oxide layer of a MOS capacitor when a voltage is applied to the capacitor. There are different types of gate oxide integrity tests. Most of these are standardized. This may currently be the best method to detect the density of very small voids

Geminate Recombination
The primary recombination of a correlated (quasi-bound) hole–electron pair immediately following photoexcitation

Germanene
A single layer of sp^2 bonded Ge atoms in a honeycomb shape

Ghosting
The change of X-ray sensitivity of the X-ray image detector as a result of previous exposure to radiation. In the presence of ghosting, a shadow impression of a previously acquired image is visible in subsequent uniform exposures

Giant-Magnetoresistive (GMR) Effect
Change in the resistivity of a stack of ferromagnetic films coupled by thin non-ferromagnetic films when the orientation of the magnetization of the films adjacent to the non-ferromagnetic film is varied. The change in resistivity with low temperatures and high magnetic fields was observed to be as large as 50%; hence the adjective *giant*

Glass Ceramics
Glass that contains crystalline particles or regions. Such materials may be transparent or smoggy

Glass Frit
Binding matrix within the thick film. This binds the active particles together and also bonds the thick film to the substrate

Glass-Transition Temperature
The approximate temperature at which a material changes from a supercooled liquid to an amorphous solid, or vice versa. The transition is marked by an abrupt but continuous change in slope of the specific volume and enthalpy versus temperature curves. Viscosity varies rapidly near the glass-transition temperature, which is also sometimes called the softening temperature

Glow Discharge Spectrometry (GDS)
A method in which a spectrometer is used to measure relevant intensities emitted from a glow discharge generated at a surface. This is a general term that encompasses glow discharge optical-emission spectrometry (GDOES) and glow discharge mass spectrometry (GDMS). GDOES is a method in which an optical-emission spectrometer is used to measure the wavelength and intensity of light emitted from a glow discharge generated at a surface. GDMS is a method in which a mass spectrometer is used to measure the mass-to-charge quotient and abundance of ions from a glow discharge generated at a surface

Gradient Freeze Growth
This technique is similar to the *Bridgman method* except that the melt is not physically removed from the furnace. Instead, the temperature gradient along the melt is controlled electrically so that solidification commences at the seed and progresses until the melt is

exhausted. Once again, both horizontal and vertical arrangements are possible, and often the reservoir is replaced by liquid encapsulation to impede As loss from the melt. This is now the favored technique for the growth of most GaAs substrate material

Grading
Grading is the gradual change from one semiconductor to another, exemplified by the gradual change from GaAs to GaAsP that is necessary in some LEDs

Grätzel Cell
Named after its inventor, Michael Grätzel, this is a dye-sensitized cell using a porous TiO_2 substrate to collect the photo-generated charge

GRINSCH Laser
A graded-refractive-index separate-confinement heterojunction laser (see *Separate Confinement Heterojunction (SCH) Laser*). Optical confinement is optimized by grading the composition of the cladding layers

Gunn Diode
(See *Negative Differential Resistance*). This is a device based on low-doped, n-type GaAs and relies on the NDR effect. It is used for the generation of low-power microwave currents

H

Hall Effect
The deflection of a charged particle moving in a magnetic field that is perpendicular to its motion. The deflection is due to the Lorentz force on the charged particle and it causes the charges to accumulate on one side of the sample. The voltage measured at right angles to the current flow is called the Hall voltage. The Hall effect can be used to characterize the mobility (cm^2/Vs), resistivity (Ω cm), type of carrier, and carrier density (cm^{-3}) of a semiconductor sample. The *Hall mobility* is the product of conductivity and the Hall constant (the transverse-electric-field Hall field divided by the product of the current density and the magnetic induction) of a conductor or semiconductor; a measure of the mobility of the electrons or holes in a semiconductor. The *Hall coefficient* and *factor* relate μ^{H} linearly to σ and μ, respectively

Hard Axis
Direction in a ferromagnetic sample at right angles to the easy axis

Hard Magnetic Bias Film (also Longitudinal Bias Film)
Permanent magnetic film abutted to the free film in a magnetoresistive or spin-valve head to eliminate magnetic domains

Head Field Slope Parameter (Q)
The maximum slope of the magnetic field of a write head in the direction of the magnetization of the recording layer normalized to the coercive field (H_c) divided by the magnetic spacing (d), $Q = \frac{\mathrm{d}H_x/\mathrm{d}x}{H_c/d}$

Heat Capacity
The amount of heat required to change the temperature of a substance temperature by 1 degree, with units of energy per degree

Heteroepitaxy
The growth of a layer of markedly different composition from the substrate, i. e., the epitaxial layer and the substrate are made from different materials, e.g., the diamond growth on an iridium single-crystal substrate. Another example is the growth of $Ga_xIn_{1-x}P_yAs_{1-y}$ layers lattice-matched to InP. The heteroepitaxial growth techniques are chemical-vapor deposition, liquid-phase epitaxy, and molecular-beam epitaxy

Heterojunction Bipolar Transistor (HBT)
A modification to the standard bipolar transistor where a heterojunction is used to control the carrier flow at the base

Heterojunction Laser
A semiconductor laser where both electrical and optical confinement exploit the properties of heterojunctions is a heterojunction laser. If the active region is sandwiched between two heterojunctions, the laser is termed a double heterojunction

Heterojunctions and Heterostructures
A heterojunction is the junction between different materials (e.g., GaAs and AlGaAs with different band gaps). Such a junction exhibits several properties that may be very useful to device manufacturers. These include changes in the energies of the valence or conduction bands, or both, and changes in the optical properties. A heterostructure is a semiconductor structure where the properties of heterojunctions are exploited

Heterostructures
Multilayer structures that have regions of different composition within them; used in advanced IR device types

Hexagonal As
The natural form of elemental arsenic

HgZnTe
An alternative Hg-based ternary system to MCT

Hierarchical Nanostructuring
The combination of introduced defects/impurities in a thermoelectric material with different characteristic length scales and meant to scatter phonons with a wide range of wavelengths

High Impedance Surface
A planar metamaterial, which acts as a ground plane that does not support propagating surface waves (see *Magnetic Mirror*.)

High Index Contrast
Waveguides or devices fabricated using two or more materials that have very different refractive indexes. High index contrast is the basis for the confinement of light to very small cross-sectional-area waveguides or very-small-volume optical cavities, either using total internal reflection or photonic band gap effects. High

index contrast is thus the basis for increased density of optical integrated circuits

High-Electron-Mobility Transistor (HEMT)
A modification of the *metal semiconductor field-effect transistor (MESFET)* where the separation of the electrons in the channel from the ionized donors is achieved by using a heterojunction. This results in higher electron mobility and thus greater speed and lower noise

Highest Occupied Molecular Orbital (HOMO)
The highest energy molecular orbital of an atom or molecule that contains an electron. If the atom or molecule were to lose an electron, it would most likely lose it from this orbital

High-Temperature Solution Growth
Slow cooling, or top-seeded (similar to Czochralski) growth of materials in a solution designed to reduce the freezing point of the desired phase below a critical temperature

Homeotropic Alignment
Alignment of the director perpendicular to the surface of a substrate

Homoepitaxy
Epitaxial growth of a layer of the same composition as the substrate

Homojunction
Junction between materials of the same chemical type but of different electrical properties. For example, a p-n junction in GaAs is a homojunction

Hopping Conduction
Electronic transport that localized electrons hop from site to site with the assistance of phonons

Hot-Carrier Phenomena
Group of effects associated with the carrier transport in high electric fields. For Si, it includes the nonlinear relation between drift velocity and electric field with saturation (n-Si) and near saturation (p-Si), anisotropy of drift velocity regarding the electric orientation relative to the crystallographic axes (the Sasaki–Shibuya effect), and the diffusion's anisotropy as regards the density gradients along and perpendicular to the strong electric field

Hot-Wire Chemical Vapor Deposition (CVD)
The same technique as catalytic CVD, which is used for thin-film growth through decomposition of source gas materials utilizing catalytic reaction on the heated filament

Huygens's Principle
Concept used to explain the propagation of a wave (and diffraction processes), in that every point on a primary wavefront acts as a source of spherical wavelets, the envelope function of which acts to reconstruct the primary wavefront a short time later

Hybrid Circuits
Circuits consisting of electronic elements made from differing enabling technologies such as thick-film, thin-film, monolithic silicon, etc.

Hybridization
In molecules, the orbitals occupied by the electrons are seldom pure s or pure p orbitals. Instead, they are mixed or hybrids, formed by combining the s and p orbitals. Examples are sp (linear), sp^2 (trigonal and planar), and sp^3 (tetragonal)

Hydrothermal Growth
Growth that takes place in aqueous-based solutions at high temperatures and high pressures

Hyperbolic Metamaterial
An artificial material composite characterized by a hyperbolic dispersion of the supported (propagating) waves. Such dispersion is typically found in composites of extreme anisotropy, where the sign of dielectric permittivity is reversed for the directions parallel and orthogonal to the anisotropy axis

Hysteresis
The state of the magnetization in response to an external magnetic field depends on the initial state of the magnetization

I

***I/V* Technique (Current–Voltage Technique)**
The *I/V* technique is a method to determine barrier heights and ideality factors of Schottky contacts from their current–voltage characteristics

Ideality Factor
The ideality factor of Schottky contacts characterizes the variation of their barrier heights as a function of applied voltage

Image Lag
Lag is the carryover of image charge generated by previous X-ray exposures into subsequent image frames. The residual signal fractions following a pulsed X-ray irradiation are referred to as image lag

Impact Ionization
Process of generation of electron–hole pairs by carriers moving in an electric field higher than the breakdown threshold, which for Si is of the order of 3×10^5 V/cm

Improper (or Extrinsic) Ferroelectric
A ferroelectric material in which spontaneous polarization is not the primary order parameter. Frequently, the primary order parameter is the spontaneous strain associated with a ferroelastic phase transition

Impurity
A foreign atom unintentionally present in the semiconductor, incorporated either during growth or processing

Inelastic Scattering
The result of a collision between a photon or electron and the nuclei or electrons of a material, such that there is a net change in the internal energies of the system and in the sum of the kinetic energies before and after the collision

Infrared-Laser-Absorption Spectroscopy (IRLAS)
Technique to determine the density of gas-phase molecules and chemical species using infrared absorption spectra

Infrared-Reflection-Absorption Spectroscopy (IRRAS)
Technique to determine the surface-bonding

configuration on the film-growing surface using light absorption during reflection of an infrared beam

In-Situ Monitoring
Tools to help in understanding layer growth kinetics and to provide monitors suitable for feedback control in epitaxial growth systems

Integrated Circuit (IC)
Combination of active and passive circuit elements to enable computational logic or analog operations

Integrated Detector Cooler Assembly (IDCA)
A commonly used infrared detector scheme in which the detector is mounted directly on the cold finger of a cryocooler (often based on Stirling cycle engines). The detector and cold finger are then enclosed in a vacuum vessel with a transparent window and optical baffles

Integrated Optics/Photonics
The manufacture of photonic elements and circuits on a planar substrate, typically using thin-film deposition, lithography, and etching steps. Typically, the substrate is a glass or semiconductor wafer, and the photonic elements are guided-wave devices

Interconnect
The system of metal conducting lines and contacts among IC components. The categories include local (between neighboring devices), intermediate (between neighboring circuit elements), and global (across the IC chip)

Interdiffused Multilayer Process (IMP)
The process of obtaining a uniform alloy composition of $Cd_xHg_{1-x}Te$ by the growth of alternate layers of the binary compounds that are thin enough to completely interdiffuse within the time of growth

Interface Trap Density
The density (cm^{-3}) of positive or negative charges located at the silicon/silicon dioxide interface, due to defects induced by oxidation, structural defects, impurities, or other defects caused by bond-breaking mechanisms such as radiation or hot carriers. These states are typically in electrical communication with the charges in the channel of a MOSFET and results in stretch-out of the capacitance–voltage characteristics. They also affect the turn-on and turn-off characteristics of a MOS transistor

Interface-Induced Gap States
Because of the quantum-mechanical tunnel effect, the wavefunctions of electrons tail across semiconductor interfaces in energy regions where occupied states overlap a band gap. These evanescent waves are the continuum of the *intrinsic* interface-induced gap states

Intergrain Critical Current Density
Macroscopic transport critical current density, which can be much smaller than the intragrain j_c because of the weak-link behavior of large-angle grain boundaries in the cuprate superconductors

Intermetallic Compounds
Substances that form between pad metallizations and the active components of molten solder (typically Sn). For Cu metallization, Sn reacts to form Cu_3Sn and Cu_6Sn_5 intermetallics. For Ni, Sn reacts to form Ni_3Sn_4. These intermetallics typically form at the interface of the solder and the metallization and are usually more brittle than the solder or the metallization

Intermetallic Reactions And Phases
Two or more metals can react chemically to produce compounds. These are revealed in phase diagrams as labeled, vertical lines. The compound is often referred to as an intermetallic phase

Internal Photoemission Yield Spectroscopy (IPEYS) Technique
IPEYS is a method to determine barrier heights of Schottky contacts and band offsets of semiconductor heterostructures by photoinjection of hot electrons over the energy barriers at metal/semiconductor and semiconductor/semiconductor interfaces, respectively, as a function of the photon energy of the exciting light

Interstitial
A site lying between regular lattice sites that can be occupied by dopant, impurity, or host atoms. The latter case is known as a self-interstitial. It generally behaves as a donor

Intersubband (ISB) Transition
Transition between confined states within the conduction or valence bands

Intragrain Critical Current Density j_c
The value of critical current density j_c within a single grain, limited only by the pinning properties

Intrinsic Point Defect
Is the general term for either a vacancy or a Si interstitial in the Si matrix

Inversion
Condition in which, for a MIS structure, the applied voltage to the gate electrode V_G results in an increase of minority carriers near the surface of the underlying semiconductor. This region is referred to as an inversion layer. When present in a MISFET, this condition results in a conducting channel between the source and drain regions. This condition occurs for applied voltages beyond the threshold voltage, i. e. $V_{th} < V_G$

Inversion Symmetry
A system in which the laws of physics are unchanged by the operation of inversion

Ion Implantation
A method of introducing impurities into the surface of a solid. The impurity atoms to be introduced are ionized and accelerated by a high voltage, up to 10^6 V in some instances. They penetrate the surface to a depth dependent on their energy. Unfortunately, this disrupts the crystal lattice by introducing irradiation damage, which in turn must be repaired by annealing at elevated temperatures before the electrical activity of the implanted atoms can be obtained

Ionization
Process of forming an electrically charged atom (ion)

Ionization Energy
The energy distance from the valence-band maximum to the vacuum level at semiconductor surfaces

Irreversibility Line
Situated well below the upper critical field, this line separates a region without pinning and zero j_c, above the irreversibility field, from a region with pinned vortices ($j_c > 0$)

Irvin Curve
The experimental resistivity ρ of Si at room temperature versus N, the free-carrier concentration

Isostructural Solid Solution
A type of alloy solid solution in which an atom substituted in a lattice has the same valence electron structure as the atom it replaces

K

Kikuchi Lines
Diffuse background of lines in a diffraction pattern formed by the elastic scattering of incoherently scattered electrons

Knudsen Cell
High-vacuum oven from which molecular beams can be produced in molecular-beam epitaxy. These ovens are usually fitted with temperature sensors. Shutters mounted in front allow the beams to be turned on and off, as required

Kramers–Kronig Relations (KKR)
Dual integral relations between the real and imaginary parts of a one-sided Fourier transform of causal functions of time, which includes all physical admittances. KKR allow us to define the optical constants based on KKR relations for amplitude and phase of complex reflection coefficients from an opaque sample of the material under measurement

Kyropoulos Technique
This is similar to the Czochralski method but the extent of pulling is limited, producing crystals of greater diameter but shorter length

L

Langmuir–Blodgett Film Deposition
Method to build up multilayer structures of organic materials by the transfer of a monolayer floating on a water surface to a solid substrate as the latter is raised and lowered through the monolayer/water interface. Deposition modes include Y-type (monolayer transfer from the water surface to the substrate on both the upward and downward motion of the latter through the monolayer/air interface), X-type (film transfer only on downward motion of the substrate), and Z-type (film transfer only on the upstroke)

Laporte's Rule
Transitions between states of the same parity are forbidden

Laser Crystallization
A useful method to fabricate polycrystalline semiconductors showing high electron mobility by irradiating laser beams on amorphous semiconductor thin films

Laser-Induced Fluorescence (LIF)
Technique to determine the density of gas-phase atoms and molecules whose optically excited states are emissive states

Lattice-Matching
Growth of quantum wells on a substrate with the same, or very similar, lattice constant

Law of Mass Action
An equation linking the concentrations of the various reacting species in a chemical-type equation, derived from defect chemistry analysis

Lifetime
Minority-carrier lifetime is one of the electrical parameters determining the performance of IR devices; it can be affected by impurities and/or dopants

Light-Induced Defect Creation
The defect creation associated with illumination of samples. This is normally observed in amorphous materials having a flexible network

Lineage
A reduction in the total dislocation strain energy can be obtained either by polygonization or by dislocations arranging themselves in linear arrays. The latter results in the creation of a small-angle grain boundary or lineage. The reader will find examples of this in most books on materials science

Liquid Crystal
State of matter with properties characteristic of both a liquid and a crystal; that is, it flows like a liquid and certain properties are anisotropic like those of a crystal. At the molecular level the phase has long-range orientational order and some element of translational disorder in the long range

Liquid-Encapsulated Czochralski Technique
An inert layer, usually B_2O_3, is used, which floats on the top of the melt to prevent loss of volatile components; this is used for As and P-containing compounds

Liquid-Phase Epitaxy (LPE)
LPE is epitaxial growth of a layer by dissolving the required material in a liquid. On cooling, the material becomes supersaturated and forms a solid film. If this film is deposited on a substrate, the growth can be epitaxial

Localized Vibrational Mode (LVM) Absorption
A form of mid to far-infrared absorption resulting from simple vibrations of light atoms in a heavier lattice. Such vibrations do not couple well to lattice vibrations and result in sharp absorption lines, whose frequencies are directly related to mass and whose strengths are proportional to concentration. LVM absorption is particularly suited for measuring carbon concentrations in SI GaAs

Long Wave (LW)
This term refers to the transparent atmospheric window between the wavelengths 7.5 and 14 μm (sometimes called the thermal band). The edges of

this window are influenced by the water-vapor content and atmospheric conditions

Longitudinal Magnetic Recording
Recording system consisting of a write head and a read head and a recording medium where the magnetization is parallel to the surface of the recording medium

Long-Range Disorder
Defined by the absence of the long-range order, i. e., the lack of periodic arrangements of atoms

Low-Dimensional Structure
Heterostructure with dimensions comparable to the wavelength of an electron or hole, typically less than 100 Å, so that quantum effects are important

Lowest Unoccupied Molecular Orbital (LUMO)
This refers to the lowest-energy molecular orbital of an atom or molecule that does not contain an electron. If the atom or molecule were to accept an electron, it would be most likely to do it with this orbital

Low-Frequency Noise
Electrical measurement of the current or voltage noise spectral densities of a semiconductor component, typically at frequencies from ≈ 1 Hz to ≈ 100 kHz. The units are in A^2/Hz for current noise spectral density and V^2/Hz for voltage noise spectral density. It is a sensitive electrical technique that can be used to probe microscopic defects in semiconductor components and as a gauge of their reliability

Low-Temperature Co-fired Ceramic (LTCC)
A composite material structure made of alumina bonded at a temperature below the sintering temperature of alumina using a glass binder. In a substrate form, LTCC can be co-fired (melting the glass and bonding the alumina while capturing the metal interconnects and lines) at lower temperatures, so it is possible to use higher conductivity materials like Cu or Ag conductors in the ceramic

Low-Temperature Solution Growth
Normally used for water-soluble materials, with growth being progressed by either slow cooling or solvent evaporation

L-Pit
See *A-Swirl*

Luminescence
In general terms, this is the emission of light by a luminescent material (also called phosphor) due to conversion of a certain type of energy into electromagnetic radiation over and above thermal radiation. The luminescence is the light emitted by nonthermal sources in contrast with the emission of radiation from a heated object, which is called incandescence. In accordance with the source of energy the luminescence may be the photoluminescence (excited by external illumination), electroluminescence (induced by the passage of electrical current), cathodoluminescence (excited by irradiation with electrons), triboluminescence (excited by mechanical treatment, e.g., grinding), chemiluminescence (emitted during chemical reaction), bioluminescence (appearing as a result of biological processes), thermoluminescence (cased by temperature rise), and so on

M

Magnetic Annealing
Thermal process involving a ferromagnetic sample in a magnetic field in which the sample has induced a direction of easy magnetization (easy axis)

Magnetic Mirror
A planar metamaterial, which acts as a mirror that preserves, rather than reverses, the phase of electromagnetic waves upon reflection

Magnetic Random-Access Memory (MRAM)
Digital memory device composed of ferromagnetic thin films coupled to current-carrying conductors used to establish the direction of the magnetization in the ferromagnetic films. The resistance of the coupled films is different when the direction of magnetization in the two ferromagnetic films changes

Magnetic Spacing
Spacing between the bottom of the slider and the center of the ferromagnetic storage layer in a recording medium characterized by the magnetic spacing parameter d

Magnetic Transition
In digital magnetic recording, the region between opposite states of the magnetization in the recording medium. The length of the transition (l) is $l = \pi a$, where a is the transition parameter

Magnetic Tunneling Junction (MTJ)
Magnetic random-access memory (MRAM) in which the magnetic state of the ferromagnetic sample is sensed by the change in resistance of electron current tunneling through a thin insulating layer when the magnetization in the two electrodes coupled to the ferromagnetic sample changes from parallel to antiparallel orientation

Magnetoresistance
Change in resistance of a ferromagnetic material due to changes in the orientation of the magnetization with respect to an induced easy axis. It is sometimes referred to as anisotropic magnetoresistance (AMR) and is characterized by the change in resistivity with magnetic field normalized to the nominal resistivity $\Delta\rho/\rho$

Magnetoresistivity (MR)
The change of resistivity ρ in the applied magnetic field. For Si, MR is a diverse tensor reflecting the symmetry of the CB and VB

Majority Carriers
Electrons in an n-type and holes in a p-type semiconductor. Majority-carrier mobility is the mobility of electrons (holes) in n-type (p-type) material

Masking Effect
Severe suppression of the magnitude of photocurrent due to the development of a dead region in front of the

active region, in which the incident solar light is absorbed and no photocurrent is generated

Media Flux
Product of the remanent magnetization and the thickness of a magnetic recording film

Media Noise
Noise voltage at the terminals of a read head caused by fluctuations in the magnetization of the recording media

Medium Wave (MW)
The term for the transparent atmospheric window between the wavelengths 3.3 and 5 μm. There is a CO_2 absorption band around 4.25 μm, which divides the band into two with the better atmospheric transmission in the 3.3 to 4.2 μm band

Mercury Cadmium Telluride (MCT)
A narrow band gap II–VI semiconductor compound, $Hg_{1-x}Cd_xTe$, which is still the pre-eminent infrared (IR) material

Mercury-Sensitized Photo-CVD
Technique for preparing thin films by decomposing source gas materials by collision with photo-excited mercury atoms

Mesogen
A molecular compound or mixture of compounds capable of forming a liquid-crystal phase over a range of temperatures between the crystal and isotropic liquid phases

Meta-Atom
See *Metamolecule*

Metafilm
See *Metasurface*

Metal Semiconductor Field-Effect Transistor (MESFET)
Probably the simplest three-terminal device that can be fabricated on GaAs. The *metal semiconductor* refers to the gate structure, which is a simple Schottky barrier. The application of a reverse bias to this gate produces a depleted region that occludes part of the cross-sectional area of the channel, and thus modifies its conductivity

Metallic Nanocomposites
Composite materials made out of metallic quantum dots embedded in organic or glass hosts

Metal-Organic Chemical Vapor Deposition (MOCVD)
Technique for depositing thin films of compound semiconductors from a chemically reactive vapor phase where at least one of the components is a metal-organic

Metal-Organic Molecular-Beam Epitaxy (MOMBE)
Form of MBE where some or all beams are generated from external gas sources, in III–V MOMBE only the group III beams are from metal organic sources

Metalorganic Vapor-Phase Epitaxy (MOVPE)
A low-temperature growth technique using metal alkyls (and elemental Hg in the case of Hg-based ternary compounds) as the sources

Metal/Oxide/Semiconductor (MOS)
Structure that is one possible realization of *MIS*. The insulator has traditionally been SiO_2 (the oxide) due to its superior material and electrical properties, resulting in the abbreviation MOS

Metamaterial
Meta (a Greek preposition that can mean *after* or *beyond*) materials are artificial materials constructed with specific geometries to produce exotic behavior. Unconventional optical responses, such as a negative refractive index (leading to superlenses), result from these structures. Terahertz metamaterials are usually formed by patterning an electrical conductor, such as gold, on a substrate of an electrical insulator, such as plastic or undoped semiconductors. Metamaterials find further application in the terahertz spectral region by offering control of polarization and the possibility of *cloaking* or *invisibility*

Metamolecule
An elementary building block of a metamaterial, which is artificially built on a sub-wavelength scale from common constituent materials such as metals and dielectrics

Metastability
A term that refers to the nonequilibrium nature of glasses or amorphous solids. Amorphous solids have excess internal energy relative to the corresponding crystalline state or states of the same material. The method of manufacture, such as melt quenching, inhibits a transition to the lowest-energy crystalline state

Metasurface
A low-dimensional (planar) form of a metamaterial, represented by a thin metal film periodically patterned on a sub-wavelength scale. Although metasurfaces are many times thinner than the wavelength of light, they can strongly interact with electromagnetic waves, which they transmit, absorb, or reflect without diffraction, acting as media of zero dimension in the direction of light propagation

Microphotonics
Refers to the chip-scale manufacture of optical and photonic waveguide circuitry, using processing techniques borrowed from the microelectronics industry. Related to this is the need for high-density integrated optics, as facilitated by high-index-contrast waveguides and photonic crystals. By usual definition, microphotonics refers specifically to the monolithic manufacture of optical and photonic elements on silicon (CMOS) chips

Microwave Plasma Chemical Vapor Deposition (MPCVD) Technique
A technique for film deposition. This is now the most widely used technique for diamond growth. Energy is transferred by the microwaves to gas-phase electrons, which transfer their energy to the gas through collisions. The gas molecules dissociate, the active species are formed, and the deposition of diamond onto the substrate immersed in the plasma occurs

Miller's Rule
An empirical rule proposed by Miller in 1964, which

suggests that $\chi^{(2)}/\{\chi^{(1)}\}^3$ is nearly constant for all non-centrosymmetric crystals

Miniband
Interval of allowed energies for carriers in a superlattice, resulting from the delocalization and broadening of the quantum-well energy levels

Minimum Thermal Conductivity
The minimum value of lattice thermal conductivity of a solid, corresponding to a phonon mean free path on the order of one interatomic spacing

Minority Carriers
Electrons in a p-type and holes in an n-type semiconductor. Many electron devices work on the base of minority-carriers transport. Minority-carrier mobility is the mobility of electrons (holes) in p-type (n-type) material

Misfit Dislocations
These are dislocations introduced near the boundary of an epitaxial layer and the substrate, when a mismatch between the lattice constants exists. The density of these dislocations is proportional to the mismatch. Although they run parallel to the boundary, they can interact and penetrate much of the epitaxial layer; see *Threading Dislocations*

Mixed State
In type II superconductors, this state exists between the lower and upper critical fields. In the mixed state, superconducting and normal regions coexist. Magnetic flux enters the superconductor in the normal cores of the flux lines

Mobility
Parameter defined as the ratio of the carrier velocity (cm/s) to the electric field through which it is moving (V/cm). It is expressed in units of cm^2/Vs. At the microscopic level, it is related to the dominant scattering time and the effective mass of the carrier. The notion includes drift mobility μ, which corresponds to the motion parallel to the field and Hall mobility μ^H, which corresponds to motion perpendicular to the electric field, when a magnetic field is applied

Mobility Edge
The boundary between localized and delocalized states in a band

Mobility Gap
Energy separation between two mobility edges of the conduction and valence bands

Modulation Transfer Function (MTF)
MTF measures the efficiency of an imaging system such as a detector to resolve (transfer) different spatial frequencies of information in an image. In other words, MTF is the relative signal response of the system as a function spatial frequency

Molecular Electronics
Exploitation of organic materials for electronics and optoelectronics applications. Examples are displays based on liquid crystals and organic electroluminescent polymers. In the case of organic polymers, the area is sometimes referred to as plastic electronics

Molecular Reorientation
Nonlinear process in which the orientation of molecules in liquid changes upon illumination with intense light

Molecular-Beam Epitaxy (MBE)
Low-temperature growth technique for epitaxial films from atomic or molecular beams from thermal evaporation sources. It is carried out in ultra-high vacuum. Chemical Beam Epitaxy (CBE) is a form of molecular-beam epitaxy in which group III and group V beams are generated from external gas sources. Gas Source MBE (GSMBE) is a form of MBE where some or all beams are generated from external gas sources, in III–V GSMBE only the group V beams are from hydride sources

Molecularly Doped Polymers (MDP)
Formulations of charge-transport materials dissolved in a polymer matrix. CTLs of OPCs are typically MDPs

Monolayer (ML)
A single layer of atoms (in III–V MBE a layer of the compound or alloy, e.g. a layer of Ga + As)

Moore's Law
Prediction based upon the empirical observation by G. Moore that the minimum cost of manufacturing integrated circuits per component actually decreases with the increase in the number of IC components, and thus with greater circuit functionality and computing power. A corollary of this observation is that the density of integrated circuit transistors will double roughly every 1.5–2 years (see *Scaling*)

Moseley's Law
States that the square root of the frequency of characteristic X-rays, for certain elements, is linearly related to the atomic number

Multi-Crystalline Silicon (mc-Si)
Wafers of silicon, cheaper to produce than the single-crystal silicon wafers but with multiple single-crystal grains in each wafer

Multiple Quantum Well (MQW)
Structure composed of a stack of QWs separated by sufficiently thick barriers so that the electron wave functions and energy levels are localized to each QW

N

Nanowire
Quantum wire formed by seeded growth on a nano-patterned substrate

Narrow Band gap
Refers to a semiconductor with a forbidden energy gap of less than about 0.7 eV, making it suitable for detection in the infrared wavebands

Native Defect
A vacancy, a self-interstitial, an anti-site, or any complex of these

Negative Differential Resistance (NDR)
(See *Transferred Electron Effect*). In GaAs, electrons that undergo the transferred electron effect are excited from the primary conduction band minimum, where their effective mass is low, to subsidiary minima, where their effective mass is considerably greater. As a result, although they have greater kinetic energy, their drift velocity is lower. This, in turn, results in a reduction of current in the external circuit. The current–voltage characteristics show a reduction in current after a critical voltage is applied (although the ratio of current to voltage will always be positive). This is NDR. It can be shown that current flow in the NDR region is unstable and that charge tends to be transported in groups, resulting in oscillations in the current flow. This is the Gunn effect and is used in some microwave sources

Negative Index Medium
A medium characterized by the refractive index less than zero

Negative Refraction
An exotic optical effect characterized by anomalous change in the direction of light propagation upon refraction, when a beam of light bends the *wrong* way while crossing an interface between two media

Nematic Phase
The simplest of the liquid-crystal phases; it has long-range orientational order but is devoid of long-range translational order

Noise-Equivalent Temperature Difference (NETD)
A measure of sensitivity for a multiplexed infrared detector and the change in scene temperature that produces a signal equivalent to the rms noise level of the detector

Nonlinear Directional Coupler
A device where a part of one of two waveguides is made out of a nonlinear material. Changing the intensity of the incident light changes the effective path length experienced by the waveguided light, thus controlling coupling between the two waveguides

Nonlinear Fabry–Pérot Interferometer
A device that consists of two mirrors separated by a nonlinear material. As the refractive index of the nonlinear material changes with an increased level of illumination, the effective path length of the resonator is altered, changing the transmission properties of the device

Nonlinear Figure of Merit
A figure of merit that describes the applicability of a refractive nonlinear optical material in terms of nonlinear index change and effective absorption

Nonlinear Kramers–Kronig Transformations
A set of two relations that permits calculation of the real (imaginary) part of nonlinear response at a given optical frequency given the knowledge of the imaginary (real) nonlinear response at all other optical frequencies

Nonlinear Mach–Zehnder Modulator
A Mach–Zehnder modulator in which a part of the waveguide is made out of a nonlinear material. Changing the intensity of the incident light changes the effective path length experienced by the light at the nonlinear waveguide, controlling transmission

Nonlinear Material Figures of Merit
A set of metrics that allows us to quantify the applicability of a nonlinear optical material to optical switching

Nonlinear Optical Medium
A material whose properties change upon illumination with intense light

Nonlinear Optical Switching
Switching of optical signals using an illumination-dependent phase shift of nonlinear materials

Nonlinear Periodic Structure
A Bragg periodic structure in which at least one set of layers is nonlinear

Nonlinear Phase Shift
A difference between the phase shift experienced by intense light and a phase shift experienced by light which intensity approaches zero

Nonlinear Polarization
Polarization that does not experience purely linear dependence on the electric field

Non-Stoichiometry
Defined as the difference between the total anion and cation concentrations, hence anion- or cation-rich

n-Type Conductivity
A semiconductor material, with electrons as the majority charge carriers, that is formed by doping with donor atoms

Nucleation Temperature
Temperature where stable defect clusters/aggregates start to form as nuclei

Numerical Aperture
Figure of merit used to described the power of a lens, depending on the angle of collection of the lens and the refractive index of the medium in which the lens is situated

O

Onsager Model
A model that describes the probability of geminate recombination as a function of the applied field with the efficiency of geminate pair photogeneration and the initial pair-separation distance as parameters

Optical Absorption Coefficient
4π times extinction index, divided by the radiation wavelength

Optical Bistability
A phenomenon in which the instantaneous transmittance of the device depends both on the level of incident illumination and on the prior transmittance of the device. Such an element enables all-optical switches

Optical Constants
The real and imaginary parts of the square root of the *dielectric constant/susceptibility*, called refraction and extinction index, respectively; they define the optical properties of bulk material and mesoscale structures

Optical Emission Spectroscopy (OES)
A technique to determine the plasma parameter and reactions in the plasma by measuring the emission intensity of line spectra from the plasma

Optical Gap
(See *Band gap*)

Optical Limiter
A device in which the transmittance decreases with increased level of illumination

Optical Properties of a Sample
These include the apparent reflectance, transmittance, and absorbance

Optical Texture
Pattern observed for thin slabs of birefringent material between crossed polarizers under a microscope. It is used as a fingerprint to help identify the many different liquid-crystal phases

Optically Detected Magnetic Resonance
Magnetic resonance observed by optical means, particularly by detection of electron spin resonance by monitoring luminescence intensity and polarization, etc.

Order Parameter
The parameter that measures the extent of long-range order characteristics of a phase. The orientational order parameter is the most important for liquid crystals; by definition it vanishes in the isotropic phase

Organic Photoconductors (OPC)
Single material or a formulated blend of materials that have photoconductive characteristics

Organic Photoreceptors
Thin-film multilayer devices made from organic photoconductive materials. These devices are often called organic photoconductors

Oscillator Strength
Measure of the probability of a transition between levels; an oscillator strength of 0.01–1 is highly probable (*allowed*) and has a short lifetime (ns), one less than 0.001 is improbable (partially *forbidden*), and has a long lifetime (μs–ms)

Oxidation-Induced Stacking Fault
A stacking fault that shows up after wafer oxidation. During oxidation, Si interstitials are injected from the wafer surface into the bulk. They aggregate around oxygen precipitates of a critical size and thereby squeeze an additional lattice plane (stacking fault) between two regular lattice planes

Oxygen Precipitates
Aggregates of oxygen atoms that form in Czochralski-grown crystals due to their relatively large oxygen content. The silica crucible that holds the Si melt is slowly dissolved during the growth process, which introduces oxygen into the melt and, hence, into the growing crystal

P

Paraelectric
Non-polar phase that transforms into the ferroelectric phase at the Curie temperature

Partial Response Maximum-Likelihood (PRML) Recording Channel
Particular form of equalization used in digital recording channels. The detector is maximum likelihood

Passivation
Refers to the removal of electrical activity of a defect, often by trapping a mobile atom of the opposite electrical type (a donor may trap a mobile acceptor, for example). The defect now becomes a complex, consisting of the original defect and the new component in close proximity, but without electrical properties. Unlike compensation, ionized impurity scattering is reduced by passivation and carrier mobility is increased

Passive Matrix Addressing
Also known as simple multiplexing, passive matrix addressing is a technique for writing images onto liquid-crystal displays. The display elements are arranged as a matrix of rows and columns, and a series of voltage pulses are applied to each row in sequence. Individual pixels are activated by applying a voltage to the relevant column, such that the sum of the row and column voltages exceeds the desired switching or threshold voltage. Each pixel responds to the root mean square voltage applied during the line-address time, and unlike the active-matrix addressed displays, there is no charge-storage facility. Thus, the number of rows that can be addressed is limited

Peltier Effect
The absorption or evolution of heat at the junction of two different conductors

Penetration Depth (λ_L)
The characteristic length scale for the penetration of a magnetic field into the surface layer of a superconductor

Perfect Absorber
A planar metamaterial that completely absorbs incident electromagnetic energy (light)

Perfect Diamagnetism (Meissner Effect)
Of the superconducting state is reflected by the fact that a magnetic field is expelled from the interior of a field-cooled superconductor as soon as the superconducting state is reached

Permalloy
Alloy of nickel and iron with approximately 80% Ni and 20% Fe. Composition of alloy with zero magnetostriction

Permittivity (ε)
A measure of the polarizability of a dielectric material, which is frequency dependent. The relative permittivity of a material is often given by ε or ε_r, such as with the parallel-plate capacitor expression for capacitance: $C = \varepsilon\varepsilon_0 A/t$ (see *Dielectric Constant*)

Perpendicular Magnetic Recording
Recording system consisting of a write and read head and a recording medium where the magnetization is perpendicular to the surface of the recording medium

Phase-Separated Structure
Blended junction having routes for electrons and holes, which are formed by percolation due to self-assembly, while maintaining donor/acceptor molecular contacts in the bulk of the organic film

Phonon Glass Electron Crystal
A crystalline solid that exhibits the thermal properties of a glassy or amorphous material and the electric properties of a good crystal

Phonons
Quantized lattice vibrations in a solid

Phosphorescence
Luminescence with a lifetime $\gtrsim 10$ ns, typically involving a metastable state in the pumping cycle

Photo-Catalysis
An enhancement of the reaction rate on the surface by shining UV radiation onto the growing film

Photochromic
Temporal coloring induced by (UV) light illumination. For instance, photo-structural changes of Ag particles, which are dispersed in oxide glasses

Photoconductivity
The part of the conductivity that is caused by the absorption of light. Negative values of the photoconductivity are possible when optical excitation activates efficient carrier traps. A photoconductive device uses the change in resistance of a slab of semiconductor to measure the extra electron–hole pairs created by the absorption of photons

Photocurrent
The current that is generated as a result of the absorption of light

Photodarkening
Quasi-stable darkening induced by light illumination. In chalcogenide glasses, it occurs with a red-shift of optical absorption edge, which is induced through athermal photo-structural processes. The process, however, is speculative

Photoemission Spectroscopy (PES) Technique
PES is a method to determine the barrier heights of Schottky contacts and band offsets of semiconductor heterostructures from energy-distribution curves of electrons photoemitted from Schottky contacts and semiconductor heterostructures excited by ultraviolet light (UPS), soft X-rays (SXPS), and X-rays (XPS)

Photoinduced Degradation
A deterioration of semiconductor properties by prolonged light exposure

Photoinduced Discharge Characteristic (PIDC)
Plot of exposed potential versus exposure using either a continuous exposure or flash exposures of varying intensity

Photoinduced Effects
Changes in the properties of a glass induced by light, involving transitions between metastable states of the glass or changes in defect sites within the glass. Typically, a laser beam is used to locally modify the refractive index, density, absorption coefficient, etc., of the glass (see *Photodarkening*, *Photo-Induced Degradation*). These processes are widely used to pattern photonic structures such as Bragg gratings, waveguides, and refractive lenses into glasses

Photoisomerization
Light-induced change in the molecular structure of a molecule

Photoluminescence
Luminescence excited by the external illumination of the material. It should be distinguished from reflection and light scattering, which are also caused by external illumination and are not connected with thermal radiation of the material. The criterion to distinguish these phenomena is the characteristic decay time after the cessation of the incident light. While reflection and scattering would decay within $\approx 10^{-14}$ s (characteristic time of electromagnetic oscillations of incident light wave), the photoluminescence would persist at least more than $\approx 10^{-12}$ s (characteristic time of atomic vibrations of luminescent material)

Photon
A quantum of electromagnetic radiation

Photonic Glass
High-purity glasses in which impurities are controlled or suppressed at ppm levels. An example is the optical fiber glass developed at the end of the twentieth century, which is very recent when compared to the long history of artificial glasses of 5000 years

Photorefractive Beam Fanning
Spreading of an intense light beam due to the photorefractive properties of a material

Photosensitivity
of an organic photoconductor is a measure of the rate of photodischarge when exposed to light. Typical characterizations are the initial slope of the photodischarge (V/J) and the energy required for photodischarge to half the initial surface potential

Photo-Thermal Ionization Spectroscopy
A very sensitive technique for the measurement and identification of shallow impurities in semiconductors. The measurement is a two-stage process; the absorption of light excites the electron on un-ionized donors into a higher level and thermal energy now ionizes this electron into the conduction band, where it can be measured as a photo-current. Because the energy of the optical ionization is dependent on the donor type, the photocurrent spectrum as a function of photon energy, displays peaks that are characteristic of the donors present

Photovoltaic Device
This utilizes a p-n junction in a semiconductor to separate electron–hole pairs (created by the absorption of photons) to generate a voltage

Photovoltaic Module
A complete encapsulated device suitable for mounting on a roof or building façade. Modules will often

comprise a number of cells and the typical size is of the order of 1 m^2

Photovoltaic Solar Cell
A semiconductor device for the conversion of solar energy into electricity

Piezoelectric Polarization
Generation of electric polarization in certain dielectric crystals as a result of the application of mechanical stress

Piezoelectricity
Property of some crystalline materials, which produce an electric charge when subjected to an externally applied force (direct effect). They also deform when subjected to an external electric field (reverse effect)

Piezoresistivity
Property of certain materials, including thick-film resistors, whereby an externally applied force gives rise to a change in resistance

Pinned Film
Coupling of a ferromagnetic to an antiferromagnetic film resulting in the magnetization of the ferromagnetic film being constrained to a fixed direction. The strength of the coupling is characterized by an exchange field parameter (H_{ua}) measured in Oe or A/m

Pixie Dust
Thin layer of Ru as used in synthetic antiferromagnetic media (SAF)

Planar Chirality
Two-dimensional form of mirror asymmetry, which implies that a planar object or a pattern cannot be brought into congruence with its mirror image (obtained by reflection across a line in the object's plane) unless it is lifted off the plane. The simplest example of a planar chiral object is the Archimedean spiral

Planar Lightwave Circuit (PLC)
Industrially established processes for manufacturing integrated optics devices in silica-based glasses deposited on silicon wafers. Typically, the glass layers are deposited by chemical vapor deposition or flame hydrolysis. These technologies were developed mainly for applications in fiber optics and are widely used to manufacture wavelength multiplexers

Plasma-Enhanced Chemical Vapor Deposition (PECVD) Technique
Like CVD, this is a technique for thin-film deposition. In contrast to the CVD technique, in the PECVD technique the deposition of a film is a nonequilibrium process. In the PECVD technique, the gas-phase reactions, which are activated by temperature in the CVD technique, originate from an interaction of electrons with the gas molecules injected in the reaction chamber. In the plasma, the dissociation of the gas precursors is obtained by their collisions with energetic electrons. The products of the reactions interact with the substrate surface and lead to the deposition of a thin film. As the dissociation of the gases is produced by electron impacts, the reactor and substrate can be kept at room temperature

Plasmon
Quantized collective motions of electron gas in a metal. In a bulk metal, the plasmon propagates as a longitudinal wave, which may be probed by an electron beam. In a metal nanoparticle, a transversal surface plasmon can be excited by light waves

Plastic Deformation
Deformation of a body caused by an applied stress, which remains after the stress is removed

Plastic Electronics
Use of polymers in electronic and optoelectronic devices (see *Molecular Electronics*)

Point Defect
Smallest structural element, or imperfection, to cause departure from a perfect lattice structure, e.g., a dopant or impurity atom

Poisson's Equation
A differential equation relating the spatial gradient of the local electric field to the local space-charge density

Poisson's Ratio (ν)
The ratio of transverse contraction strain to longitudinal extension strain in the direction of stretching force. Tensile deformation is considered positive and compressive deformation is considered negative. The definition of Poisson's ratio contains a minus sign so that normal materials have a positive ratio

Polarity
Property of a physical system that has two points with different characteristics, such as one that has opposite charges or electric potentials

Polarization Ratio
The density of states at the Fermi energy in an energy band for electrons in a metal with spins parallel (antiparallel) to the local magnetization is $D(E_F^{\uparrow})$ and $D(E_F^{\downarrow})$, respectively. The polarization ratio is $P = \frac{D(E_F^{\uparrow}) - D(E_F^{\downarrow})}{D(E_F^{\uparrow}) + D(E_F^{\downarrow})}$

Poles of a Write Head
Structure in a write head that couples the magnetic fields to the write gap

Polycrystalline Solid
Polycrystalline material is not a single crystal as a whole, but is composed of many small crystals randomly oriented in different directions. The small crystals in polycrystalline solids are called grains. Theses grains have irregular shapes and orientations. A polycrystalline material has grain boundaries where differently oriented crystals meet. Polycrystalline silicon is produced in the form of a ribbon or thin film

Polydimethylsiloxane (PDMS)
$CH_3[Si(CH_3)_2O]_nSi(CH_3)_3$ is mainly used as silicon-based organic polymer

Polygonization
The motion of dislocations to form structures that resemble three-dimensional polygons. In this way, they minimize their strain energies. Readers are

referred to the many excellent books on materials science that discuss dislocations and their interactions

Polymer Thick Films
Thick films that are cured at much lower temperatures than their cermet counterparts. The binding matrix is a polymer material and the resulting films can be used in flexible circuits

Polymethyl-Methacrylate (PMMA)
$(CH_2{=}C(CH_3)COOCH_3)_n$ is an organic compound that is widely used to transfer graphene sheets

Positron Annihilation
Analytical technique that is sensitive to open defects, such as vacancies, in a crystal. The lifetime of positrons is greater when the total number of electrons is reduced, as happens at vacancies. Measuring positron lifetime can give semiquantitative estimates of the concentrations of these defects

Power Stabilizer
Optical device that can provide a fixed output intensity upon varying input intensity. The principle may be based on multi-photon absorption, which becomes efficient when light is more intense

Precursor
Volatile compound containing the element required for deposition onto the substrate

Process Integration
The carefully engineered combination of materials and processes to enable the fabrication of an integrated circuit technology. The careful consideration of materials properties, device physics, and electrical engineering principles is required for successful integration of materials into an IC chip

Proper Ferroelectric
Ferroelectric material in which the spontaneous polarization is the primary order parameter

Pseudomorphic Layers
True epitaxy only occurs when the lattice constants of the substrate (material A) and layer (material B) are equal. If they are different, misfit dislocations or even gross bending of the structure can occur. In pseudomorphic growth, the lattice constants can be very different. However, before misfit dislocations can be formed, either the growth of B is stopped or a layer of the substrate material, A, is grown on top of the structure. In either case, the structure is stabilized with material B being severely strained. Manufacturers use this technique to produce devices with advanced electrical or optoelectronic properties

p-Type Conductivity
Semiconductor material in which the dopants create holes as the majority charge carrier. It is formed by doping with acceptor atoms

Pulse Width
Width of a pulse in a digital magnetic recording read head when sensing a recorded transition. Characterized by the 50% width (PW_{50})

Pyroelectric Effect
Generation of an electric polarization change or a charge separation in a material in response to a change in material temperature

Pyrolytic Boron Nitride (pBN)
The favored crucible material for GaAs growth from the melt and for Knudsen cells for MBE. Pyrolytic refers to its high-temperature capabilities

Q

Quantum Cascade Laser (QCL)
The QCL is a source of radiation suited to the terahertz and infrared regions. *Quantum* refers to quantization of energy levels within a narrow region realized by interleaved energy wells and barriers formed by alternating layers of different semiconductor alloys. *Cascade* refers to the operation of a single electron tumbling down many potential steps, in contrast to other laser designs where many charge carriers encounter a single potential step. The *lasing* operation means that only one frequency (or a small range of frequencies) is available, and this is often built in during the manufacture, which is a limitation of lasers generally. QCLs promise future compact, robust, and reliable sources of terahertz radiation but presently suffer the drawback of having to be cooled to operate

Quantum Confined Stark Effect (QCSE)
The change in near-band-edge optical absorption in quantum wells that takes place when a high electric field is present

Quantum Dot (QD)
A semiconductor quantum heterostructure that is quantum confined in all three dimensions, for example, InAs islands embedded in a layer of GaAs and Ge islands in Si

Quantum-Dot Infrared Photodetector (QDIP)
Infrared detector based on intersubband transitions in quantum dots

Quantum Efficiency
Indicates either the probability that the absorption of a photon will result in the creation of a free electron and hole or the ratio of the number of luminescence photons to the number of stimulating photons. When determined by xerographic discharge of the photoreceptor, QE is a measure of the overall effectiveness of surface charge neutralization per absorbed (or incident) photon. It is sometimes called xerographic gain or supply efficiency. When determined by spectroscopic methods, such as fluorescence quenching, it is a measure of charge generation within the light-absorbing moiety

Quantum Size Effect
Quantum effect associated with quantization of the band and level. It is observed in two, one, and zero-dimensional systems whose size becomes small

Quantum Well (QW)
Low-dimensional semiconductor quantum heterostructure where a thin layer with a lower band gap is sandwiched between layers (barriers) with a higher band gap, leading to spatial confinement of carriers along one dimension for which the energy is

quantized in discrete levels. Carriers have free motion in the plane perpendicular to the confinement direction. May be repeated to produce a multiple quantum well (MQW)

Quantum Well Intersubband Photodetector (QWIP)
Long-wavelength (IR) detector based on light absorption through intersubband electron transitions in n-doped QWs

Quantum Wire
Semiconductor quantum heterostructure with two-dimensional confinement of carrier motion. Carriers have just one direction of free motion

Quasi-Fermi Levels
Levels that correspond to the energy positions the equilibrium Fermi level would need to have in the gap in order to produce carrier densities equivalent to the ones that are generated by the illumination

Quasi Particles
Unpaired electrons excited above the energy gap

R

Radiation Resistance
This is important for solar cells operating in space where high doses of gamma rays and high energy particles can significantly degrade the efficiency of the cells

Radio-Frequency (RF) Circuits
High-speed and microwave analog circuits that operate in the range 0.1−100 GHz

Reactive Sputtering
Technique for preparing thin films by sputtering with a mixture of reactive gas and conventional sputtering gas such as oxygen and argon

Reactor Cell
Chamber where the precursors react to deposit a film onto the substrate

Read Head
In magnetic recording the ferromagnetic device used to generate a voltage proportional to the state of magnetization in the recording medium

Readout Integrated Circuit (ROIC)
Commonly describes the silicon chip on which the detector material is mounted. The role of the ROIC is to integrate the signal, perform some signal processing and readout the array. Other terms are: multiplexer or mux

Reciprocal Lattice
Theoretical lattice constructed from a real lattice, such that any vector from the origin to a diffracted spot is normal to a particular plane in the real lattice, with reciprocal length of that plane spacing

Recombination
Process whereby non-equilibrium populations of electrons and holes return to their equilibrium values. Depending on whether the recombination rate is proportional to the excess carrier density or the square of that quantity, the processes can be referred to as linear and quadratic, or alternatively as a monomolecular and bimolecular recombination. Radiative recombination refers to the transfer of at least some of the energy of the excess carriers into photons. Non-radiative recombination involves only the production by lattice phonons (heat)

Reflectance-Transmittance (R–T) Method
Defines the optical constants, based on two equations connecting the former to the reflectance and transmittance of the slab sample of material under measurement

Reflection High-Energy Electron Diffraction (RHEED)
Glancing-angle electron diffraction technique, sensitive to surface reconstruction and morphology. Key in situ analytical technique in MBE

Reflectometer
Instrument used for reflecting light off the substrate to monitor the growth process. This is normally achieved through detecting the interference modulation of the light intensity from a growing film

Reflow
Process of heating a glass above its glass-transition temperature, to the point that its viscosity is sufficiently reduced to enable the material to flow. In combination with surface tension effects or other external forces, reflow is often exploited in the reshaping of optical devices

Remanent Magnetization
Magnetization that remains in a sample after the magnetic fields are removed

Remanent Polarization
Dielectric polarization that remains in a ferroelectric material after an electric field has been applied

Resistivity
Parameter of a semiconductor that depends on the free electron and hole densities (cm^{-3}) and their respective mobilities (cm^2/Vs), and is expressed in units of Ω cm. It is the reciprocal of conductivity and it depends strongly on temperature in a semiconductor

Resolution
The smallest separation of two points in an object that can be distinctly reproduced within an image

Resonant Nonlinear Response
The nonlinear response taking place in the absorbing spectral region

Responsivity
Signal term often measured using a two-temperature black body. Units can be V/W (used for photoconductors) or V/photon (often used for multiplexed photodiodes)

Retrograde Solidus
Describes the shape of the solidus when it shrinks as the temperature is reduced. In GaAs, the increased width of the solidus at high temperatures indicates that concentrations of Ga or As, in excess of stoichiometry, can exist in the solid crystal. These concentrations must reduce as the crystal cools because of the retrograde solidus

Rutherford Scattering
Elastic scattering of electrons due to an electrostatic interaction with the nucleus and surrounding electrons of an atom

S

Saturated Vapor Pressure (SVP)
Partial pressure of a substance in equilibrium with its liquid, so the partial pressure is determined solely by the temperature of the liquid and vapor

Saturation Intensity
Intensity at which the effective absorption decreases to a half of its initial value

Saturation Magnetization
Maximum magnetization that a ferromagnetic sample can attain in magnetic fields larger than the coercive field

Saturation of Absorption
Resonant nonlinear process in which absorption decreases with an increased level of illumination

Scaling
Calculated reduction of integrated circuit element dimensions according to physical and engineering principles and constraints, as well as economic considerations (See *Moore's Law*)

Scanning Probe Microscopy
Generic term given to microscopy techniques that use a scanned micro or nanoscale tip in immediate proximity to a surface to image topography or other physical features with almost atomic resolution. The main types are atomic force microscopy (AFM) and scanning tunneling microscopy (STM)

Schottky Contacts
Metal–semiconductor contacts are also named Schottky contacts

Schottky–Mott Rule
Equates the barrier heights of n-type (p-type) Schottky contacts with the difference of the metal work function and the electron affinity (ionization energy) of the semiconductor. The rule is incorrect since it does not consider the *intrinsic* interface-induced gap states

Schrödinger Equations
Partial differential equations in quantum mechanics, which describe how the quantum state of a quantum system changes with time

Screen
Mask used to define the desired thick-film pattern. It is usually made of stainless steel, polyester, or nylon

Screen Printing
Method by which thick films are deposited onto substrates. See *Antiferromagnetically Coupled Media (AFC)*

Secondary Electrons
Low-energy (< 50 eV) electrons that escape from the near sample surface, used to form topographic images

Secondary-Ion Mass Spectrometry (SIMS) and Glow Discharge Mass Spectrometry (GDMS)
Mass-spectrometric techniques that are well suited for the chemical analysis of semiconductors. In addition to being extremely sensitive to most impurities, they are quantitative and can give valuable information regarding the distributions of concentrations with depth. In SIMS, high-energy primary ions are focused on the sample surface. These sputter atoms from the material under investigation. Those that are charged are passed into a mass spectrometer for analysis. In GDMS, the sputtering is accomplished by a glow discharge. SIMS is, by convention, generally classified as dynamic, in that the material surface layers are continually removed as they are being measured, and static, in which the ion dose during measurement is restricted to less than 10^{16} ions/m^2 in order to retain the surface in an essentially undamaged state

Seebeck Effect
The voltage induced on a material due to a temperature difference across it

Segregation Coefficient (k)
In growth from the melt the incorporation of an impurity into the crystal depends on the equilibrium ratio of the solubilities in the melt and the solid. For a dilute solution, this ratio is given by the ratio of the equilibrium value of impurity concentration at the solidus and the liquidus at the growth temperature. This ratio is the segregation coefficient, k. For most impurities, k is less than unity and the growing crystal contains a lower impurity concentration than in the source melt. The exploitation of this fact has resulted in the purification technique of *zone refining*

Selection Rule
Quantum-mechanical rule based on wavefunction and operator symmetry that determines oscillator strength; typically set by parity or angular-momentum considerations

Selective Epitaxy
Growth of a single-crystal layer in a window without any deposition on the surrounding mask layer

Selenization
Process of forming the CIGS or CIS layer by exposing a copper, indium, and gallium precursor layer to Se to form the alloy

Self-Assembly
Spontaneous formation of a layer of organic material on a solid substrate surface. The process usually takes place by immersing the substrate into a solution of the organic compound. The driving force for self-assembly can be chemical and/or electrostatic attraction

Self-Defocusing
A nonlinear process associated with negative refractive nonlinearity that results in spatial spreading of intense light

Self-Focusing
A nonlinear process associated with positive refractive nonlinearity that results in focusing of intense light

Semiconductor Detector
Device that converts the incident photons directly into electrical pulse

Semiconductor Nanocrystals
Composite materials made out of semiconductor quantum dots embedded in organic or glass hosts

Semi-Insulating
A term given to semiconductors whose resistivity lies

above about $10^6\ \Omega$ cm. In GaAs, semi-insulating properties normally lie in the range of $10^7-10^8\ \Omega$ cm

Separate Confinement Heterojunction (SCH) Laser
In the SCH laser, the optical and electrical confinements are achieved separately by altering the thickness and the alloy composition of the cladding layers

Shallow-Energy-Level Dopant
Doping impurities whose energy level lies very close to the conduction or valence band for donors or acceptors

Shear Modulus
Sometimes also called rigidity, this relates stress and strain according to Hooke's law and is a measure of a material's resistance to shearing stress. The shear modulus, therefore, has units of pressure

Sheet Resistance
Resistivity of a semiconductor sample divided by its thickness, measured in $\Omega/\square$. It is commonly used by integrated circuit designers when designing resistances by specifying the number of squares required to give a certain value of resistance

Shields
Soft ferromagnetic films used to direct the flux from a recording layer away from sensor films in a read head

Short Wave (SW)
Often used for wavelengths between 1.0 and 3 μm. The atmosphere is transparent in relatively narrow bands within the SW region, the most common one is between 2.0 and 2.25 μm, although 1.5 μm is also important, as this is the wavelength for eye-safe lasers

Short-Range Atomic Structure
Atomic bonding structures within a scale of ≈ 0.5 nm, which are characterized by coordination number (the number of nearest-neighbor atoms), bond length, and bond angle. It is demonstrated for such simple glasses as SiO_2 that the short-range structure is nearly the same with that in a corresponding crystal

Signal Decay Rate
Rate (R) at which the amplitude of a signal read back from a recording system decays with time

$$R = 100\frac{\frac{A(t)}{A(t_0)}-1}{\log(t/t_0)}$$

Signal Processing in the Element (SPRITE)
A device used in the UK common module camera. It relies on a strip of CMT with a high voltage bias to drift photon generated holes at the same speed as the image is scanned, thus resulting in an amplified signal at the end of the strip

Silicene
A single layer of sp^2-bonded Si atoms in a honeycomb shape

Single-Layer Organic Photoconductor
A photoconductor with an architecture where the charge-generation and charge-transport functions are combined into a single layer

Slider
In a disk drive, the structure used to support an air bearing over the recording medium on the write and read heads

Sliding Boat
Liquid-phase epitaxy technique in which the substrate is slid under the melt in a horizontal orientation

Slope Parameter
(In perpendicular magnetic recording) The slope of the magnetization curve at the coercive field times

$$\alpha = 4\pi\left(\frac{dM}{dH}\right)_{H=-H_c}$$

Slush
A homogeneous charge of a ternary is held across the liquidus–solidus gap with the lower end solid, the upper end liquid, and the central section in a slushy state, during recrystallization

Smectic Phase
Liquid-crystal phase with some long-range translational order in addition to the long-range orientational order of a nematic. The constituent rod-like molecules are arranged in layers giving translational order in one dimension

Soft Underlayer (SUL)
Magnetically soft (low-coercivity) film underneath the recording layer in a perpendicular magnetic recording system. Used as a low-reluctance path for the flux from the write head

Solar Cell
Semiconductor device that converts the energy of sunlight into electric energy. Also called photovoltaic cell

Solid/Liquid/Gaseous Phase Equilibria
These phase equilibria are essential for understanding both the various growth techniques used and the post-growth heat treatments, i. e., cool-down after growth and subsequent annealing stages

Solid-State Recrystallization (SSR)
Solid-state recrystallization is a growth technique that produces a homogeneous but polycrystalline charge that is subsequently recrystallized in the solid state to produce multi-grained material

Solidus
In an equilibrium phase diagram, the solidus is the line below which all the components are solid

Solitonic Propagation of Pulses
Propagation of pulses characterized by a lack of temporal pulse spreading

Spatial Frequency
Spatial frequency is the reciprocal of a spatial dimension (e.g., height x or width y in a two-dimensional image) similar to the temporal frequency, which is the reciprocal of time. However, the unit of spatial frequency is preferably expressed as line pairs/mm (lp/mm), instead of cycles/mm

Specific Heat (Capacity)
Amount of heat required to change a unit mass (or unit quantity, such as mole) of a substance by 1 degree in temperature

Spherical Aberration
A blurring of resolution due to the spread of path lengths of rays traveling from an object to the image

plane, arising from a variation of the focal length of a lens as a function of distance from the center of the lens

Spin Valve
Read head that uses the giant magnetoresistive effect in three metallic films: a ferromagnetic free film, a non-magnetic spacer film, and a ferromagnetic pinned film

Spontaneous Polarization
The electric polarization that a substance possesses in the absence of an external electric field

Sputter Depth Profile
Compositional depth profile obtained when the surface composition is measured as material is removed by sputtering. Note: in some analytical methods such as SIMS, the sputtering is often accomplished by the ion beam used for analysis, but in other methods an ion beam may need to be added

Sputtering
Process in which atoms and ions are ejected from the sample as a result of particle bombardment

Squeegee
Device used to transfer the thick-film paste through a screen and onto the substrate

Stepanov Technique
Crystals are pulled from a crucible containing a crystal-shaped aperture

Stoichiometry
State of a perfect compound where the ratio of the numbers of atoms of the elements is a simple fraction. In GaAs, for example, stoichiometry exists when the number of As and the number of Ga atoms are equal

Stokes Shift
Difference in energy between the maximum of the emission spectrum and the maximum of the excitation spectrum

Strain (ε)
Defined in elementary form as the change in length divided by the original length; it can be thought of as the movement of one corner of a cubic box from its initial position under stress

Strained Quantum Well
QW layer grown on a substrate with a different lattice constant, resulting in a significant strain of the QW layer lattice

Stress
Force per unit area provided either by gravity or by the flow of viscous fluid

Strong Anchoring
Strong anchoring of the director at a surface parallel to the easy axis is said to occur when an applied field is unable to alter the orientation of the director at the surface but can in the bulk

Structural Relaxation
Essentially an aging effect associated with glasses. Because glasses are metastable materials with random network structures, they are inherently subject to short or long-term changes in material properties. Often, structural relaxation is manifested by a change in specific volume (densification) at fixed temperature versus time. The rate of such changes is extremely sensitive to the difference between the glass transition temperature and the observation temperature. Structural relaxation can be induced rapidly by an annealing step, in which the glass is heated near its glass-transition temperature for some period of time

Substitutional Impurities
Impurities that replace the crystal's base atom at that base atom's lattice position

Substrate
Base material onto which a film is deposited. Examples of typical substrates include materials such as alumina, beryllia, aluminum nitride, silicon, insulated steels, and various plastics. In epitaxial processes, substrates are normally near lattice-matched pieces of material of a sufficiently large area for use in the various epitaxial growth processes, normally from similar, i. e., common-cation, ternary systems, e.g., CdZnTe for MCT

Superconductors of Type I
Characterized by the fact that normal and superconducting regions cannot coexist in these materials. The value of $\kappa = \lambda_L/\xi$ is smaller than $1/\sqrt{2}$

Superconductors of Type II
Type II superconductors, for which $\kappa = \lambda_L/\xi > 1/\sqrt{2}$, show perfect diamagnetism only below the lower critical field B_{c1}. Between the lower and the upper critical fields type II superconductors are in the mixed state. Magnetic flux enters the superconductor via the normal conducting cores of the flux lines

Supercooling Temperature
Difference between the glass-transition temperature and the in-use temperature for a glass-based device. For a large (small) supercooling temperature, the structural relaxation rate is low (high)

Superlattice (SL)
Structure of repeated QWs with thin barriers allowing the coupling of wavefunctions from adjacent QWs and the subsequent delocalization of the energy levels

Superlattice Avalanche Photodiode (SL-APD)
Avalanche photodiode architecture where an SL is incorporated in the carrier multiplication region for the purpose of reducing the dark current as well as the excess noise factor

Superparamagnetism
In small ferromagnetic particles the magnetization can flip from one state to the opposite state under thermal excitation. This behavior is similar to a paramagnet. The resistance of the particle to switching is characterized by a thermal stability factor $= \frac{K_u V}{k_B T}$, where K_u is the uniaxial anisotropy factor for the particle, V is the particle volume, k_B is the Boltzmann constant, and T is the absolute temperature

Supersaturation
Ratio between the species concentration and its

solubility limit/equilibrium concentration at a given temperature when this ratio is larger than 1

Superstrate
Describes the thin-film configuration where the glass substrate acts as the window for solar radiation and, therefore, needs a TCO layer before the photovoltaic structure can be deposited

Surface Passivation
Semiconductor surfaces are often electrically active and appear to be covered with a high density of deep-level states. These can greatly affect the properties of a device. Fortunately, it is often possible to treat the surface to substantially reduce this density to values that do not affect device operation. This is surface passivation. In GaAs, passivation is often accomplished by covering the surface with a layer of GaAlAs (see *Passivation*)

Surface-Mount Devices (SMDs)
Electronic components that are attached to the surface of a circuit board as opposed to having through-hole connections. They are a characteristic feature of a hybrid circuit

Susceptor
This is normally made of high-density graphite and is used to transfer the heat from the heater (possibly RF coupling straight into the susceptor) to the substrate

Synthetic Antiferromagnet
Sequence of films: antiferromagnet/ferromagnet/ruthenium/ferromagnet. An example is MnFe/Co/Ru/Co. With a thin Ru film, the final ferromagnetic film is antiferromagnetically coupled to the first ferromagnetic film. The coupling between the two ferromagnetic films is characterized by the exchange coupling parameter J_{12} ($\mathrm{erg/cm^3}$ or $\mathrm{J/m^3}$)

Synthetic Ferrimagnetic Media (SFM)
Magnetic recording media in which there are two ferromagnetic layers of unequal thickness coupled by a thin layer of ruthenium (Ru), sometimes referred to as *Pixie Dust*. The two layers are antiferromagnetically coupled. The coupling between the ferromagnetic films is characterized in terms of the antiferromagnetic coupling between the thinner layer (layer 2) and Ru, and the media flux from that layer by an exchange magnetic field $H_{\mathrm{ex}} = J_{\mathrm{ex},2}/(M_2 t_2)$

T

T Nonlinear Figure of Merit
Figure of merit that describes the applicability of a refractive nonlinear optical material in terms of the Kerr coefficient and two-photon absorption

Tail States
Localized states in the tail of band, i. e., conduction band and valence band, which generally have an exponential density-of-states function

Tandem Cell
Cells connecting more than two unit cells

Tauc Gap
Tauc discovered that in many chalcogenide glasses, such as As_2S_3, optical absorption spectra α around the fundamental edge can be fitted as $\alpha\hbar\omega \propto (\hbar\omega - E_g)^2$, where E_g is called the Tauc gap. The energy is often used as a measure of the optical band gap, while its theoretical interpretation is not conclusive

Technology Node
Minimum half-pitch of metal interconnect is most representative of the process capability enabling high-density (low cost/function) integrated circuits and is selected to define an ITRS technology node. For each node, this defining metal half-pitch is taken from whatever product has the minimum value. Historically, DRAMs have had leadership on metal pitch, but this could potentially shift to another product in the future. Other parameters are also important for characterizing IC technology. For example, in the case of microprocessors (MPUs), physical bottom gate length is most representative of the leading-edge technology level required for maximum performance. Each technology node step represents the creation of significant technology progress in a metal half-pitch – approximately 70% of the preceding node, 50% of two preceding nodes

Temperature Coefficient of Resistance (TCR)
Denotes the sensitivity of a resistor material to changes in temperature. It is usual to quote TCR in terms of ppm per °C

Tensile Strain
Type of strain obtained when a strained Si layer is grown on a relaxed $Si_{1-x}Ge_x$ layer

Terahertz
One terahertz is the frequency of precisely 10^{12}, or one trillion, cycles per second. As such one terahertz corresponds to one thousand gigahertz and to one million megahertz: $1\,\mathrm{THz} = 10^{12}\,\mathrm{Hz} = 10^3\,\mathrm{GHz} = 10^6\,\mathrm{MHz}$. A photon of frequency one terahertz has an energy of $\approx 4.14\,\mathrm{meV}$ and, in free space, a wavelength of exactly $299.792458\,\mu\mathrm{m}$ and spatial frequency of approximately $33.36\,\mathrm{cm^{-1}}$. Physically, therefore, terahertz may be described as meV or *submillimeter* radiation, characterized in *wavenumbers* by tens of $\mathrm{cm^{-1}}$. More loosely, *terahertz* is taken to refer to a range of frequencies around $\approx 1\,\mathrm{Thz}$, a convenient spectral range being the two decades from 0.1 to 10 THz. In this sense, *terahertz* means $10^{12\pm1}$ Hz

Ternary and Quaternary Alloys
These are alloys containing three or four components, respectively. GaAlAs and GaAlAsP are examples

Thermal Budget
Term describing the temperature–time product associated with an IC annealing process step. Material stability and morphology are typically very sensitive to the annealing temperature for a period of time

Thermal Conductivity or Heat Conductivity
Heat flow across a surface per unit area per unit time, divided by the negative of the rate of change of temperature with distance in a direction perpendicular to the surface

Thermal Expansion Coefficient
Fractional change in length or volume of a material for a unit change in temperature

Thermal Nonlinearities
Nonlinear effect associated with heating of the materials by intense light

Thermally Stimulated Current (TSC) Spectroscopy
TSC is a useful technique for assessing concentrations of deep levels in high-resistivity semiconductors. These levels are filled optically with light above the band gap energy. They are emptied sequentially, with the sample under bias, as the sample temperature is raised. Defects of different ionization energies produce separate peaks in the graph of current as a function of temperature

Thermistors
Thermally sensitive resistors that exhibit a change in resistance when the temperature is altered. The most common forms have a negative TCR, meaning that the resistance decreases as the temperature increases

Thermoelectric Figure of Merit
A measure of the efficiency of a material for the conversion of heat to electricity, determined by its Seebeck coefficient and electrical and thermal conductivities

Thermoelectric Power Factor
The "electrical" part of the thermoelectric figure of merit, consisting of the product of the square of the Seebeck coefficient and the electrical conductivity

Thermoelectricity
The collective effects involving the conversion of a temperature difference to electricity and vice versa

Thermomechanical Fatigue
Occurs when materials with different CTE are joined and used in an environment that experiences cyclic temperature fluctuations resulting in imposed cyclic strain, which results in damage to the joined materials

Thermophotovoltaic (TPV)
Absorption of solar radiation and re-emission of infrared radiation that is then converted into electricity by absorption in a narrow-band gap cell

Thermotropic
Liquid crystals are those where the transition from one phase to another occurs on changing the temperature

Thick Film
Layer deposited onto a substrate by the process of screen printing

Threading Dislocations
This term is applied to dislocations that are formed at an interface and that thread their way into the epitaxial layer

Threshold Voltage (V_{th})
Voltage at which an inversion layer forms in the semiconductor substrate of an MIS structure. For applied voltages beyond this threshold, the transistor turns on, i. e., a conducting channel is established between the transistor source and drain, as observed by the increase in drive current

Time Division Multiplexing
A multiplexing technique used in modern optical networks that allows close spacing in time of bits in a single channel

Time-Domain Charge Measurement (TDCM)
TDCM is a rapid technique for the non-contacting measurement of electrical resistivity in SI materials. Its speed and high spatial resolution allows TDCM to be used in a mapping system

Tipping
A *liquid-phase epitaxy* technique in which the melt is moved over the substrate in a tipping furnace

Transferred Electron Effect
This is a somewhat unusual effect where conduction-band electrons can exist in alternative conduction-band states. In GaAs, the lowest conduction-band minimum corresponds to zero electron momentum. The application of an electric field can excite electrons into subsidiary minima of somewhat greater energy from where they will relax back to their original states. If the effective mass of the electrons in the subsidiary minima is greater than that in the primary minimum, negative differential resistance can be realized. This effect can be found in GaAs, InP, and certain alloys

Transformation Optics
A mathematical technique aimed at designing complex electromagnetic media (metamaterials) that allow one to control the flow of light in a desired manner. The transformation optics approach enables the recreation of an electromagnetic phenomenon in a warping virtual space as an optical illusion in the physical Euclidian space

Transistor
A three-terminal device in which the current flow between two terminals (called the source and drain regions) is controlled by the voltage applied between a third terminal (the gate electrode) and one of the two terminals

Transit Time
Refers to the difference in time between the moment a charge carrier is generated at one end of the sample and its arrival at the other end. It is the primary result in time-of-flight experiments. In xerography, the transit time is the time for a photoinjected carrier to traverse the charge-transfer layer

Transparent Conducting Oxide (TCO)
Thin layer of highly conducting material that is used as the front contact in thin-film solar cells. The requirement of high optical transmission over a wide spectral range is important to allow as much sunlight through as possible to the absorber layer

Transverse Magnetic Bias Film
In a magnetoresistive head, an antiferromagnetic film coupled to the pinned film to maintain the magnetization of the pinned film in a direction transverse to the magnetization of the recording film

Trapping Centers
Irregular sites in the photoconductor with localized

electronic energy levels inside the band gap. Such sites will trap charge carriers and thus inhibit electrical conduction

Traveling Heater Method
A molten zone is made to migrate through a homogeneous solid source material

Trimming
Process by which the value of thick-film elements can be adjusted. Usually achieved by using a laser or air abrasive jet

Tunneling Conduction
Process for charge conduction where the charge carriers pass through an energy barrier by quantum-mechanical tunneling

Tunneling Magnetoresistance (TMR)
With two ferromagnetic films coupled by a thin insulating layer, electrons can tunnel through the insulating layer and the magnetoresistance coefficient is given in terms of the polarization ratio for the two contacts as $\frac{\Delta R}{R} = \frac{2P_1P_2}{1-P_1P_2}$.

Twin Crystal
Crystal having two or more crystals or crystal sections that, when regularly positioned, are in reverse position relative to the other sections

Two-Photon Absorption
Nonlinear process in which a simultaneous absorption of two photons results in an electronic transition

Type I Band Alignment
Electrons and holes are confined within the same layer

Type II Band Alignment
Electrons and holes are confined in different (adjacent) layers

U

Ultrafast Nonlinear Response
Nonlinear response taking place in the non-absorbing spectral region

Ultra-High Vacuum (UHV)
A vacuum better than 10^{-9} Torr

Underfill
Dielectric composite organic material that is bonded between the chip and substrate of a flip-chip device to help mechanically interlock the chip to the substrate. The underfill material is typically a silica-filled anhydride resin polymer

Uniaxial Anisotropy
Magnetic anisotropy along one direction in a ferromagnetic material and characterized by a uniaxial anisotropy parameter K_u (erg/cm^3 or J/m^3)

Uniform Planar Alignment
of the director is when the director is parallel to the surface and to a particular direction in the surface. This has also been referred to as homogeneous alignment

Unipolar Avalanche Photodiode (UAPD)
QWIP detector employing avalanche multiplication of only one type of carrier via intra-QW impact ionization by carrier–carrier scattering

Upper Critical Field (B_{c2})
The highest magnetic field allowing the existence of the superconducting mixed state in the type II superconductor considered

V

Vacancy
Regular lattice site from which the host atom is missing. Anion (cation) vacancies are generally donors (acceptors)

Valence Band
Highest range or band of energies in a semiconductor where electrons are normally present at zero temperature. When electrons are promoted from this band, holes are left behind that contribute to the electrical conductivity

Vapor Growth Techniques
Growth takes place via a vapor phase: particularly useful for high-melting-point materials, or those with high partial pressures of one constituent, e.g. ZnS

Vapor-Phase Epitaxy (VPE)
A form of epitaxy where the components of the layer to be grown are transported to the substrate as a vapor. Decomposition of these components to produce the layer occurs because the substrate is heated, often on a support called a susceptor

Vegard's Law
States that the lattice parameter of an alloy material is given by the concentration weighted average of the constituents

Vehicle
Liquid component of the thick-film paste. Typically contains a resin dissolved in a solvent. It is removed during the drying and firing processes

Verneuil Technique
Rapid growth method used for many high-melting-point materials, mainly oxides

Vertical Superlattice Structure
An ideal nanostructure which enables the efficient dissociation of photogenerated excitons at the donor/acceptor interfaces within the exciton diffusion length and the transport of electrons and holes to the respective electrodes

Vertical Transport
Mechanisms of carrier transport parallel to the growth direction in a semiconductor quantum-confined structure

Vertical-Cavity Surface-Emitting Laser (VCSEL)
QW diode laser emitting through its top semiconductor surface

Vertical-Gradient Freeze Technique
Similar to the Bridgman method but freezing is controlled by moving a temperature gradient along a stationary crucible

V/I Boundary
Denotes the spatial location of the transition from the vacancy-dominated region to the Si interstitial dominated region and vice versa

VI Recombination
Mutual annihilation between vacancies and Si interstitials

Virtual Gap States
The virtual gap states are the *solutions* of Schrödinger's equation for complex wave vectors in the energy gap. The continuum of these *virtual* states is the source of *real* impurity states in the bulk, as well as of surface states and the interface-induced gap states at *real* surfaces and interfaces, respectively, provided the corresponding boundary conditions are considered

Void
See *Crystal-Originated Particle (COP)*

W

W Nonlinear Figure of Merit
Figure of merit that describes the applicability of a refractive nonlinear optical material in terms of nonlinear index change and linear absorption

Wannier Exciton
Weakly bound electron–hole pairs

Wavelength Division Multiplexing
A multiplexing technique used in modern optical networks that involves sending many signals in parallel at closely spaced wavelengths along the same fiber

Weak Links
Large-angle grain boundaries in cuprate superconductors, which act as barriers for the supercurrents

Web Photoreceptors
Devices where the layers are coated on an insulating polymeric support and subsequently fashioned into a loop

Wire Bonding
Process where a thin wire (can be less than 25 μm) made of Au or Al is bonded to the surface of an integrated circuit and then to a pad or a leadframe in the package

Work Function
The energy (usually measured in electron volts) needed to remove an electron from the Fermi level in a solid to outside the surface

Write Efficiency
Ratio of the magnetic field times the write gap to the magnetomotive force (turns times current) in the write coil

Write Gap
Region in a write head that generates the magnetic fields that couple to the recording medium. Characterized by the gap length g

Write Head
In magnetic recording, the ferromagnetic device used to generate magnetic fields from current that can switch the state of the magnetization in the recording medium. In disk drives, the ferromagnetic device is made using thin films

Wrong Bond
Homo-polar bonds in stoichiometric glasses, such as As–As in As_2S_3. The defective bond nominally does not exist in the corresponding crystal. However, specifically in covalent glasses such as As_2S_3, the bond exists with a concentration of $\approx 1\%$, which depends upon preparation methods, and so forth

Wurtzite Structure
Comprises two interpenetrating close-packed hexagonal lattices, one for cations and the other for anions. Each anion (cation) has four cation (anion) nearest neighbors. In principle, diffusion should be anisotropic but the meagre evidence available indicates only slight effects

X

Xerographic Discharge
Time-dependent decrease in the surface potential with exposure of a charged OPC

Xerographic Gain
or quantum efficiency of supply is the fractional number of surface charges neutralized per absorbed photon

Xerography
Name coined by Chester Carlson for electrophotography using dry powder marking particles

X-Ray
The form of energetic electromagnetic radiation of the wavelength, ≈ 0.1 nm

X-Ray Diffraction
A highly sensitive technique for measuring the lattice constant of crystalline solids

X-Ray Photoelectron Spectroscopy (XPS)
A method in which an electron spectrometer is used to measure the energy distribution of photoelectrons and Auger electrons emitted from a surface irradiated by X-ray photons

X-Ray Sensitivity
The X-ray sensitivity of a photoconductive detector is the collected charge per unit area per unit exposure of radiation

X-Ray Topography
A method for sampling the diffraction condition of X-rays from a surface in order to observe changes in lattice constant. The X-rays are scanned over the surface and an image is built up from changes in the fraction diffracted at a particular angle. Changes in lattice constant resulting from strain or changes in composition can be imaged in this way

Y

Yield Strength
Applied stress (in pounds per square inch or psi in the English system, megapascals or MPa in the metric system), under which an object experiences plastic deformation

Young's Modulus
Ratio of a simple tension stress applied to a material to the resulting strain parallel to the tension. Therefore, Young's modulus has units of pressure

Z

Zincblende Structure
A crystal structure that has two interpenetrating face-centered cubic (fcc) lattices, one for the cations and the other for anions. Each anion (cation) has four anion (cation) nearest neighbors. Diffusion is isotropic

Zone Refining
Technique used to repeatedly pass zones of molten material through a solid bar in order to purify it, either for use directly in applications or to produce pure starting materials, e.g., elements for compound semiconductors

trap-assisted tunneling (TAT) 878
TRAPATT diode 514
trap-free space-charge-limited current density (TFSCLC) 976
trap-free transport 976
trap-limited conduction (TLC) 1118
trapped carrier density 1114
trapped plasma avalanche-triggered transit (TRAPATT) 513
trapping centers 1490
traveling heater method (THM) 275, 284, 343, 347, 380, 861, 1491
triangular lattice 1015
triboluminescence 997
trichlorosilane ($SiHCl_3$) 295
trimming 1491
triode sputtering 659
triphenylenes 940
triple phase boundary (TPB) 1413
tri-*p*-tolylamine (TTA) 986
trisazo compound 986
TROK model 167
true specific heat capacity 429
tuneable lasers 915
tungstate 289
tungsten bronze
– $PbNb_2O_6$ (lead metaniobate) 597
tuning photonic crystal response 1029
tunnel conductivity 1235
tunnel magnetoresistance (TMR) 1205, 1218
tunneling 927, 1046
– conduction 1491
– current 616, 624
– magnetoresistance (TMR) 1491
– magnetoresistive head 1218
– single electron 1231
– transition of charge carrier 211
– transition probability 201
turbo-disc reactor 324
twin crystal 1491
twinning 357
twist deformation 942
twist vector 1373
twisted nematic (TN) 951
– display, chiral dopant 952
twisted vertically aligned (TVAN) 954
two-beam experiment 1086
two-beam system 160
two-color detector 360
two-dimensional (2-D)
– electron gas (2DEG) 40, 105, 335, 785
– hole gas (2DHG) 789
– projection 344
– structure 1039
two-electron transition (TET) 774, 775
two-photon absorption 1491
two-step absorption 1083, 1087
type I band alignment 1040
type I superconductor 1233
type II band alignment 1040, 1051
type II superconductor 1232
– mixed state 1233
– pinning 1243
– vortex–vortex interaction 1243
type of film 669
Tzero technology 449

U

ultrafast nonlinear response 1491
ultrafine printing 1270
ultrahigh vacuum (UHV) 329, 649, 1491
ultrahigh vacuum-electron cyclotron resonance-radio-frequency magnetron sputtering (UHV-ECR-RMS) 766
ultrahigh-vacuum chemical vapour deposition (UHV-CVD) 523, 535
ultrahigh-vacuum environment 358
ultra-large-scale integration (ULSI) 293, 622
ultrasonic 716
– bonding 716
– micro-spectroscopy (UMS) 749
ultrathin films 1244
ultraviolet light absorption spectroscopy (UVLAS) 574
Umklapp process 432
unbalanced magnetron technique 662
under bump metallurgy (UBM) 1319
underfill 1323, 1491
uniaxial anisotropy 92, 1491
uniform planar alignment 1491
uniformly doped (UD) 789
unipolar avalanche photodiode (UAPD) 1052, 1491
unit cell 669
upper critical field
– cuprate superconductor 1240
– iron-based superconductor 1251
– MgB_2 1247
upper critical field (B_{c2}) 1491
upper shield 1214
Urbach law 685
Urbach tail 61
UV lithography 1018
UV poling 1088

V

V/G parameter 116
V/I boundary 128, 1491
vacancy (V) 113, 1491
– aggregate 115
– concentration 135, 137
– flux 136
– formation energy 114
vacuum
– deposition 649
– distillation (VD) 861
– evaporation (VE) 1089
– ultraviolet (VUV) 72
valence band (VB) 56, 899, 1083, 1491
– amorphous semiconductor 558
– deformation potentials 737
valence change glass 1009
valence electron 60
valence-alternation pairs (VAP) 559
valence-band offset
– $Al_{1-x}Ga_xAs/GaAs$ 185
– core-level XPS 180
– GaN and Ge heterostructure 187
– SiO_2 and Si heterostructure 186
van der Pauw technique 457
van Hove singularities 58
vanadium oxide (VOx) 869
vapor
– growth 278, 281, 284–286, 1491
– phase epitaxy (VPE) 5, 270, 310, 365, 879, 882, 899, 1491
– pressure constant, precursor 322
– sensing 1295
– transport deposition (VTD) 858
vapor-liquid-solid (VLS) 325, 799
– nanowire growth 1053
vapor-pressure-controlled Czochralski (VCZ) 281
vapor-solid (VS) 799
variable-range hopping (VRH) 203, 696, 1117, 1168
Varshini 771, 783
VCSEL technology 337
Vegard's law 727, 728, 1491
vehicle 1491
velocity–field characteristic 835
– AlN 836
– GaN 836
– group III–V nitride semiconductor 836
– InN 836
Verdet constant 69
Verneuil 271
– technique 1491
vertical
– external cavity surface emitting laser (VECSEL) 918
– gradient freezing (VGF) 270, 275, 283, 380, 884, 1491
– superlattice 1334
– transport 1491
vertical cavity 796
– surface emitting laser (VCSEL) 796, 899, 916, 1037, 1048, 1491
vertical external cavity surface emitting laser (VECSEL) 918
vertical unseeded vapor growth (VUVG) 284
vertically aligned nematic (VAN) 954
very high mobility 335
very-large-scale integration circuit (VLSI) 801
V-grove nanowire 1053
VI recombination 118, 1492
via-hole device 880
vibration dynamics 239
vibrational mean energy 426
videotape 97
virtual gap states (ViGS) 181, 1492
viscosity 1061
viscosity coefficient
– Miesowicz experiments 945
– nematodynamics 947
viscous torque 946
visible (VIS) 72
visual graphics array (VGA) 949
V-MRAM 108
void 112, 1492
– density 121
– morphology 123
volatile organic compound (VOC) 1282
Volmer–Weber (VW) 374
– growth 374
voltage noise measurement 475, 476
– low-impedance device 476
voltage scaling 618
voltage-controlled magnetism 107
vortex
– property 107
– transistor 108
VPE growth
– group II–VI wide bandgap 372
– source materials 372

W

W nonlinear figure of merit 1492
wafer scale packaging (WSP) 13
Wannier–Mott excitons 62
Wannier-type exciton 1331
waste in electrical and electronic equipment (WEEE) 1321
water-soluble materials 276
wave function, Bloch-type 486
wave soldering 716
wave-function overlap 924
wavelength 1340
– dispersive x-ray (WDX) 385
– division multiplexing (WDM) 543, 1030, 1068, 1492
wavenumber 1340
weak absorption 77
– tail (WAT) 61
weak link 1492
weak-link behavior, polycrystalline cuprate superconductor 1242
web photoreceptors 1492
Wentzel–Kramers–Brillouin (WKB) 697
white-light LED 1006
wide bandgap
– compounds 365, 374
– epitaxial growth 371
– group II–VI compound semiconductors 367
– group II–VI compounds 371
– material 743
– quantum dot 374
– quantum well 374
wide-band x-ray 863
– imager (WXI) 863
widegap compounds 316
width at one-half amplitude PW_{50} 1194
Wiedemann–Franz–Lorenz law 435
wire bonding 716, 1492
– digital applications 1315
– materials 1315
WO_3 168
work function 635, 690, 1492
write
– efficiency 1492
– gap 1492
– head 1189, 1205, 1492
write-head material 1191
wrong bond 1492
wurtzite 589, 743, 745
– GaN 835

– group III nitride alloy 782
– group III–V binaries 737, 738
– group III–V semiconductors 737
– structure 1492
WZ-GaN 747

X

xerogel 640
xerographic discharge 978, 1492
xerographic gain 971, 1492
xerography 968, 969, 1492
XeroX Copier 969
x-ray 1492
– absorption near-edge structure (XANES) 1153
– absorption spectroscopy (XAS) 748
– detector 314
– diffraction (XRD) 372, 385, 1151, 1178, 1286, 1492
– fluorescence (XRF) 390
– imaging 1008
– lithography 1024
– photoconductor property 1127, 1128
– sensitivity 1140, 1141, 1492
– storage phosphor (XRSP) 1008
– topography 1492
x-ray diffraction (XRD) 390
x-ray photoelectron spectroscopy (XPS) 413, 626, 627, 1492
– primary excitation 415

Y

YAG (yttrium aluminium garnet) 715
yellow luminescence (YL) 777
yield strength 1492
yoke 1191
Young's modulus 748, 1173, 1493
– semiconductors 730
yttrium iron garnet (YIG) 105
Y-type construction 1287

Z

ZBLAN glass 429
Zeeman energy 87
zeolite 1090
zero band-gap semiconductor 1176
zero temperature coefficient of resistance (ZTCR) 259
zero-dimensional (0-D) structure 1053
zero-phonon transition 1002
zinc compound 671
zincblende structure 1493
zirconia auto exhaust 259
zirconia based system 260
Zn-based compound 316
ZnO 590
– single crystals 377
ZnSe
– epitaxial layer 371
– single crystal 379
zone refining 4, 1493
